The cardiac plexuses are mixed in that both vagal and sympathetic fibres contribute to their formation; the sympathetic fibres are predominantly post-ganglionic, while the vagal fibres are preganglionic, and the ganglion-cells situated in the plexuses and in the heart-wall therefore belong to the vagal system. In the heart, ganglion-cells are found most abundantly in relation to the atria, though not exclusively so; this accords with the view that the atria have a richer parasympathetic supply and the ventricles a richer sympathetic (Woollard, 1926).

The supply to the coronary vessels is rich—**coronary plexuses**—and both sympathetic and parasympathetic fibres innervate them; the larger branches of the coronary vessels are mainly innervated by the sympathetic, but their smaller branches by the vagus. Vaso-constriction of these vessels is probably controlled by vagal fibres and vaso-dilation by sympathetic fibres.

The conducting system of the heart is richly innervated, especially the sinu-atrial node and the atrio-ventricular node and bundle (Fig. 1066, p. 1236. Nerve-fibres proceed into the heart-wall along extensions of the conducting system, but Stotler & McMahon (1947) consider, apart from the supply of the conducting system, that the nerves within the heart-wall are vascular or, in the case of the subendocardial plexus, sensory.

Abdomino-Pelvic Plexuses

In this group there are several great accumulations of both sympathetic and parasympathetic nerves and ganglia which serve to distribute nerves to the abdomino-pelvic viscera and blood-vessels. Three great plexuses are included—the **cœliac**, the **hypogastric**, and the **pelvic**; and ramifications from each of these extend usually along blood-vessels to the various viscera—such ramifications being as a rule designated according to the vessels they accompany. The above plexuses and their extensions are all to be regarded as gangliated plexuses wherein at times cells may predominate and be aggregated into macroscopically identifiable "ganglia"; frequently, however, cells are dispersed here and there amongst bundles of fibres with no obvious ganglia. Vagal or sacral parasympathetic fibres and the sympathetic fibres once having entered a plexus can no longer be identified as such.

The branches which contribute to these plexuses come from the thoracic, lumbar, and pelvic parts of the sympathetic trunk: in general the abdominal plexuses are derived from the thoracic part and the pelvic plexus from the lumbar part; sacral sympathetic contributions to the pelvic plexus are relatively few. There are also parasympathetic fibres—some from above, through the vagal branches which enter the abdomen with the œsophagus, and some from below, in the pelvic region, through the pelvic splanchnic nerves. The cœliac plexus is placed high in the abdomen, the pelvic plexus in the pelvic cavity, while the hypogastric plexus in some measure links these together.

Cœliac Plexus.—This is the largest of the prevertebral plexuses and lies on the posterior abdominal wall in relation to the aorta about the level of the first lumbar vertebra. Three large vessels arise here and have considerable importance in the morphology of the plexuses, viz., the cœliac artery, the superior mesenteric artery, and the renal artery.

The plexus is formed by a closely interwoven network of nerves interspersed with minute ganglia. Certain macroscopic, dissectable ganglia are fairly regularly found and merit individual description. The *cœliac ganglia*, generally of irregular shape, are found with some constancy flanking the aorta at the level of origin of the cœliac artery. Each lies on the corresponding crus of the diaphragm; the left is behind the peritoneum of the lesser sac above the pancreas, while the right ganglion is in part covered by the pancreas and above this is overlapped by the inferior vena cava. The *aortico-renal ganglia* lie below the cœliac ganglia at the level of origin of the renal arteries, behind which they are commonly partly

insinuated. The aortico-renal ganglion may be fused with the cœliac ganglion and even when separate it is closely linked to it by nerve-strands.

The *superior mesenteric ganglia* lie on the aorta on each side of the origin of the superior mesenteric artery. Not uncommonly they form several smaller

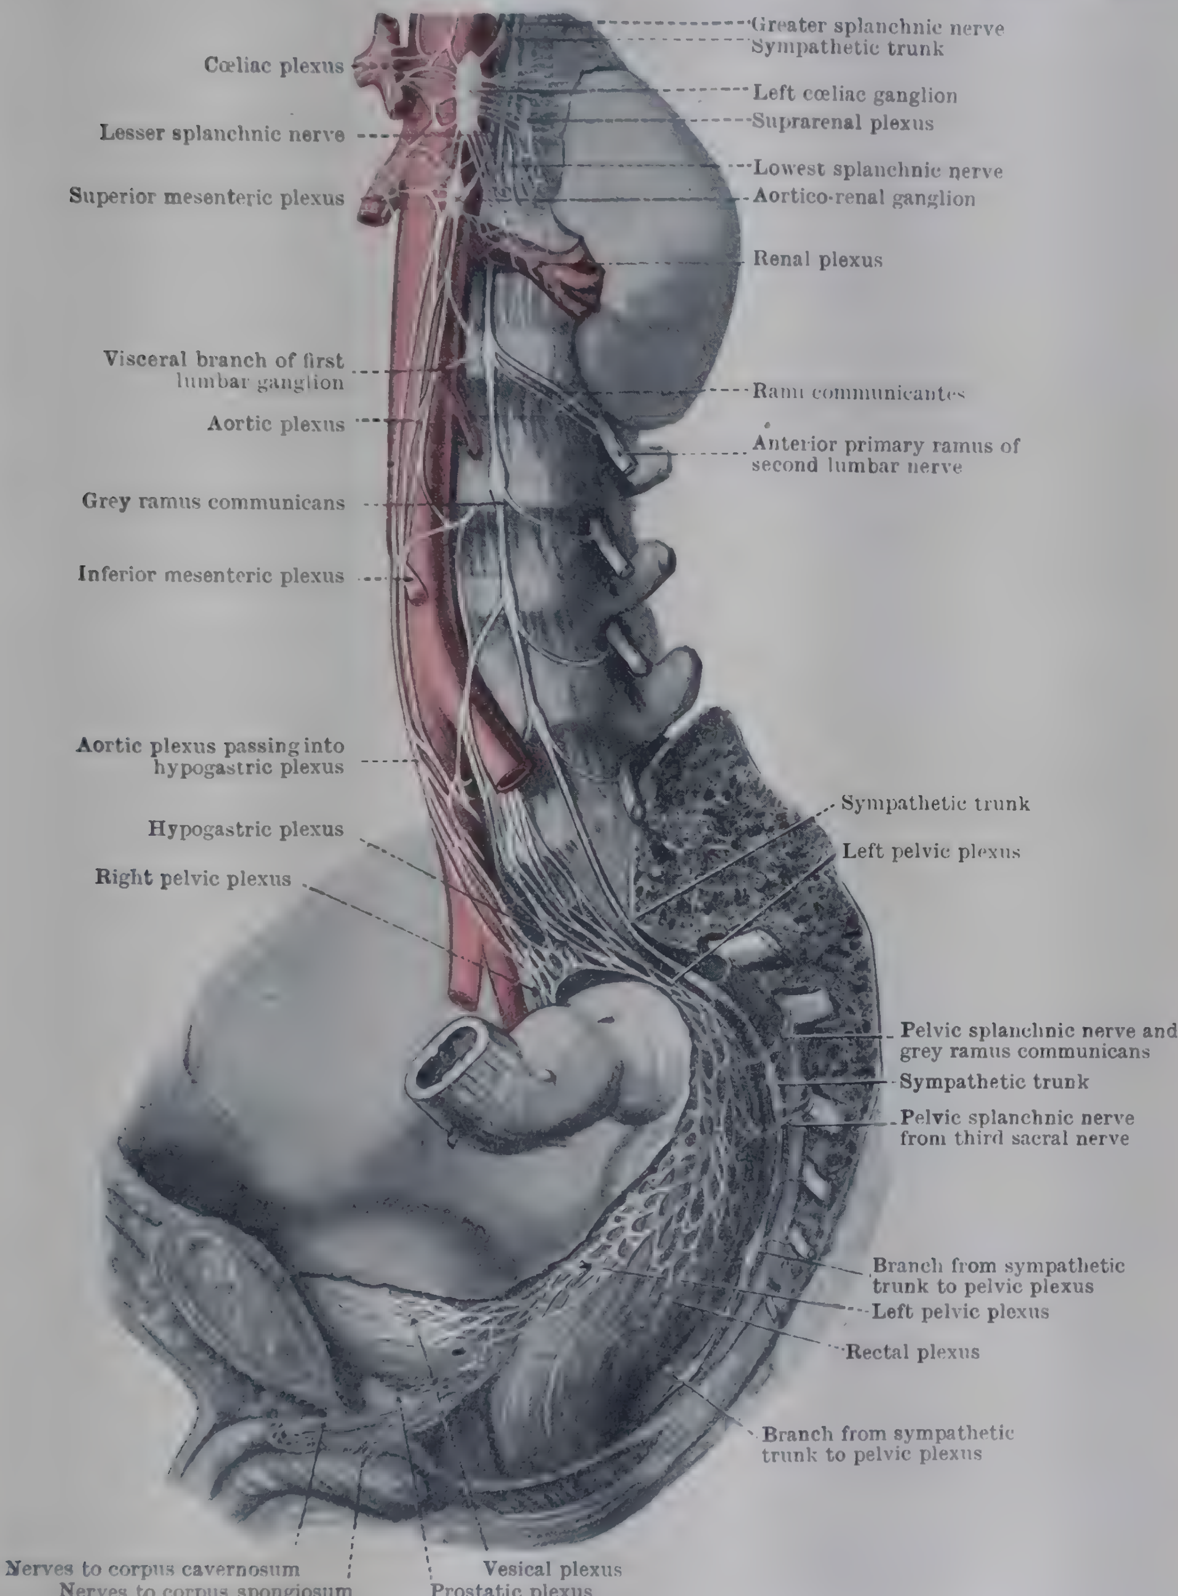

Fig. 967.—Plexuses of Autonomic System in Abdomen and Pelvis.

ganglia around the artery. All the ganglia above described are linked together within the general plexus and the plexuses and ganglia of the two sides intercommunicate freely in front of the aorta.

Afferent Branches of Cœliac Plexus.—The **sympathetic branches** are the splanchnic nerves from the thoracic part of the trunk. The **greater splanchnic nerve** enters the abdomen through the crus of the diaphragm and very soon joins the upper pole of the cœliac ganglion, where most of its fibres appear to end; but

some run directly to the suprarenal gland and a few extend beyond the cœliac ganglion to reach the aortico-renal ganglion. The **lesser splanchnic nerve** enters the abdomen lateral to the greater and gives branches to all three named ganglia of the cœliac plexus. The **lowest splanchnic nerve**, when it exists, joins the aortico-renal ganglion or adjacent plexus. The **vagal branches** are given off by the posterior gastric nerve very soon after it has entered the abdomen. They are distributed through the cœliac and superior mesenteric ganglia. Other vagal branches go direct to the stomach and liver without participation in the cœliac plexus (see p. 1041).

Efferent Branches of Cœliac Plexus.—The efferent branches of the cœliac plexus and its contained ganglia are numerous and not devoid of variation so far as their gross pattern is concerned. They are all, however, to be regarded as extensions of the plexus—*i.e.*, intermingled fibres and ganglion-cells, and, amongst the fibres, there are both pre- and post-ganglionic efferent neurons as well as splanchnic afferent neurons. A great many of the branches accompany blood-vessels and are commonly named after the vessels concerned: such nerves have a double significance, viz., they are in part vasomotor to the vessels they accompany, and they contain also the fibres destined for the supply of viscera within the field of distribution of the vessel. Both parasympathetic and sympathetic fibres run together to the viscera. The vasomotor nerves are presumably of sympathetic origin. It will be sufficient to indicate very briefly the various branches or extensions of the cœliac plexus.

(*a*) Extensions of the plexus accompany the branches of the cœliac artery itself:—the **left gastric plexus** supplies branches to the œsophagus and stomach; the **hepatic plexus** supplies branches to the liver, gall-bladder, stomach, duodenum, and pancreas; and the **splenic plexus** sends offsets to the spleen, pancreas, and stomach.

(*b*) The **phrenic plexus** accompanies the phrenic artery and is distributed to the diaphragm, suprarenal plexus, inferior vena cava, and the œsophagus. It joins the phrenic nerve, with which some of its fibres are distributed; on the right side, at its junction with the phrenic nerve, there may be a *phrenic ganglion*.

(*c*) The **suprarenal plexus** is large and derived widely from the cœliac plexus as well as directly from the splanchnic nerves. The fibres are to be regarded in this case as *preganglionic* sympathetic neurons which are for distribution to the medulla of the suprarenal gland: the medullary cells of the suprarenal are, developmentally considered, equivalent to postganglionic neurons (Elliott, 1913; Young, 1939; MacFarland & Davenport, 1941).

(*d*) The **renal plexus** is derived from the aortico-renal ganglion in the main, from the lesser and lowest splanchnic nerves and from the abdominal aortic plexus (Mitchell, 1935 *a*). It extends along the renal vessels to the hilum of the kidney. Communication is established between renal and suprarenal plexuses.

(*e*) The **testicular** and **ovarian plexuses** are offshoots of the cœliac plexus in the region of the aortico-renal ganglion. The community of origin of the renal and gonadal plexuses recalls their developmental association. Each accompanies its corresponding testicular or ovarian vessels; the testicular plexus supplies the spermatic cord, epididymis, and testis, while the ovarian plexus supplies the ovary, broad ligament, and uterine tube and ends in communication with the uterine plexus (derived from the pelvic plexus).

(*f*) The **superior mesenteric plexus** is at its commencement closely associated with the cœliac plexus and derives its fibres from that plexus generally as well as from the obvious ganglia embedded in it. It accompanies the superior mesenteric artery and its various branches and so reaches the gut between the layers of the mesentery. In this manner both parasympathetic and sympathetic nerves reach the small intestine, cæcum, and appendix, and the ascending and transverse portions of the colon. In the gut-wall, the parasympathetic fibres are relayed through the terminal (myenteric and submucous) plexuses.

(*g*) The **abdominal aortic plexus** is formed by an extension of the cœliac plexus downwards in front of the aorta as several strands towards the origin of the inferior mesenteric artery; it must be regarded in the main as the counterpart of

the superior mesenteric plexus destined for more distal parts of the intestine. The nerve strands running downwards from the cœliac plexus in front of the aorta are reinforced near the origin of the inferior mesenteric artery by visceral branches of the upper two lumbar ganglia (Fig. 968). The plexus is distributed in two parts—the first forms the perivascular plexus which accompanies the inferior mesenteric artery and the second is the extension which descends to join the hypogastric plexus.

(*h*) The **inferior mesenteric plexus** is composed of sympathetic contributions from the aortic plexus and the upper two lumbar ganglia as well as certain components that ascend from the sacral parasympathetic (Fig. 968). The latter are said (Telford & Stopford, 1934) to ascend alongside or incorporated in the hypogastric plexus and to reach the inferior mesenteric plexus a short distance below the origin of the artery. Thereafter they are distributed in company with the sympathetic components of the plexus. Offshoots accompany all the branches of the artery and are distributed to the descending colon, pelvic colon, and upper part of rectum. The plexus so formed around the inferior mesenteric artery and its branches is a gangliated plexus: numerous microscopic aggregations of nerve-cells are disposed throughout the plexus but no inferior mesenteric ganglion as such is present in Man.

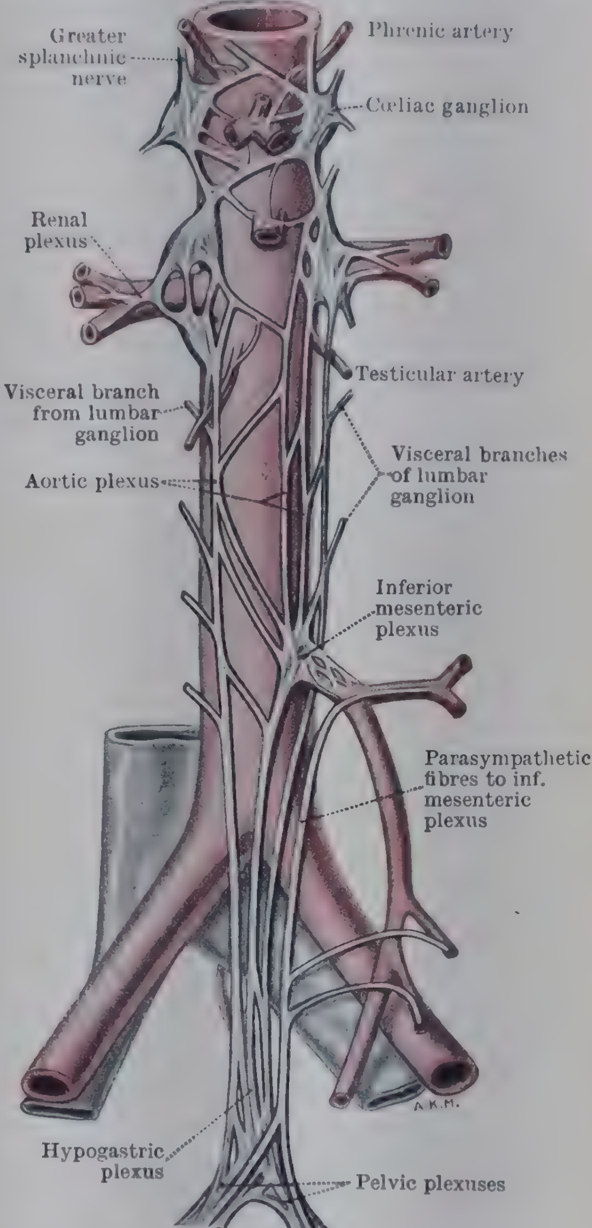

Fig. 968.—The Aortic and Hypogastric Plexuses.

Hypogastric Plexus.—This plexus has two main components. (*a*) From the aortic plexus there is a downward continuation over the aortic bifurcation in the form of several strands of fibres (Fig. 968). (*b*) Visceral branches from the lumbar ganglia contribute largely to its formation: from the upper two ganglia branches join the aortic plexus near the origin of the inferior mesenteric artery and run down with it to join the hypogastric plexus; and from the lower two lumbar ganglia visceral branches run more directly to the plexus. There is thus formed a plexiform mass of fibres and interposed ganglion-cells which occupies the interval between the common iliac arteries in front of the body of the fifth lumbar vertebra. The visceral branches contain both afferent and efferent fibres.

The commonly employed surgical name, "presacral nerve", is misleading, since the structure is not a nerve in the generally accepted sense nor is it presacral in position. Although generally plexiform, it may be condensed into a few strands, but in all cases it is composed of intermingled nerve-fibres and ganglion-cells and is thus a typical gangliated plexus. It represents the continuation downwards of the abdominal plexuses towards the pelvic region.

Pelvic Plexus.—There are two pelvic plexuses, right and left, embedded in the areolar tissue which occupies the interval between the viscera and the lateral pelvic wall. The whole mass is irregularly disposed and consists of a network of fibres with interposed nerve-cells. It is closely associated with the blood-vessels

of the region. In the male, the pelvic plexus flanks the rectum and adjacent parts of the bladder and seminal vesicle. In the female, its posterior extremity, lying alongside the rectum, contributes to the formation of the utero-sacral folds; it then extends forwards beside the vagina. Entering each pelvic plexus are three sets of fibres. (1) The corresponding half of the **hypogastric plexus,** which descends to reach the postero-superior part of the pelvic plexus. This is essentially a *sympathetic* contribution and contributes largely to the bulk of the pelvic plexus. The other contributions are derived from (2) the **second and third sacral ganglia of the sympathetic trunk**—a relatively minor group of fibres, and (3) the **pelvic splanchnic nerves** (*sacral parasympathetic*) from second and third or third and fourth sacral nerves.

From the plexus, branches—or rather extensions—proceed to various organs which occupy the pelvis and the perineum. Some **recurrent branches**—parasympathetic—ascend from the plexus *via* the hypogastric plexus to reach the *inferior mesenteric plexus,* of which they form a part and through which they are distributed with its sympathetic elements (Telford & Stopford, 1934; Mitchell, 1935 *b*).

Extensions from the main pelvic plexus, carrying both sympathetic and parasympathetic elements, are distributed as follows:—

(*a*) The **rectal plexus** accompanies vessels to the wall of the rectum and anal canal. This is joined by a continuation of the inferior mesenteric plexus on the wall of the gut. In addition, some few direct rectal branches are given off from the sacral sympathetic ganglia. All the various nerves intercommunicate in a plexus on the wall of the gut.

(*b*) The **vesical plexus** proceeds forwards from the anterior part of the pelvic plexus, invests the ureter in its terminal part, and disposes itself around the wall of the bladder. It supplies branches to the bladder, the terminal part of the ureter, the seminal vesicle, and the vas deferens. The last extend as far as the epididymis.

(*c*) The **prostatic plexus** is of considerable size and extends from the antero-inferior part of the pelvic plexus. Besides supplying the prostate, branches are given to the prostatic and membranous parts of the urethra and to the seminal vesicle.

(*d*) The **uterine plexus** passes upwards into the broad ligament with the uterine artery. The lower branches are distributed to the cervix of the uterus, while longer branches ascend to the body, the fundus, and the uterine tube.

(*e*) The **vaginal plexus** is formed mainly from the visceral branches of the sacral nerves which enter the pelvic plexus. It supplies (parasympathetic) the walls of the vagina and the urethra. The uterine and vaginal plexus together correspond to the prostatic plexus.

(*f*) The **cavernous plexus.** In the male, extensions from the prostatic plexus reach the erectile tissues of the penis, and in the female similar nerves proceed to the clitoris from the vaginal plexus. It is suggested that the pudendal nerve also carries autonomic fibres, both sympathetic and parasympathetic, to the penis or the clitoris.

Innervation of Bladder and Rectum

It will be realized that three sets of fibres are involved in the innervation of pelvic structures:—(1) The **pudendal nerve,** *i.e.*, a somatic nerve with both afferent and efferent fibres. The efferent fibres supply the striated sphincter of the urethra and the external anal sphincter. The afferent fibres are concerned in the innervation of the mucosa of the anal canal and probably the prostatic part of the urethra. (2) **Sympathetic nerves** derived from the lower part of the thoraco-lumbar outflow. They reach pelvic viscera either along the inferior mesenteric plexus or by way of the hypogastric plexus and the pelvic plexus. (3) **Parasympathetic fibres** leave the spinal cord in the second and third or the third and fourth sacral nerves and then, as the pelvic splanchnic nerves, they are distributed to the pelvic plexus.

The sympathetic and parasympathetic nerves are both afferent and efferent.

The *afferent fibres* appear to be distributed mainly to the muscular coats of the bladder

and rectum. Impulses leading to pain caused by overstretching of the muscular walls probably travel by the sympathetic fibres, but the more important proprioceptive afferent impulses normally aroused by the stretching of the walls during the filling of the viscus travel in the sacral parasympathetic fibres. These proprioceptive impulses are of great importance since they initiate the stretch-reflex so important in the onset of defæcation and micturition.

The *parasympathetic efferent fibres* are concerned in contraction of the expulsive musculature and inhibition of the non-striated sphincters of the bladder and rectum. The *sympathetic efferent fibres* have the opposite effect.

Of the two parts of the autonomic system, the parasympathetic is to be regarded as the more important on both afferent and efferent sides of the reflex arcs involved in normal micturition and defæcation.

In seminal ejaculation, the sympathetic control would appear to be of greater importance since it brings about the contraction of the seminal vesicles and ejaculatory ducts, and also leads to inhibition of the detrusor muscle of the bladder and to contraction of the non-striated sphincter of the urethra. In this way micturition is inhibited during ejaculation and the reflux of seminal fluid into the bladder avoided.

INNERVATION OF BLOOD-VESSELS

In the description of the autonomic plexuses given in the previous pages frequent reference has been made to **perivascular plexuses**. All blood-vessels are accompanied by nerve-fibres, both medullated and non-medullated, some of which are afferent and others motor. Ganglion cells are not encountered in these plexuses. The motor or vaso-constrictor fibres are in general of sympathetic origin, although in certain regions vaso-dilator fibres exist and are of parasympathetic origin, *e.g.*, in the chorda tympani branch of the seventh cranial nerve and in the sacral parasympathetic fibres to the erectile-tissue of the external genitalia. It is more than likely, however, that in the vast majority of blood-vessels the state of constriction or dilatation reflects variations in constrictor (sympathetic) tone rather than a double innervation by sympathetic and parasympathetic fibres.

The *vessels of the limbs* have a double source of **vasomotor fibres**: some extend into the proximal part of the limb as a perivascular plexus derived directly from the sympathetic trunk; this is the *proximal supply*, and does not extend far along the main artery of the limb. It is replaced by the *distal supply*, derived from the peripheral nerves of the limb; these fibres are given off from the peripheral nerves at various levels to the arteries of the limb. It is evident that the latter group of fibres are those which have been contributed to the spinal nerves from the sympathetic trunk via the grey rami communicantes. The vessels of the abdomen and pelvis, however, are innervated only by perivascular plexuses which extend along them from the sympathetic trunk directly.

All vessels are not equally supplied with vasomotor nerves: it would appear that cutaneous vessels generally and those in the distal parts of the limbs (Pick & Sheehan, 1946) are particularly well supplied with sympathetic fibres; further, certain special regions in the vascular bed, *e.g.*, arterio-venous anastomoses (Fig. 1072, p. 1246), have a richer vasomotor innervation than others.

Vasosensory fibres are widely distributed; they are found intermingled with the vasomotor fibres; but whereas the vasomotor are most often non-medullated the vasosensory fibres are usually medullated. The impulses which they convey do not as a rule arouse any conscious state; it must be presumed, however, that they have a rôle in vascular reflexes. The sensory mechanism associated with blood-vessels is highly specialized in certain regions and much attention has been paid recently to these special localized vasosensory zones. Around the carotid sinus, in the aortic arch and also in the heart-wall and the adjacent parts of the great veins. there are areas which respond to pressure changes in the lumen. The nerve-endings in each case are to be regarded as specialized *vasosensory receptors*; the afferent fibres concerned run in the ninth nerve (carotid sinus) and the vagus (heart and aorta), *q.v.*

Associated with the above zones are certain nests of epithelioid cells (Campenhout, 1946). Adjacent to the carotid sinus lies the carotid body which receives an abundant blood-supply from the adjacent artery and is richly innervated particularly by the ninth nerve (see p. 808). Experimental evidence suggests that it functions as a *chemo-receptor*, its cells being responsive to variations in the chemical constitution of the blood. Other discrete collections of cells (*aortic glomera*) are to be found adjacent to the heart and great vessels, but their function has not been ascertained. Certain of them, however, from their histological resemblance to the carotid body and from their vascular and nervous (vagal) connexions would appear, on anatomical grounds, to subserve a comparable function.

DEVELOPMENT OF AUTONOMIC NERVOUS SYSTEM

It was noted earlier (p. 1117) that certain cells of the neural crest—the **sympathoblasts**—provide the neuronal basis of the peripheral sympathetic system. These cells, retaining their nervous potentialities, migrate to the sympathetic trunk and to various sympathetic plexuses. Comparable cells are found in association with the neural crest of the head-region of the embryo, and they take part in like manner in the formation of the cranial parasympathetic ganglia and plexuses. It is more than likely, however, that the neural crest is not the sole producer of sympathoblasts; evidence accumulates to suggest that many cells migrate along the anterior nerve-roots from the cord to take part in the formation of sympathetic ganglia (Raven, 1937), and Keuning (1944) has brought forward evidence for the differentiation of ganglion cells in the gut wall from mesodermal tissues.

In the **spinal region** sympathoblasts detach themselves from the ventral border of the primitive spinal ganglion and migrate outwards along the paths of the developing posterior roots of the spinal nerves. Meanwhile, other cells have wandered out from the neural tube along the anterior roots to join the cells of neural-crest origin. These two sets of cells intermingle and thenceforward it is impossible to distinguish between them, nor is it possible to say what part each plays in the subsequent development of the sympathetic system. Leaving the spinal nerves, these wandering cells migrate to the neighbourhood of the aorta where, by rapid proliferation, they form compact masses which fuse from segment to segment and produce a continuous longitudinal gangliated cord—the **sympathetic trunk**. Primarily the ganglia are segmentally arranged and placed closely together. With growth of the embryo and with the development of nerve-fibres, the ganglia become separated by interganglionic cords. Pick & Sheehan (1946) suggest that the primordial ganglia consist of rostral and caudal portions and that the definitive ganglia of the sympathetic trunk are compounded of fusions of adjacent rostral and caudal portions. This would account for the multiplicity of rami which may be associated with one ganglion; and variations in the process of fusion would lead to the commonly observed fluctuations in the total number of ganglia.

Other cells leave the region of the sympathetic trunk and migrate farther afield to form **gangliated plexuses** closer to the viscera to be supplied, *e.g.*, the cœliac plexus. These cells have the same origin as those which form the ganglia of the trunk. The cells of such plexuses are, however, not derived only from spinal sources, for many of them are the result of migrations of cells along the vagus nerve (parasympathetic) and along the pelvic parasympathetic nerves. In the terminal plexuses in the wall of the gut and other viscera the cells are of parasympathetic origin.

In the meantime connexions are established between the spinal cord and the migrated sympathetic cells. From nerve-cells in the grey matter of the cord (the future intermedio-lateral cell-column) processes grow out along the anterior nerve-roots into the anterior primary rami and from here they pass as **white rami communicantes** to reach the sympathetic trunk, where they undergo synapse with sympathetic neurons; or others may pass through the trunk to activate cells in more peripherally placed ganglia.

Receptor neurons of the spinal ganglia also send peripheral processes through the white rami communicantes to be distributed to the regions innervated by the sympathetic system. These fibres (splanchnic afferents) have no synaptic relationship with the cells of such sympathetic ganglia as they may traverse.

The cells of the various ganglia send out processes (postganglionic fibres) which may travel in a variety of directions. Many such processes from the ganglia of the sympathetic trunk take a recurrent course, as **grey rami communicantes**, to join a spinal nerve and travel in it to reach peripheral structures such as sweat-glands and blood-vessels. Others pass as direct visceral branches to various organs; these visceral branches frequently run through plexuses and many of them reach their destination by accompanying blood-vessels as perivascular nerves.

In the **head-region** the autonomic (parasympathetic) ganglia are not segmentally arranged, but their neurons are derived in a manner comparable with that of sympathoblasts in the spinal region. They also have arisen from the neural crest in the head-region, and here too it would appear that other types of cells, unassociated with the neural crest, may contribute to the formation of the ganglia. The cells, however derived, migrate outwards along the pathway of growth of one or other of the cranial nerves. The extensive distribution of the vagus nerve leads to a very distant migration of the cells which have arisen developmentally in association with it; the cardiac and pulmonary plexuses and the various abdominal plexuses, including the terminal plexuses in the gut-wall, are to be regarded in greater or less degree as vagal plexuses, and the cells within them as elements migrated from the neural crest or from the wall of the neural tube along the pathway of vagal growth. (Keuning, 1944, has however suggested a possible local mesodermal source for the neurons in the plexuses of the gut-wall.) The ganglia which remain in the head-region are all composed of cells which have had their developmental origin mainly in the trigeminal ganglion, though the third, the seventh, and the ninth nerves have all played some part in providing cells for these ganglia (Cowgill & Windle, 1942).

The **ciliary ganglion** derives its cells mainly from the trigeminal ganglion by way of the ophthalmic nerve but also from cells which have migrated outwards along the oculomotor nerve. This ganglion receives its preganglionic innervation from cells which lie in the mid-brain and whose processes grow outwards in the oculomotor nerve.

The **sphenopalatine ganglion** is composed of cells which have migrated from the trigeminal ganglion along the maxillary nerve and also of cells which have travelled peripherally along the

facial nerve and its greater superficial petrosal branch. Its preganglionic connexions with the brain-stem run in the seventh nerve.

The **otic ganglion** arises from cells which migrate along the lesser superficial petrosal nerve from the part of the neural crest associated with the ninth nerve. Cells from the trigeminal ganglion also contribute by migration along the mandibular nerve. The otic ganglion receives its preganglionic innervation by way of the ninth nerve.

The **submandibular ganglion** and smaller ganglionic masses in its neighbourhood are composed of cells which have migrated peripherally along the mandibular nerve and along the facial nerve (chorda tympani). It is innervated by preganglionic fibres which have travelled outwards in the seventh nerve.

The various conflicting views regarding the development of the autonomic nervous system have been reviewed by Campenhout (1930) and Yntema & Hammond (1947).

THE SKIN AND THE SENSORY ORGANS

by C. M. West, *M.C.*, M.B., B.Ch., Sc.D.,
Professor of Anatomy, University of Wales

The **sensory organs** in general constitute the apparatus by which Man and other animals are made acquainted with their surroundings. Sensory stimuli may be received by highly developed sense-organs localized in particular parts of the body, for example, the eye and the internal ear, or by end-organs distributed widely over the surface and in the deeper parts of the body. As the skin, in addition to its other functions, is one of the principal sense-organs in virtue of the numerous nerve-endings and special end-organs that it contains, it is included in this Section.

Every sense-organ consists of (*a*) a peripheral or receptive portion, where impulses are generated in response to external stimuli, (*b*) an intermediate or conducting portion, along which the impulses are conveyed, and (*c*) a central or perceptive portion, where the impulses are collected and transformed into sensations. The conducting and perceptive portions of the various sense-organs have been described in the Sections on the Nervous System; their peripheral or receptive portions form the subject-matter of this Section, and are grouped under two headings. (1) Those associated with the *general sensations* of touch, pressure, pain, and temperature. (2) Those associated with the *special senses* of sight, hearing, smell and taste; the internal ear contains, in addition to the organ of hearing, a special organ associated with the function of equilibration. Special nerve-endings occur also in relation to muscle-fibres and tendons and are of importance in the orientation and equilibration of the body.

THE SKIN

The **skin** covers the body, and it is continuous at the orifices on its surface with the mucous lining of the alimentary canal and other passages. It contains the peripheral terminations of many of the sensory nerves, and it serves as a protection to the deeper tissues. It plays an important part in regulating the body temperature, and, by means of its sweat-glands and sebaceous glands, it acts as an excretory organ. Its superficial layers are modified in certain situations to form the hairs and nails.

The skin is very elastic, and its colour, determined partly by its own pigment and partly by that of the blood, is deeper on exposed parts and in the regions of the external genital organs, axillæ, and mammary areolæ, than elsewhere. The pigmentation of the skin is due mainly to the accumulation of granules of *melanin* in the basal-cell layer of the epidermis, but four other pigments have been identified in the human skin: *melanoid*, diffused throughout the epidermis; *carotene*, in the horny zone and in the fat of the corium and subcutaneous tissue; *reduced hæmoglobin* and *oxy-hæmoglobin* in the vessels of the corium and subcutaneous tissues. Females have whiter skin than males, with less melanin and more blood-pigment and carotene (Edwards & Duntley, 1939). The darker colour of the skin of the negro is due to a wider distribution of melanin and melanoid throughout the layers of the epidermis. Mankind is divided into three groups on the basis of skin colour:

Melanoderms, or black-skinned; Xanthoderms, or yellow-skinned; and Leukoderms, or white-skinned.

On the surface of the skin there are the openings of the hair-follicles and of the ducts of the sebaceous glands and sweat-glands. The palmar surface of the hand and the plantar surface of the foot show numerous permanent *ridges*, which, particularly in the case of those of the terminal phalanges of the digits of the hand, may be employed for purposes of identification by means of finger-prints, since they are always characteristic in the details of their arrangement for every individual. Where subcutaneous muscles exist the skin can be thrown into wrinkles by their contraction. Over the greater part of the body it is freely movable; but it is bound down to the underlying tissues on the scalp and lateral surfaces of the auricles, the palms and soles, and at the flexure-lines of joints. In the digits special **skin-ligaments** occur which prevent lateral bulging of the skin at the joints during flexion.

Fig. 969.—Schematic Vertical Section of Skin.

Structure.—The skin is composed of a deep layer called the corium or *derma*, and a superficial layer called the epidermis (Figs. 969-971).

The **corium** or *true skin* is derived from the embryonic mesoderm, and consists essentially of a felted interlacement of white and elastic fibres. Its superficial part is thrown into numerous folds, the **papillæ of the corium**, which project into corresponding recesses in the overlying epidermis and constitute its **papillary layer**. The deeper part is known as the **reticular layer**, on account of the network-like arrangement of its connective tissue fibres. The deeper layer passes, as a rule, without any line of demarcation into the layer of subcutaneous fatty tissue, but in some parts it rests upon striated or plain muscle-fibres.

The papillæ of the corium are usually developed more in the hand and foot, where the ridges of the epidermis, referred to above, are found, and usually two or more papillæ project towards the under surface of each ridge. The papillæ contain vascular loops and, in many cases, certain special sensory nerve-endings. The fibres of the corium are arranged all over the body in definite lines. These often produce characteristic creases, for example on the dorsum of the hand, and are of particular interest because, in penetrating wounds by a round instrument, invariably a linear slit results, its direction being determined by the tension of the fibres of the corium (Wood Jones, 1941).

The **epidermis** or *scarf-skin* is derived from the embryonic ectoderm and covers the corium. Its thickness varies in different parts of the body and ranges from 0·3 mm. to 1 mm. or more; it is thickest on the palms of the hands and soles of the feet, and thinnest on the eyelids and penis. It is non-vascular and may be divided into the following layers or strata, when traced from the surface inwards: the stratum corneum, stratum lucidum, stratum granulosum, and stratum germinativum. The **s. germinativum** lies next to the corium, and is so named because it is from

this layer that the more superficial layers are continually being derived. It is often called, after its discoverer, the *Malpighian layer* (Malpighi, 1628-1694). The cells in the superficial part of this layer are joined together by protoplasmic bridges so that they form in reality a continuous sheet of cells, *i.e.*, a syncytium. These bridges appear as spines or prickles on the individual cells and so this layer is sometimes known as the *s. spinosum*, or *prickle-cell layer*. The deepest part of the s. germinativum is known as the *basal-cell layer*; its cells are rather elongated or columnar in shape, but they become more flattened in the superficial part of the stratum. The s. granulosum is a layer two or three cells thick; as its name implies, the cells contain granules, which may be associated with the elaboration of the keratin that is characteristic of the s. corneum. There is a gradual change in the character of the cells of the epidermis as they are traced towards the surface. They lose their nuclei and their cell-boundaries, and this is apparent in the next layer, the s. lucidum, which receives its name on account of its clear appearance and seemingly acellular nature. The s. corneum, is the most superficial layer, and is composed of degenerating cells which have acquired a horny or keratinous character, and which are continually being shed to be replaced by cells migrating towards the surface from the deeper layers. S. corneum, s. lucidum and s. granulosum together constitute the *horny zone* of the epidermis, and the s. germinativum is the *germinative zone*.

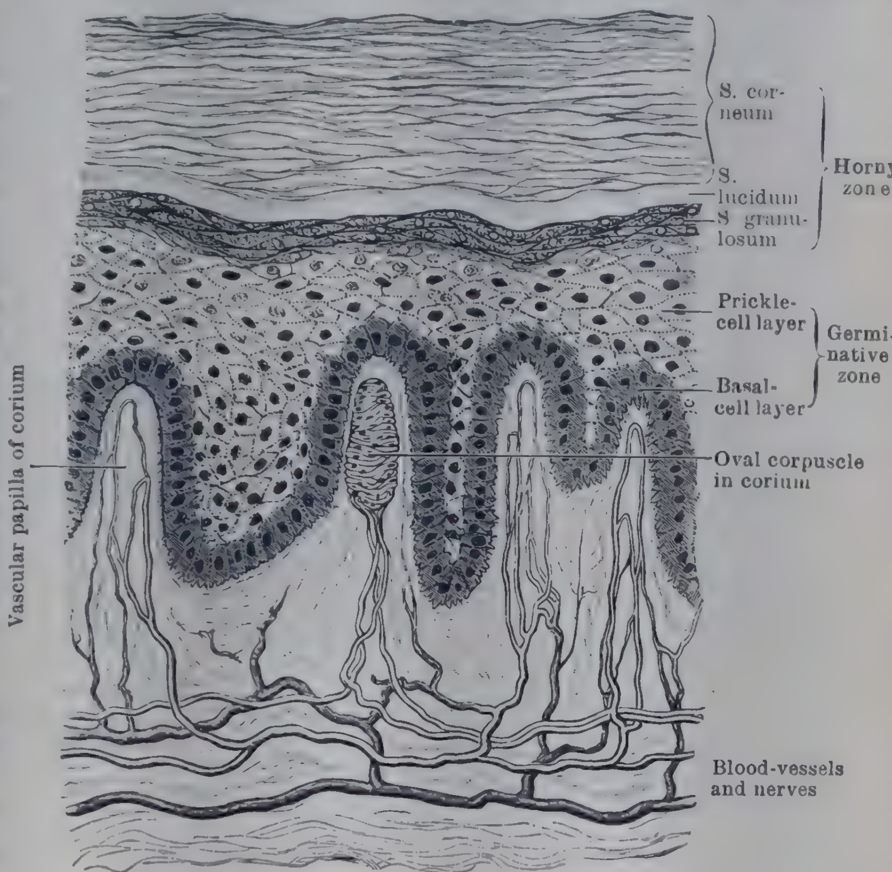

Fig. 970.—Vertical Section of Epidermis and Papillæ of Corium.

Vessels and Nerves.—In the subcutaneous tissue the **arteries** form a plexus from which branches extend into the corium, where they supply the hair-follicles and glands, and form a second plexus under the papillæ, to which small loops are given. The **veins** and the **lymph-vessels** begin in the papillæ, and, after forming subpapillary plexuses, open into their respective subcutaneous vessels. In the pads of the fingers and toes, and in some other parts of the body, complicated arterio-venous anastomoses occur in the deeper parts of the corium (Boyd, 1939; see also Lewis, 1927).

Since the skin is the main receptor of external stimuli of various kinds, it is plentifully supplied with nerves. These constitute the cutaneous distribution of the peripheral nerves, and many different modes of termination of the nerve-fibres are found, associated with the different stimuli to which they respond. These various nerve-endings are described and illustrated on pp. 1158-1160 and in Figs. 971, 975-977.

Appendages of the Skin

The appendages of the skin are the nails, the hairs, the sebaceous glands, and the sweat-glands.

Nails.—The **nails** (Figs. 972, 973) are epidermal structures, and represent the hoofs and claws of the lower animals. They are a special modification of the superficial layers of the epidermis, particularly of the s. lucidum. As can be seen in a longitudinal section (Fig. 973), it is as if the skin had been deeply invaginated and then greatly cornified. Thus, the various strata of the skin can all be recognized, modified to a greater or less degree. The visible part of the nail is its **body**; the hidden part, from which growth of the nail occurs, is the **root**. It is covered by a fold of skin called the *eponychium* which at its free edge is composed of s. corneum only, and constitutes the *cuticle*, which is removed in manicuring the hands. The nail rests on the **nail-bed**, and the most distal part of this is called the *hyponychium*.

The sides of the nail are buried, but less deeply than the root, by **nail-walls.** Dermal papillæ are found in the nail-bed, as on the palmar surface of the digits, and they are arranged in longitudinal rows that give rise to the striations seen on the body of the nail. Extending for some distance beyond the eponychium there is a white semilunar area of the nail called the **lunula**. Its development varies considerably in different persons and in the various digits.

Hair.—**Hairs** are developed more or less over the whole surface of the body with the exception of the palm and the sole, the terminal phalanges of the digits, the red part of the lips, the glans and prepuce of the penis, and the inner surface of the

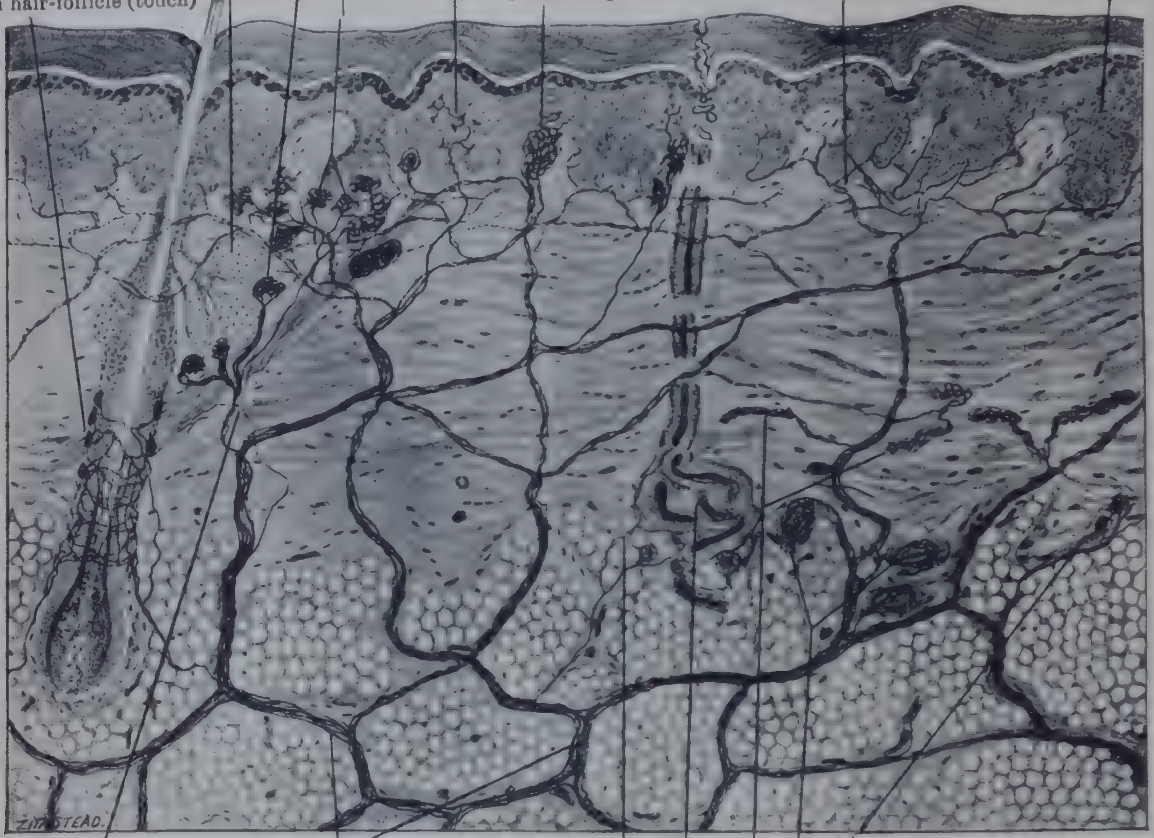

Fig. 971.—Composite Diagram showing the Innervation of the Human Skin. (Woollard, Weddell, & Harpman, 1940.)

labia majora. Over most of the body the hairs are rudimentary, giving an appearance of hairlessness, though in reality their number is greater in certain areas than in supposedly hairy animals such as the chimpanzee and the gorilla. The distribution and 'lie' of the hairs follows a definite arrangement, giving rise to the so-called *hair-tracts* (Kidd, 1903; Wood Jones, 1941; Le Gros Clark, 1945). There is also a sexual differentiation in the distribution of the hairs. As is well known, they show much greater development on the face of men than of women, and in the pubic region their distribution is more restricted in the female than in the male (Dupertuis, Atkinson & Elftman, 1945). The character of the hair is employed in classifying the races of Man; thus straight hair is characteristic of Mongolians, wavy of Europeans, and frizzly or woolly of Negroes.

The **root of the hair** is embedded in a depression of the skin termed the **hair-follicle** (Fig. 969); the *shaft* is the free portion of the hair, and consists from without inwards of cuticle, cortex, and medulla. The *cuticle* is formed of a layer of imbricated scales which overlap one another from below upwards. The *cortex* consists of longitudinally arranged fibres made up of elongated, closely applied, fusiform cells which contain pigment and sometimes air-spaces—the latter especially in white hairs. The *medulla*, absent from the fine hairs of the body generally and from the hairs of young children, forms a central core which appears black by transmitted

light and white by reflected light; it is composed of polyhedral nucleated cells which contain pigment, fat-granules, and air-spaces.

The **hair-follicle** is an oblique invagination of the epidermis and corium, and in curly hair it is twisted; the ducts of the sebaceous glands open into the hair-follicles just deep to the papillary layer of the corium. The portion of the follicle derived from the corium consists of a sheath of fibrous tissue arranged as an external longitudinal layer and internal circular layer, the latter being lined with a hyaline layer directly continuous with the basement-membrane

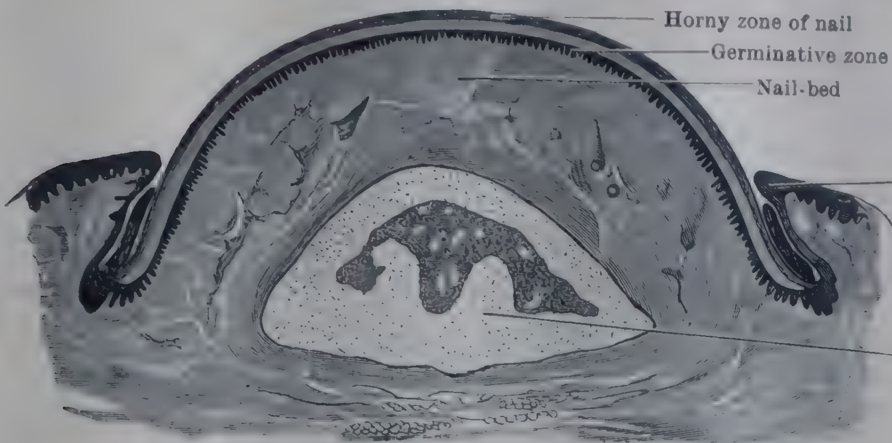

Fig. 972.—Transverse Section of Nail.

of the corium. The parts of the follicle derived from the epidermis are named the **inner** and **outer root-sheaths**. Below the orifices of the ducts of the sebaceous glands the outer root-sheath is formed only by the germinative zone of the epidermis, while above these orifices all the epidermal layers contribute to it. The outer root-sheath is clearly continuous with the germinative layer of the epidermis; it is the thickest component of the wall of the follicle, but becomes gradually thinner towards the hair-root. The inner root-sheath surrounds the cuticle of the hair, and comprises from without inwards:—(*a*) *Henle's layer*—a layer of nucleated cubical cells. (*b*) *Huxley's layer*—one or two layers of polyhedral nucleated cells. (*c*) A delicate *cuticle* composed of a layer of flattened imbricated cells, with atrophied nuclei. The bottom of the hair-follicle is moulded over the summit of a vascular **papilla**, derived from the corium and capped by the **bulb of the hair** or expanded part of the hair-root. The cells of the bulb are continuous round its edge with those of the outer root-sheath, and an upward growth from the bulb gives rise to the hair itself. The vessels form capillary loops in the papilla of the hair, and send twigs into the outer layer of its fibrous sheath; the inner and outer root-sheaths

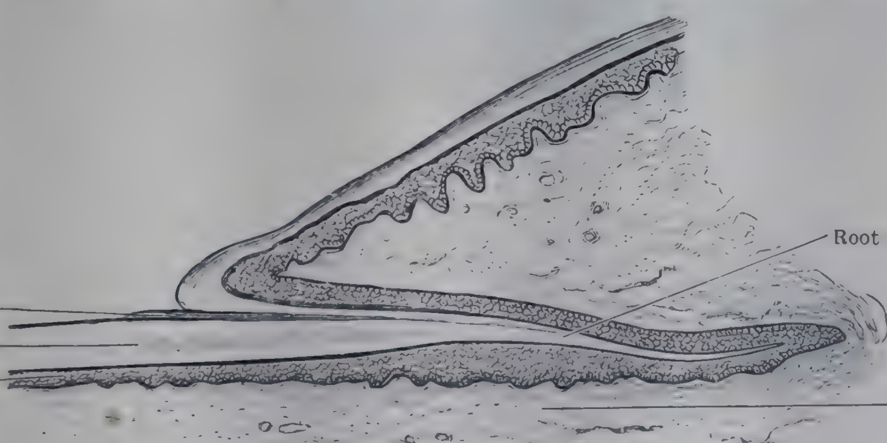

Fig. 973.—Longitudinal Section through Root of Nail.

and the hair itself are non-vascular. The nerves end in longitudinal and annular fibrils below the level of the sebaceous glands and outside the hyaline layer of the follicle.

Sebaceous Glands.—These glands exist wherever there are hairs, and their ducts open into the superficial parts of the hair-follicles (Fig. 969); the number of glands associated with each follicle varies from one to four. On the labia majora and minora, glans penis and mammary areolæ they open on the surface independently of hair-follicles, and in the areolæ they undergo great enlargement during pregnancy. The deep end of each gland expands into a cluster of oval or flask-shaped **alveoli** which are surrounded by a basement-membrane, and are filled with polyhedral cells containing oil-droplets. By the breaking down of the internal cells, their oily contents are liberated as the *sebum cutaneum* and discharged into the hair-follicle;

they are thus examples of *holocrine glands*, in which the secreting cells disintegrate. The glands are then restored by a proliferation of the deeper cells. The size of the glands bears no proportion to that of the hairs, the glands being very large in the minute hair-follicles of the fœtus and new-born child, and also in the follicles of the rudimentary hairs of the nose and certain parts of the face.

Bundles of plain muscular fibres are associated with the hair-follicles, and are named the **arrectores pilorum muscles.** Attached to the deep part of the hair-follicle, and forming with it an acute angle, they pass outwards close to the sebaceous glands, and end in the papillary layer of the corium. They are situated on the side towards which the hair slopes, so that, on contraction, they diminish the obliquity of the hair-follicle and make the hair more erect, and, at the same

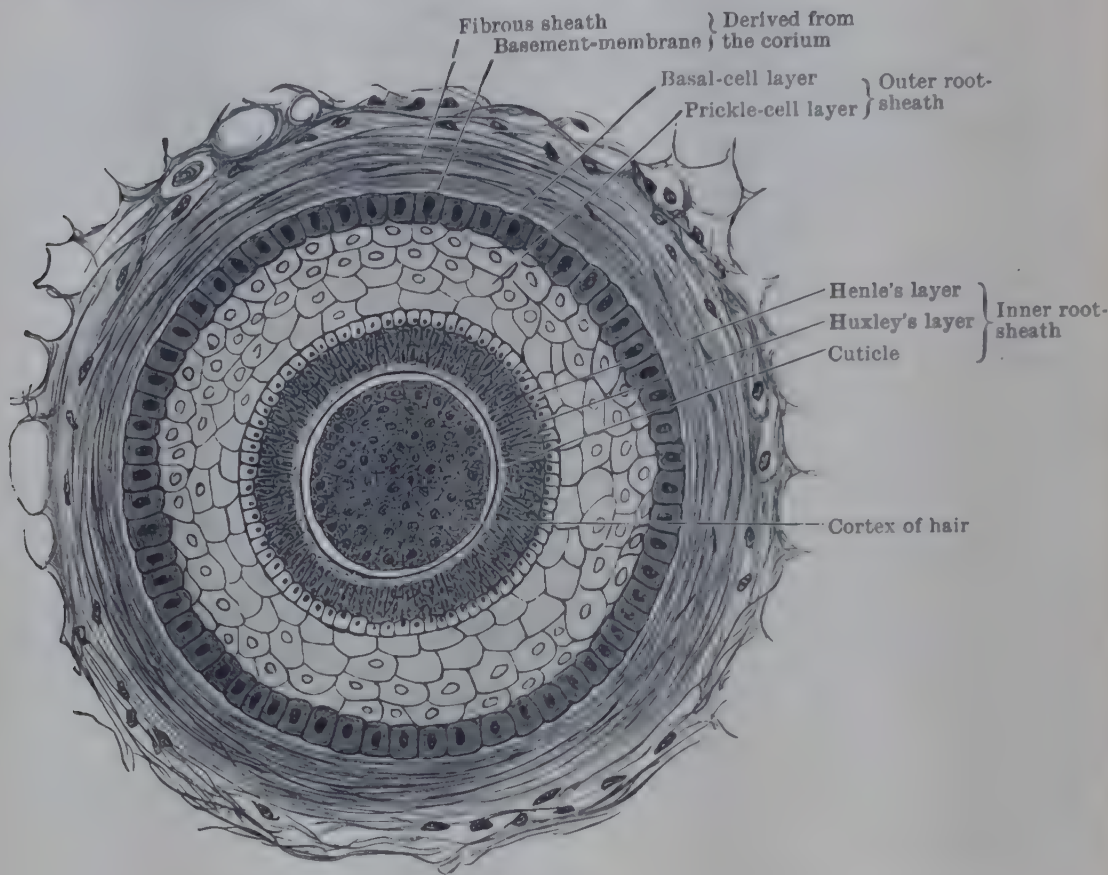

FIG. 974.—TRANSVERSE SECTION OF HAIR-FOLLICLE AND HAIR (semi-diagrammatic).

time, compress the sebaceous glands and expel their contents. The condition of "goose-skin" is caused by the contraction of these slender muscles.

Sweat-Glands.—The sweat-glands are found in the skin of nearly every part of the body; they are relatively few in number on the back of the trunk, but are very plentiful on the palms and soles, where they open on the summits of the skin-ridges and can easily be seen in the living body. Each consists of an elongated tube; the deeper portion of the tube forms its secretory part, and is coiled in the subcutaneous tissue or in the deep part of the corium to form an oval or spherical structure termed the **body** of the gland (Fig. 969). The superficial part of the tube, or **duct**, extends through the corium and epidermis, and opens on the surface by a funnel-shaped orifice called the **sweat-pore**; where the epidermis is thick the duct is spirally coiled.

The bodies of the glands, as a rule, vary in diameter from 0·1 mm. to 0·5 mm., but in the axilla they measure from 1 mm. to 4 mm. Each is surrounded by a capillary network and by a capsule of fibrous tissue inside which there is a homogeneous basement-membrane. The lumen of the tube is lined with cubical epithelial cells, between the deep ends of which and the basement-membrane there is a layer of cells with their long axis parallel to that of the tube; these are considered to be muscle-fibres and to assist in the expulsion of the secretion of the glands. The excretory ducts are devoid of the layer of muscle-fibres, and consist of a basement-membrane lined with two or three layers of polyhedral cells which are covered, next the lumen of the duct, with a thin cuticle.

The **ciliary glands**, at the margins of the eyelids, and the **ceruminous glands** of the external auditory meatus, are modified sweat-glands. The ciliary glands are, however, not coiled; the cell-protoplasm of the ceruminous glands contains yellowish pigment, and their ducts, in the fœtus, open into hair-follicles.

Development of Skin and its Appendages

Skin.—The corium is developed from the mesoderm, the cells of which, immediately underlying the ectoderm, have, by the first month of intra-uterine life, become aggregated together and flattened parallel to the surface of the embryo. By the third month they form two layers, the superficial of which becomes the corium, and the deeper the subcutaneous tissue; the papillæ of the corium make their appearance in the fourth month. The epidermis, nails, hairs, sweat-glands, and sebaceous glands are of ectodermal origin.

The epidermis at first consists of a single layer of cells, but by the end of the second month two layers are present—a superficial layer of flattened cells, and a deeper layer of cubical cells. By the third month three strata are seen, of which the two deeper layers come to form the future germinative zone, while the superficial layer is called the *epitrichium*, since it lies superficial to the emerging hairs, by which it is pushed off to help in the formation of the greasy covering of the child at birth, called the *vernix caseosa*. Cells arise from the germinative zone and become pushed nearer and nearer to the surface, where they undergo gradual cornification and so form the various layers of the horny zone. (See Hanson, 1947.)

Nails.—When seen in section, particularly a longitudinal one (Fig. 973), it is clear that the nail is a modification of the epidermis, and most of the layers of the epidermis can be recognized in the structure of the nail; the only layers unrepresented are the epitrichium and the s. granulosum.

The nail begins to develop about the third month as a thickening of the superficial layers of the epidermis under the epitrichium on the dorsal surface of the terminal phalanx of the digit. This thickening is soon overgrown proximally and at the sides by folds of the whole thickness of the epidermis—the proximal and lateral **nail-folds**. In the nail-thickening, keratinization of the s. lucidum of the epidermis gives rise to the horny zone of the nail; the s. granulosum is unrepresented; and the s. germinativum remains relatively unaltered at the root of the nail. In the nail-folds the epitrichium soon disappears, and the s. corneum persists as the *eponychium*.

The nails grow in length, or are renewed in case of removal, by a proliferation of the cells of the germinative zone, which ultimately become cornified, just as they do in the case of the skin. The growing area of the nail underlies the lunula and is sometimes spoken of as the *nail-matrix*. It has been shown (Le Gros Clark & Buxton, 1938; Gilchrist & Buxton, 1939) that in the hand nail-growth is at the rate of about 3 mm. a month; it is most rapid in the third digit and slowest in the fifth. It is more rapid in boys than in girls, and also in nail-biters; and it is less rapid in poorly nourished than in well nourished children.

Hair.—The hair-rudiments appear about the third month of intra-uterine life as solid downgrowths of the s. germinativum of the epidermis which pass obliquely into the subjacent corium. The deep end of each downgrowth of cells expands to form the hair-bulb, and this becomes moulded round a papilla derived from the corium; the cells immediately overlying the papilla are those from which the future hair will be derived, and therefore are known as the *germinal matrix* of the hair. Growth of the germinal matrix towards the surface gives rise to the hair and its inner root-sheath. The outer root-sheath is derived from the peripheral cells of the original invagination. The surrounding corium is condensed to form the fibrous sheath of the hair-follicle, the hyaline layer of which is continuous with the basement-membrane covering the corium. The hair gradually elongates, and, reaching the neck of the follicle, its extremity lies at first under the epitrichium, but becomes free by pushing this off about the fifth month of intra-uterine life. The first crop of hairs is called the *down*, and is well developed by the seventh month; it consists of very delicate hairs, some of which are shed before birth and the remainder shortly after—the last to drop out being those of the eyelashes and scalp—and are replaced by stronger hairs. Shedding and renewal of the hairs take place during life; prior to the shedding of a hair active growth and proliferation of the cells of the hair-bulb cease, and the papilla becomes atrophied, while the hair-root, gradually approaching the surface, at last drops out. New hairs arise from epidermic buds which extend downwards from the follicle, and their development is identical with that of the original hairs.

It has been shown (Trotter, 1924) that hair-follicles have periods of growth and of quiescence, of about equal duration. While there are differences in rate of growth in different parts of the body and at different age periods, the average rate of growth is about 1·5 mm. to 2 mm. per week.

Sebaceous Glands.—These appear about the fifth month of intra-uterine life as solid outgrowths from the sides of the hair-follicles, and consist of epidermal offshoots continued from the cells of the outer root-sheath. Their deep ends become enlarged and lobulated to form the secreting part of the gland, and the narrow neck which connects this with the follicle forms its duct. The sebaceous secretion helps in the formation of the *vernix caseosa*.

Sweat-Glands.—These, like the hairs, arise as solid downgrowths of the s. germinativum. They descend, however, perpendicularly, instead of obliquely, and are of a yellowish colour; they appear on the palms and soles early in the fourth month of intra-uterine life, but much later over the hairy parts of the body. The downgrowths extend through the corium, and, on

reaching the subcutaneous tissue, become coiled to form the body or secreting part of the gland. The ducts of the glands do not open on the surface until the seventh month.

ORGANS OF GENERAL SENSATIONS

Under this heading will be described the terminations of those sensory nerves which are widely distributed throughout the body and are associated with "muscle-sense" and the senses of touch, pressure, heat, cold, and pain. Those nerves may end (*a*) as fine ramifications of the naked axons lying *free* amongst the tissues, or (*b*) in *special end-organs* where the terminations of the axons are surrounded by capsules of fibrous tissue.

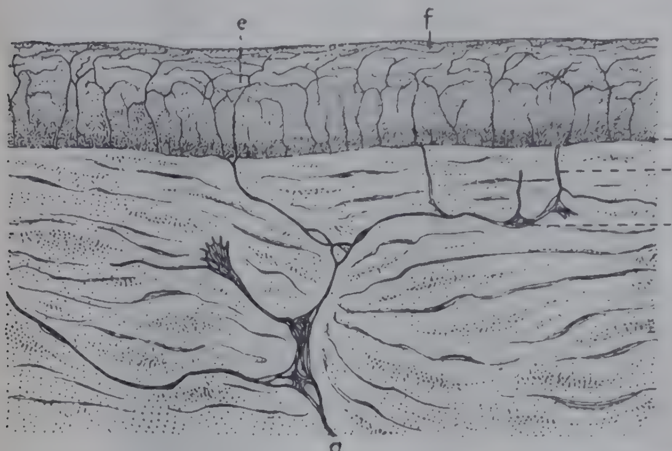

FIG. 975.—TRANSVERSE SECTION OF CORNEA STAINED WITH CHLORIDE OF GOLD (Ranvier).

a, *b*, Primary plexus in substantia propria of cornea ; *c*, branch passing to sub-epithelial plexus, *d* ; *e*, intra-epithelial plexus ; *f*, terminations of fibrils.

The following account is based largely on the work of Woollard, Weddell, and Harpman (1940) on the innervation of the skin (Fig. 971), and on subsequent papers by Weddell (1941 *a*, *b*); see also Le Gros Clark (1947).

FREE NERVE-ENDINGS

Free nerve-endings are found in the s. granulosum and in the s. germinativum of the epidermis, in the cornea, the teeth, the tympanic membrane, the walls of the blood-vessels, tendons, periosteum, and mucous membranes; and they constitute the peripheral pain end-organs.

Both medullated and non-medullated nerve-fibres may terminate in this way, the medullated fibres gradually losing their sheaths as they approach their termination. Usually two sets of plexuses—sub-epithelial and intra-epithelial—occur, from which the free nerve-endings are derived. Free nerve-endings occur also around the sweat-glands, in the papillæ and root-sheaths of the hair-follicles, and in serous membranes.

SPECIAL END-ORGANS

The special end-organs vary in size and form, but in all of them the termination of the nerve-fibre is enclosed in a capsule of varying thickness. The following are the different types of special nerve-endings: bulbous corpuscles, lamellated corpuscles, oval corpuscles, and the special sensory nerve-endings in muscle known as neuro-muscular spindles and neuro-tendinous spindles.

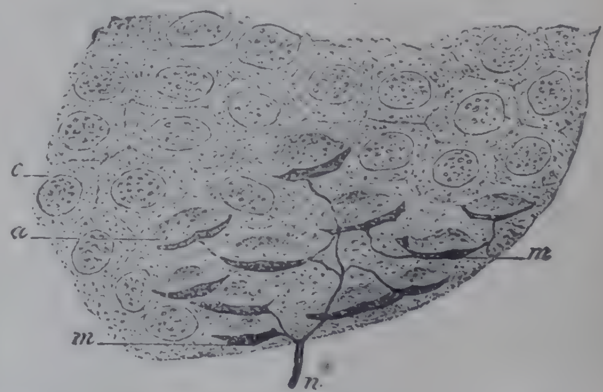

FIG. 976.—ENDING OF NERVE IN TACTILE DISCS OF THE PIG'S SNOUT (Ranvier). (From Quain's *Anatomy*.)

n, Medullated fibre ; *m*, terminal discs or menisci ; *c*, ordinary cell of epidermis ; *a*, modified cell to which a tactile disc is applied.

Bulbous Corpuscles.—These are minute cylindrical or oval bodies, first described by Krause. Each consists of a thin capsule derived from the perineurium of the nerve and enclosing a core of homogeneous or nucleated semifluid substance. As the nerve-fibre pierces the capsule it loses its medullary sheath and is continued into the core, where it may pursue a rather tortuous course, but more frequently divides into minute varicose fibrils which form an intricate plexus. Bulbous corpuscles occur in the conjunctiva, the lips and tongue, in the synovial membrane of certain joints, along the course of some of the larger nerve-trunks, and in the skin generally; in the skin of the glans of the penis and of the clitoris they may attain a considerable size and have thicker capsules than elsewhere.

The bulbous corpuscles have been shown to be associated with the sensation of cold, and they have been found to occur in multiple groups beneath each "cold spot" in the skin of the forearm

about 1 mm. from the surface; each is carried on a separate nerve-fibre, and the fibres approach the "spot" from different directions (Weddell, 1941 *b*). Rather similar endings, known as *Golgi-Mazzoni bodies*, occur in the skin and are associated with the sense of pressure (Fig. 971).

Lamellated Corpuscles.—These were described by Pacini, and consist of a fibrous-tissue capsule, composed of a number of concentric layers, arranged "like the coats of an onion" (Schafer) round a central core of more or less clear protoplasm. The deeper layers of the capsule are closely applied to each other, but those towards the circumference of the corpuscle are here and there separated by narrow lymph-spaces. Each corpuscle is of an oval shape, and its capsule is pierced at one end by a medullated nerve-fibre which loses its sheath on reaching the core of the corpuscle; the naked axon then passes to the other end of the core, where it terminates in one or more enlargements in which the neuro-fibrillæ form a dense network. Lamellated corpuscles occur in the deeper parts of the body in general; in the deeper layers of the skin of the hands and feet, in the loose areolar tissue of the posterior abdominal wall, in the subcutaneous tissue near joints, and along the course of certain nerves. They subserve the sense of pressure (Fig. 971).

Oval Corpuscles.—These corpuscles, which were described by Wagner and Meissner, are specially concerned with tactile impressions. They are oval in shape and are pierced at one end by a medullated nerve-fibre which then loses its sheath; the axons, which are frequently varicose, take a spiral or convoluted course towards the other end of the core, where they terminate in slight enlargements. Running with the medullated nerve-fibres there are several fibres which have lost their sheaths at some distance from the corpuscle; they pierce the capsule and break up into a very complicated network of horizontal branches. Oval corpuscles are most numerous in the papillæ of the corium of the palm of the hand and of the sole of the foot, and of the tips of the fingers and toes. It has been shown (Weddell, 1941 *b*) that in the pad of the fourth finger oval corpuscles are arranged in groups, there being an average of ten groups per square millimetre with two or three corpuscles in each group. The number of groups, but not the number of corpuscles in each group, becomes reduced towards the dorsum of the finger.

Also associated with the sense of touch there are certain disc-like nerve-endings, first described by Merkel (Fig. 971). As might be suspected from their function, they are particularly well developed in the pig's snout (Fig. 976).

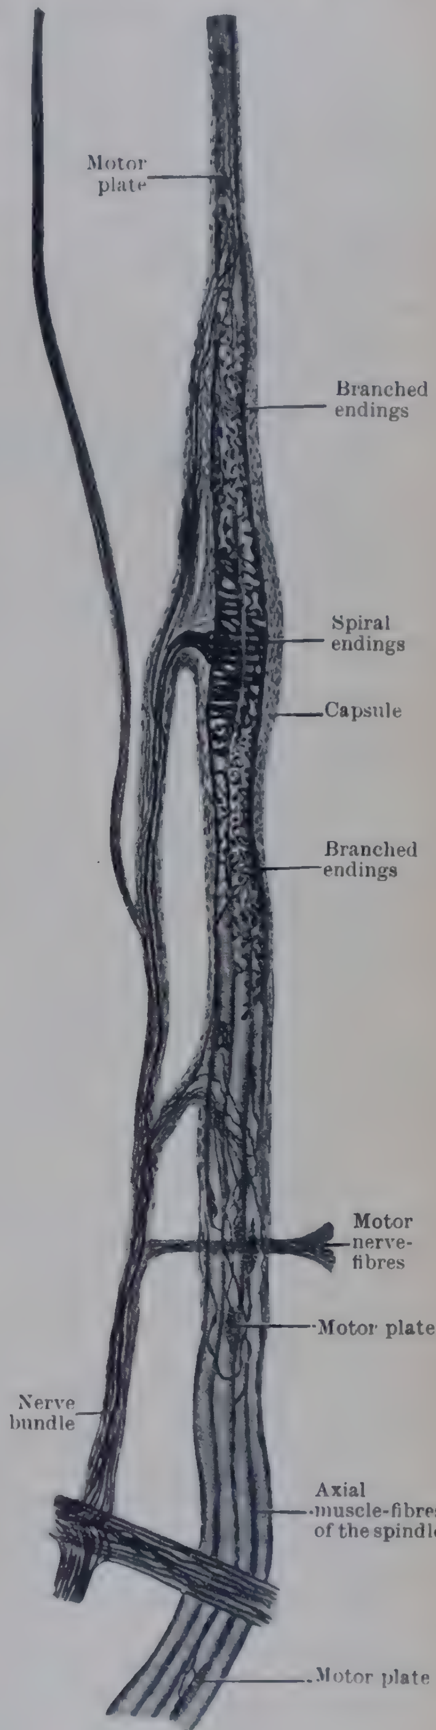

Fig. 978.—Neuro-Muscular Spindle of a Cat showing Nerve-Endings. (Maximow and Bloom, *Text-Book of Histology*. After Ruffini.)

Fig. 977.—Three Types of Special End-Organs.
A, Bulbous corpuscle; B, Lamellated corpuscle; and C, Oval corpuscle. (After Ranvier.)

There also occur in the fingers rather different corpuscles, which were described by Ruffini. They are oval or fusiform and are found in the subcutaneous tissue of the fingers, where the axons break up into a close-meshed network which lies between the smaller fasciculi of fibrous

tissue or partly encircles them. They are associated with the sense of warmth and some of them with the sense of pressure (Fig. 971).

Neuro-Muscular and Neuro-Tendinous Spindles.—These special sensory nerve-endings occur in nearly all the voluntary muscles and are associated with contractile tension or stretching of the muscle. As the names imply, they are spindle-shaped structures composed partly of nervous elements and partly of muscular or tendinous elements; the neuro-tendinous spindles are always situated close to the junction of muscle-fibre and tendon. In each case there is a fibrous capsule of several layers surrounding an internal core of specialized fibres of muscle and tendon; since these fibres lie in the interior of the spindle-shaped or fusiform body, they are known as **intrafusal fibres**. In the case of the neuro-muscular spindle the intrafusal fibres display many of the characteristics of embryonic muscle; they are smaller in both length and diameter than ordinary muscle-fibres, and they contain more protoplasm; they have numerous nuclei near the middle of the spindle, and their cross striation is less distinct there. The

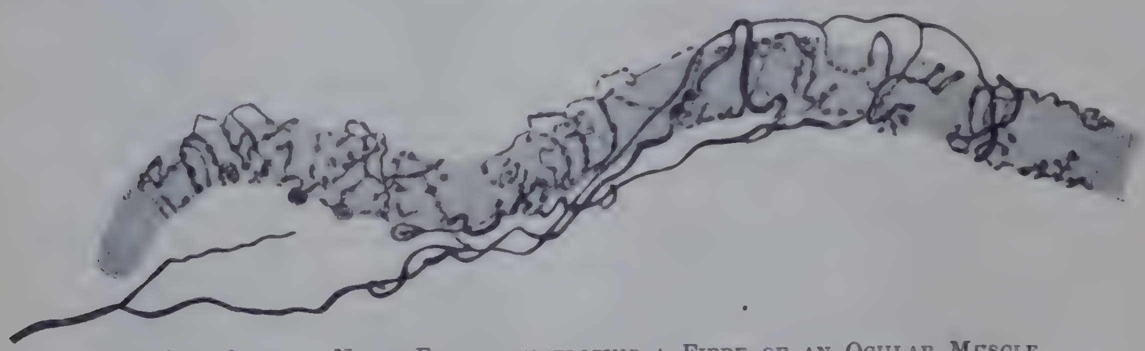

FIG. 979.—SENSORY NERVE-ENDING ENVELOPING A FIBRE OF AN OCULAR MUSCLE. (Maximow and Bloom, *Text-Book of Histology*. After Dogiel.)

intrafusal tendon-fibres also are slightly modified. In each type of spindle there is a lymph-space between the capsule and the axial core of fibres which is largest in the middle of the structure and thus gives it its spindle-shape. The nerve-fibres pierce the side of the capsule (usually near its middle) and lose their medullary sheaths as they do so; the axons then divide and surround the muscle-fibres or tendon-fibres in an annular or branching manner, or, as is more usual, in a spiral manner, forming a complicated plexus (Fig. 978).

In addition to these rather complicated modes of termination, sensory nerves may end by forming annular or spiral networks (Daniel, 1946) around non-specialized muscle-fibres, the essential difference being that, in these simpler formations, there is no capsule (Fig. 979).

Development of Nerve-Endings.—It has been shown (Jalowy, 1939) that tactile discs, oval corpuscles, and lamellated corpuscles appear in the fourth month of intra-uterine life. The tactile discs are fully developed at the seventh month, the lamellated corpuscles at the eighth month, and the oval corpuscles in the first year after birth.

ORGANS OF THE SPECIAL SENSES

ORGAN OF SIGHT

EYEBALL

The eyeball is the peripheral part of the **organ of sight**; associated with it are certain accessory structures, namely, the eyelids, the conjunctiva and the lacrimal apparatus.

The eyeball is situated in the anterior part of the orbit. It is not quite spherical, being composed of the segments of two unequal spheres, viz., a smaller anterior, corneal segment, and a larger posterior, scleral segment (Fig. 980). The anterior or corneal segment projects in front of the scleral portion, the union of the two parts being indicated, externally, by a slight groove called the **sulcus scleræ**. The central points of the anterior and posterior surfaces of the eyeball are its **anterior** and **posterior poles**; a straight line joining the two poles is termed the **optic axis**; and a line encircling the eyeball, midway between the poles, is named the **equator**. The axes of the two eyeballs are almost parallel, converging only slightly behind; but the axes of the optic nerves converge markedly behind, and, if prolonged backwards, would meet in the region of the dorsum sellæ of the sphenoid. The antero-posterior, horizontal and vertical diameters of the eyeball are nearly equal, being about one inch. Its volume is just over 8 c.cm. Females

have larger eyes, in proportion to their body weight, and in relation to the size of the orbit, than males, and the size of the eye relative to that of the orbit is much greater in the fœtus and the infant than in the adult (Schultz, 1940).

Fascial Sheath of Eyeball.—The fascial sheath is a thin fibrous coat which closely envelops the eyeball from the entrance of the optic nerve to the sclero-corneal junction; it forms a socket for the eyeball, and separates it from the other contents of the orbit. The sheath is separated from the eyeball merely by a potential space which, though it has sometimes been described as a lymph-space, is not lined with endothelium, but is traversed by a meshwork of fine areolar

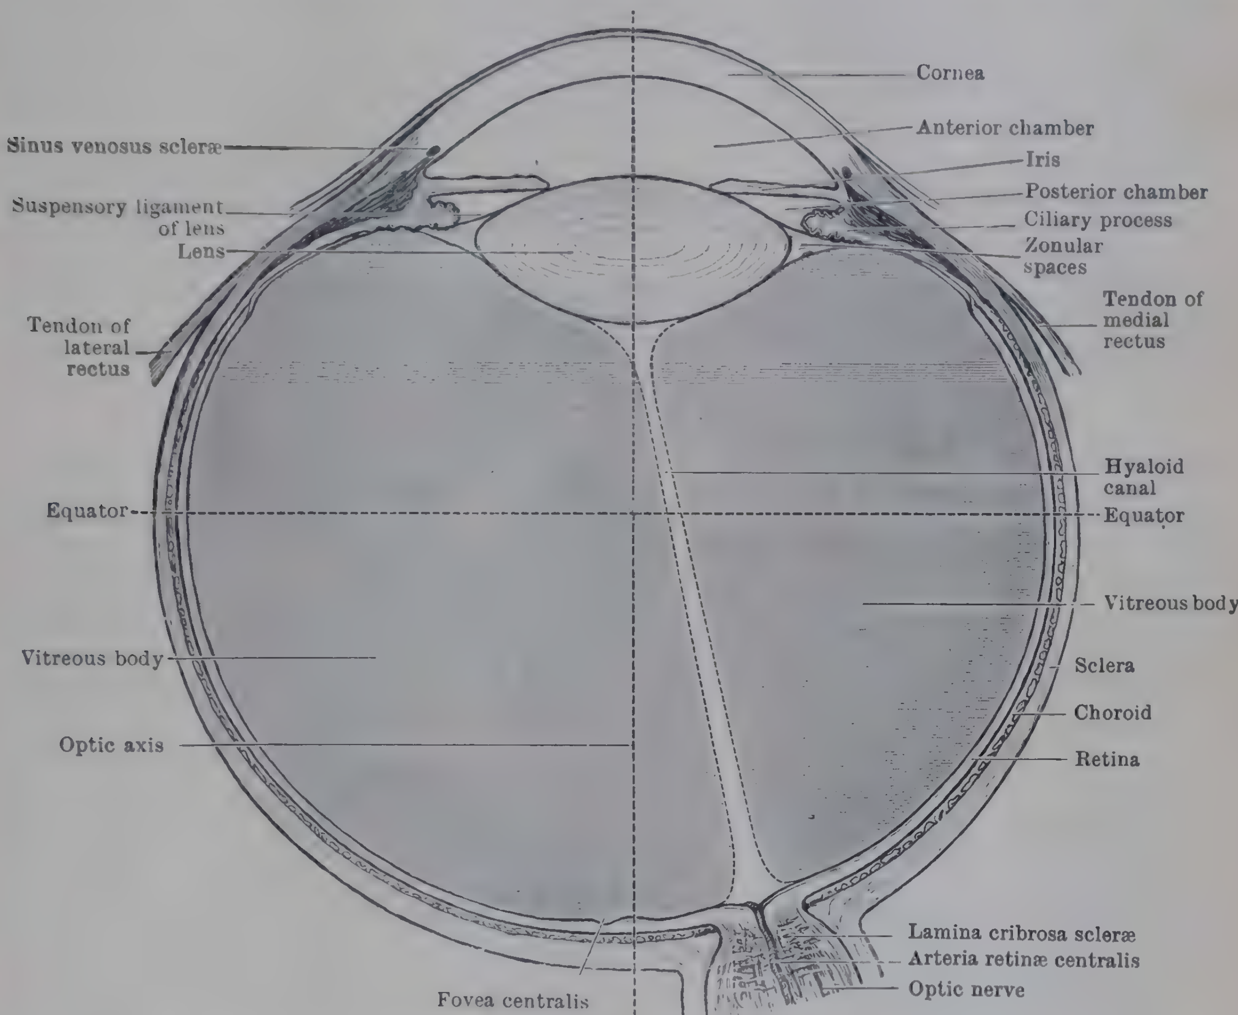

Fig. 980.—Diagram of Horizontal Section through Left Eyeball and Optic Nerve (×4).

tissue. Posteriorly, around the entrance of the optic nerve the sheath is difficult to define, for here it is pierced by the ciliary nerves and the posterior ciliary vessels; it is not continued backwards to form a sheath for the optic nerve. It is pierced near the equator by the venæ vorticosæ, and farther forwards by the orbital muscles on their way to their insertion into the sclera. The part of the sheath in front of the insertions of the recti muscles is thin; it lies between the ocular part of the conjunctiva and the sclera, and it fuses with the sclera immediately behind the sclero-corneal junction. The sheaths of the orbital muscles are thin and almost invisible posteriorly, but they become thick anteriorly and blend with the fascial sheath of the eyeball at the points where it is pierced by the muscles (Fig. 363, p. 428).

Offsets from the outer surfaces of the muscle-sheaths pass to the walls of the orbit, and, as they probably check the actions of the muscles, they are named **check ligaments**; they are developed best in association with the lateral and medial recti. The lateral part of the sheath of the lateral rectus is greatly thickened anteriorly, and forms a triangular mass of tissue which constitutes the check ligament for that muscle; it is attached to a tubercle on the orbital surface of the

zygomatic bone, and to the lateral palpebral ligament. The check ligament of the medial rectus also is triangular; it is fixed to the lacrimal bone, behind its crest, and to the lacrimal caruncle. The sheath of the superior rectus blends with that of the levator palpebræ superioris, and the sheet so formed is attached to the superior conjunctival fornix. The sheath of the inferior rectus is joined to those of the medial and lateral recti, and, as these are fixed to the medial and lateral walls of the orbit by the check ligaments, a continuous band, named the **suspensory ligament** (Lockwood, 1885), is slung from side to side beneath the eyeball like a hammock. The ends of the suspensory ligament blend not only with the check ligaments but also with the medial and lateral horns of the aponeurosis of the levator palpebræ superioris. The sheath of the superior oblique extends as far as the pulley through which the tendon passes and is attached to it. The sheath of the inferior oblique blends with that of the inferior rectus, and the united sheaths send forward one thin lamella into the lower eyelid, and another to unite with the fascial sheath of the eyeball.

The wall of the eyeball (Fig. 980) consists of three concentric coats; enclosed within it there are three transparent refracting media. The three coats are: (1) an outer, fibrous coat; (2) a middle, vascular, pigmented and partly muscular coat; (3) an inner, nervous coat. The three refracting media are named, from behind forwards, the **vitreous body**, the **lens**, and the **aqueous humour**.

FIBROUS COAT OF EYEBALL

The fibrous coat of the eyeball is divided into an opaque, posterior part named, on account of its hardness, the **sclera**, and a transparent, anterior part called the **cornea**, because it was thought to resemble a thin slice of horn.

Sclera.—The sclera is the firm, opaque, white coat of the eye. It has a blue tinge in childhood, since it is then thinner than in the adult and allows the pigment of the choroid to show through it; in old age it has a yellow hue. It is thicker at the back (1 mm.) than in front (0·6 mm.), or at the equator (0·5 mm.). At the back, 3 mm. to the nasal side of the posterior pole and slightly *above* the horizontal meridian (Traquair, 1946), the sclera is pierced by the optic nerve. The part of the sclera through which the nerve-bundles pass is called the *lamina cribrosa scleræ*; the dural sheath of the nerve blends with the sclera. Around the entrance of the optic nerve there are fifteen or twenty small apertures for the passage of the ciliary nerves and the short posterior ciliary arteries. On each side of the nerve, at a little distance from its entrance, the two long posterior ciliary arteries pierce the sclera. Near the equator there are four openings—two above and two below—for the exit of the venæ vorticosæ; and near the sulcus scleræ there are the openings for the anterior ciliary arteries. The deep surface of the sclera is intimately associated with the choroid, so that, when the two are separated, the inner surface of the sclera shows a brown colour from the pigment of the choroid which adheres to it. Nevertheless, it is customary to speak of the two coats being separated

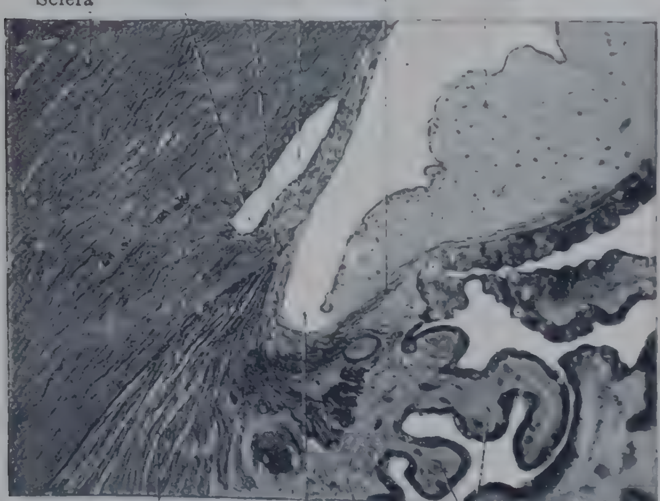

Fig. 981.—Section of Irido-Corneal Angle. (Thomson, 1912.)

from each other by the **perichoroidal space** which is traversed by the ciliary nerves and arteries just mentioned, and by a delicate meshwork of fine, pigmented areolar tissue, called the **suprachoroid lamina.** At the sclero-corneal junction the fibrous tissue of the sclera passes into that of the cornea, and in the deeper part of the junction there is a circular canal called the **sinus venosus scleræ** (Fig. 981). In a meridional section, *i.e.*, one passing through the optic axis, the sinus venosus scleræ appears as a narrow cleft distinguishable from the frequent adjacent scleral clefts by its having an endothelial lining; its outer wall is the compact tissue of the sclera and its inner wall is formed posteriorly by a projecting spur of sclera, and anteriorly by the backward prolongation of the posterior elastic lamina of the cornea, which is known as the **pectinate ligament of the iris** and is continued posteriorly into the scleral spur. The sinus communicates with the anterior ciliary veins, and, through the spaces of the irido-corneal angle, with the anterior chamber of the eye.

Structure.—The sclera consists of bundles of white fibrous tissue and some fine elastic fibres; the bundles form equatorial and meridional layers which interlace with each other. Fibroblasts are numerous between the bundles and pigmented cells occur in the inner layers.

Vessels and Nerves.—The **arteries** of the sclera are branches of the anterior and short posterior *ciliary arteries*; its **veins** open into the *venæ vorticosæ* and anterior *ciliary veins.* The **nerves** of the sclera are derived from the ciliary nerves, which, after losing their medullary sheaths, pass between the fibrous bundles.

Cornea.—The **cornea** is transparent and forms the anterior part of the outer coat. It is slightly thicker than the sclera—measuring 0·9 mm. at its centre, and 1·2 mm. at the periphery. Its anterior surface is covered with a stratified epithelium continuous with that of the conjunctiva; its posterior surface forms the anterior wall of the anterior chamber of the eye. The degree of curvature of the cornea varies in different persons, and is greater in youth than in old age; it is, as a rule, slightly greater in the vertical than in the horizontal plane, and diminishes from the centre to the circumference of the cornea; an abnormal degree of inequality of curvature is known as *astigmatism*, and gives rise to the inability to focus vertical and horizontal lines at the same point. The arc of the cornea is equal to about one-sixth of the total circumference of the eyeball.

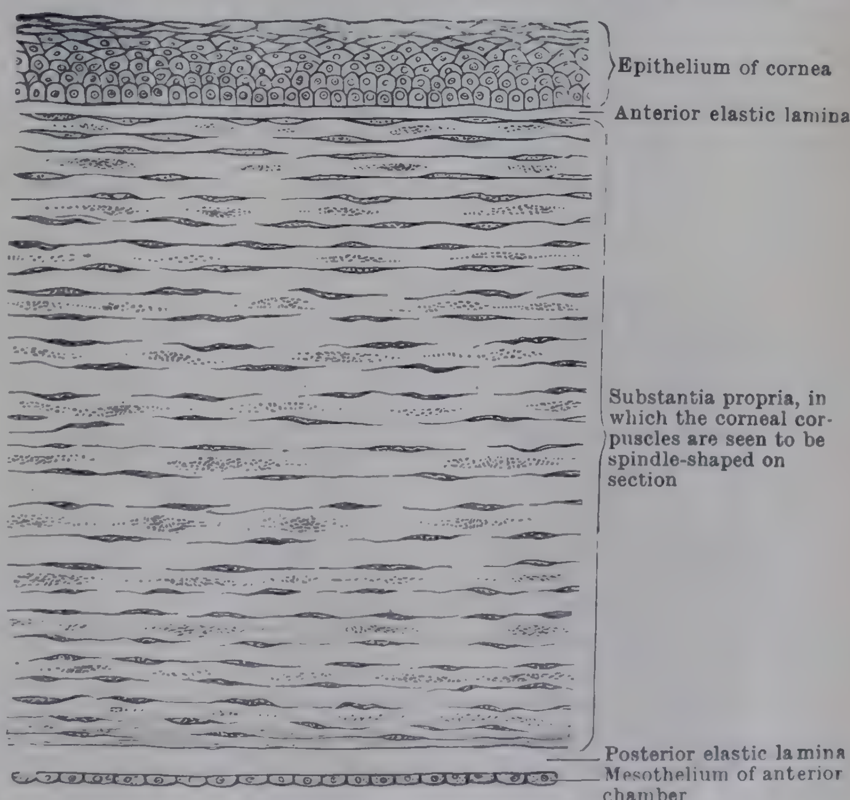

Fig. 982.—Diagrammatic Section of Cornea.

The cornea is continuous with the sclera at the **sclero-corneal junction.** The union is of such a kind that the sclera is bevelled at the expense of its inner surface and the cornea of its outer; the bevelling is most marked at the upper and lower parts of the junction, and thus the cornea, when seen from in front, is not quite circular in outline but slightly elliptical, the longer diameter being horizontal. Between the sclero-corneal junction and the front of the circumference of the iris there is a narrow recess which on section appears as an acute angle and is named **the irido-corneal angle.**

Structure.—The cornea is composed of the following strata from before backwards (Fig. 982):—

1. Epithelium of the cornea.
2. Anterior elastic lamina.
3. Substantia propria.
4. Posterior elastic lamina.
5. Mesothelium of anterior chamber.

1. The **epithelium of the cornea** is continuous with the epithelium on the free surface of the conjunctiva, and consists of six or eight strata of cells. Deepest of all is a single layer of columnar cells, the flattened bases of which rest on the anterior elastic lamina, while their opposite ends are round and contain the nuclei. Superficial to that layer there are three or four strata of polygonal cells, most of which exhibit finger-like processes which join with the corresponding processes of neighbouring cells; the most superficial layers consist of squamous cells.

2. The **anterior elastic lamina** is merely a differentiation of the anterior part of the substantia propria, from which it is separated only with difficulty; it differs from true elastic tissue in not being stained yellow by picrocarmine, and in being easily soluble in boiling water.

3. The **substantia propria** presents, in a fresh condition, a homogeneous appearance; but, with the assistance of reagents, it is seen to consist of modified fibrous tissue, with a few elastic fibres. An amorphous interstitial substance binds the fibres into bundles and cements the bundles into lamellæ which are flattened from before backwards. The fibres of any one lamella cross those of adjacent lamellæ almost at right angles.

The cells of the cornea are very irregularly stellate bodies, and are situated between the lamellæ. In fixed preparations they appear to lie in spaces which they do not completely fill

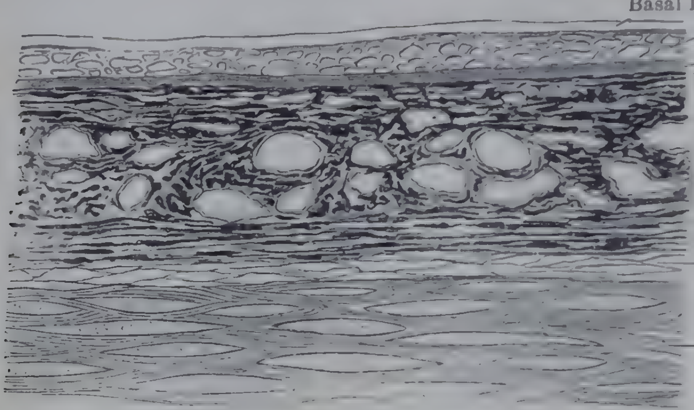

Fig. 983.—Transverse Section of Choroid and Inner Part of Sclera.

and it has been suggested that the rest of the space is occupied by lymph, that the various spaces or lacunæ communicate with each other by means of fine canaliculi, and that a path is thus established for the circulation of nutritive fluids to the cornea. The matter is not definitely settled, but it seems probable that the cells do in reality completely fill the spaces, and that the canaliculi are artificial clefts between the bundles and lamellæ and may be due to increased intra-ocular tension during life or to the action of reagents in the preparation of microscopic specimens.

After middle age a greyish opaque ring, 1·5 to 2 mm. in breadth, is frequently seen near the periphery of the cornea; it is termed the **arcus senilis**, and results from a deposit of fat in the lamellæ and in the corneal cells.

4. The **posterior elastic lamina** is a clear homogeneous membrane that covers the posterior surface of the substantia propria, to which it is less firmly attached than is the anterior elastic lamina. In the living eye, as revealed by the Gullstrand slit-lamp (Mann, 1925; Butler, 1927), it has the appearance of an olive-yellow, shining surface covered with small hexagonal dots; in old age the hexagonal pattern becomes less distinct and regular and round dark patches appear in places. At the sclero-corneal junction the posterior elastic lamina splits into bundles of fine fibres which interlace and are continued towards the circumference of the iris as the **pectinate ligament of the iris**. The spaces between the interlacing fibres are termed the **spaces of the irido-corneal angle**, and are lined with mesothelium prolonged from that of the anterior chamber of the eye. They communicate internally with the irido-corneal angle and externally with the sinus venosus scleræ, and constitute important channels through which fluid may filter from the anterior chamber into the sinus and thence into the anterior ciliary veins. When the pectinate ligament is followed backwards, most of its fibres are seen to be attached to the anterior surface of an inwardly directed rim of scleral tissue, but a few are carried past the edge of the rim, round the irido-corneal angle, and into the iris, where they are directly continuous with the fibres of the dilatator pupillæ muscle (Arthur Thomson, 1912).

5. The **mesothelium of the anterior chamber** consists of a single layer of polygonal cells; it is continued as a lining for the irido-corneal angle and is reflected on to the anterior surface of the iris.

Vessels and Nerves.—In the fœtus the cornea is traversed, almost as far as its centre, by capillaries; but in the adult it is devoid of blood-vessels, except at its margin. The capillaries of the conjunctiva and sclera pass into this marginal area where they end in loops. The rest

of the cornea is nourished by the lymph which percolates through the intercellular substance, the scleral conjunctiva being the only part of the eye in which lymph-vessels occur.

The **nerves** of the cornea are derived from the *ciliary nerves*. Around its periphery they form an annular plexus from which nerve-fibres pass into the cornea; they then lose their medullary sheaths and ramify in the substantia propria, forming the main *stroma plexus*. Fibres extend from this plexus through the anterior elastic lamina and form a *subepithelial plexus* from which fine filaments ramify between the epithelial cells as far as the superficial layers.

VASCULAR COAT OF EYEBALL

The vascular and pigmented coat of the eyeball comprises, from behind forwards, the choroid, the ciliary body, and the iris (Fig. 980).

Choroid.—The choroid is a dark-brown membrane which intervenes between the sclera and the retina. It is usually described as being loosely attached to the sclera by the suprachoroid lamina, except at the point of entrance of the optic nerve and where the blood-vessels pierce the sclera; here the connexion is much closer. After death it may easily be separated from the sclera, but microscopically the two layers are directly continuous with each other and the suprachoroid lamina is not a separate layer. The choroid extends forwards as far as the ora serrata of the retina, where it is succeeded by the ciliary body, which connects it with the circumference of the iris.

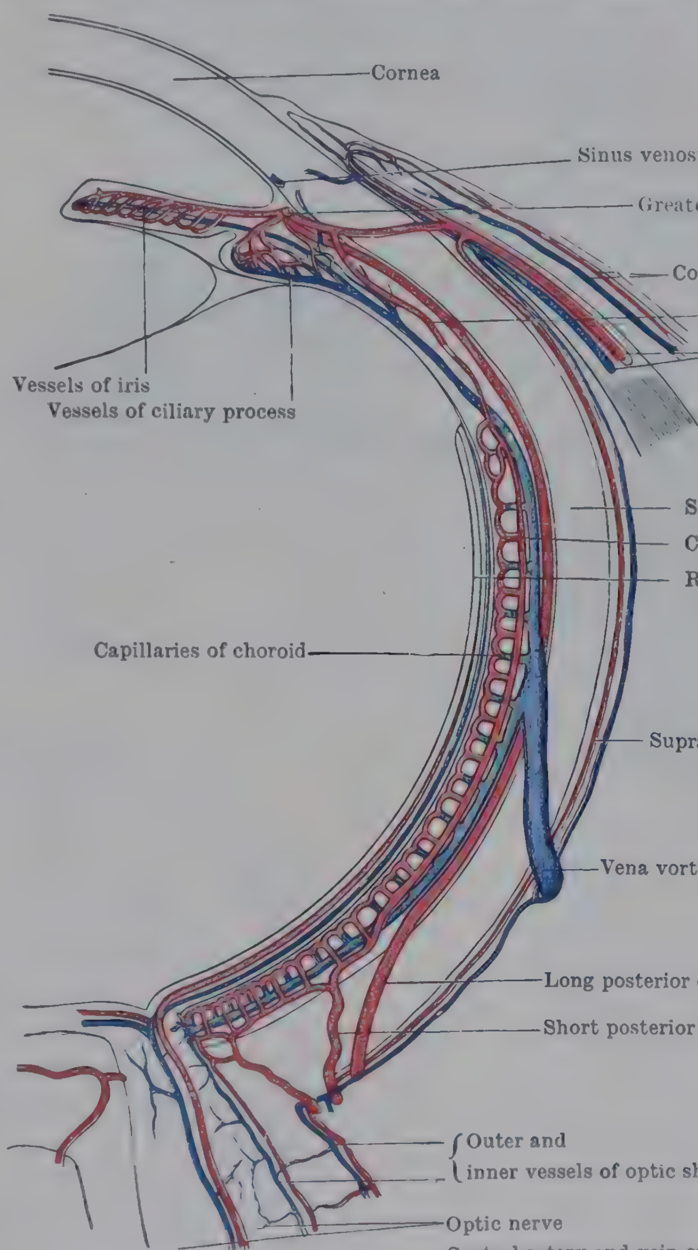

FIG. 984.—DIAGRAM OF CIRCULATION IN THE EYE. (Leber.)

Structure.—The choroid is composed, from without inwards, of three layers:—(*a*) a pigmented layer, the suprachoroid lamina; (*b*) a vascular layer, the proper tissue of the choroid; and (*c*) a glassy layer, the basal lamina (Fig. 983).

The **suprachoroid lamina** is the pigmented layer which intervenes between the sclera and the proper tissue of the choroid; it consists of a delicate network of elastic fibres, amongst which are stellate, pigmented cells and some large phagocytic cells. The pigment cells are, however, not restricted to the suprachoroid lamina, but are found both in the inner part of the sclera and among the vessels of the proper tissue of the choroid.

The **proper tissue of the choroid** consists of an outer layer—the **vascular lamina**—which contains larger blood-vessels, and an inner—the **chorio-capillary lamina**—which is composed of a close network of capillaries in a fine fibro-elastic intercellular substance. A condensation of this fibro-elastic tissue along the outer surface of the chorio-capillary lamina is called the *intermediate stratum* and serves to separate the vascular and chorio-capillary laminæ (Fig. 983).

The **basal lamina** separates the proper tissue of the choroid from the pigmented layer of

the retina, to which it is very closely adherent. It appears as a thin glassy membrane in the outer part of which very fine elastic fibres can be recognized.

Vessels.—The **arteries** of the choroid are derived from the *short posterior ciliary vessels*, which pierce the sclera around the entrance of the optic nerve and form a wide-meshed plexus in the vascular lamina. The **veins** are superficial to the arteries and converge to form whorls which open into the venæ vorticosæ.

Tapetum.—In many animals, especially the ruminants and carnivores, there is seen on the postero-lateral part of the choroid a brilliant iridescence to which the name **tapetum** is applied. Absent in Man, it may be due, as in the horse, to a thin fibrous layer between the two laminæ of the proper tissue of the choroid (tapetum fibrosum), or, as in the seal, to the presence of five or six layers of flattened iridescent cells (tapetum cellulosum) that lie immediately outside the chorio-capillary lamina.

Ciliary Body.—The ciliary body connects the choroid with the circumference of the iris (Fig. 980), and comprises three zones—(*a*) the ciliary ring, (*b*) the ciliary processes, and (*c*) the ciliary muscle.

The **ciliary ring** is a zone, about 4 mm. wide, that immediately adjoins the choroid and extends from the level of the ora serrata of the retina to the posterior

6. Mesothelium of iris.

end of the ciliary processes; it is faintly marked on its inner surface by a series of radial ridges.

The **ciliary processes** are a series of about seventy prominent radial ridges arranged in a circle behind the periphery of the iris, against which they stand out sharply by their paler colour (Fig. 986). They have an average length of about 2 mm., and are much wrinkled ; when traced backwards they merge into the ciliary ring, and when traced forwards to the periphery of the iris their ends project freely over its deep surface and give attachment to some of the fibres of the suspensory ligament of the lens.

Structure.—The ciliary ring and processes are essentially similar in structure to the choroid, except that the suprachoroid lamina is less well developed and the chorio-capillary lamina is absent. Instead of being lined with the retina proper, the ciliary ring and processes are covered on their inner surface with two layers of epithelium which represent the original two layers of the embryonic optic cup, of which the outer is deeply pigmented. These two layers are known as the **ciliary part of the retina**. The great wrinkling of the processes causes the epithelium to

be invaginated into the substance of the processes so as to form tubular glands from which the aqueous humour may in part be derived.

The **ciliary muscle** is placed between the sclera which is superficial and the ciliary ring and processes which are deep to it. It is composed of meridional and circular fibres; the meridional fibres are attached anteriorly to the inwardly projecting spur of sclera which has been referred to (p. 1163) as giving attachment to most of the fibres of the pectinate ligament of the iris; from this point the fibres radiate backwards, to be attached to the ciliary processes and ciliary ring; the circular fibres form a small zone of muscular tissue to the medial side of the meridional fibres and behind the irido-corneal angle. The ciliary muscle, by its contraction, draws forward the ciliary ring and the ciliary processes and the lens becomes more convex, owing to the relaxation of its suspensory ligament. Considerable individual differences exist as to the degree of development of the two portions of the ciliary muscle; the meridional fibres are always more numerous than the circular fibres, which are absent or rudimentary in myopic eyes, but are well developed, as a rule, in hypermetropic eyes.

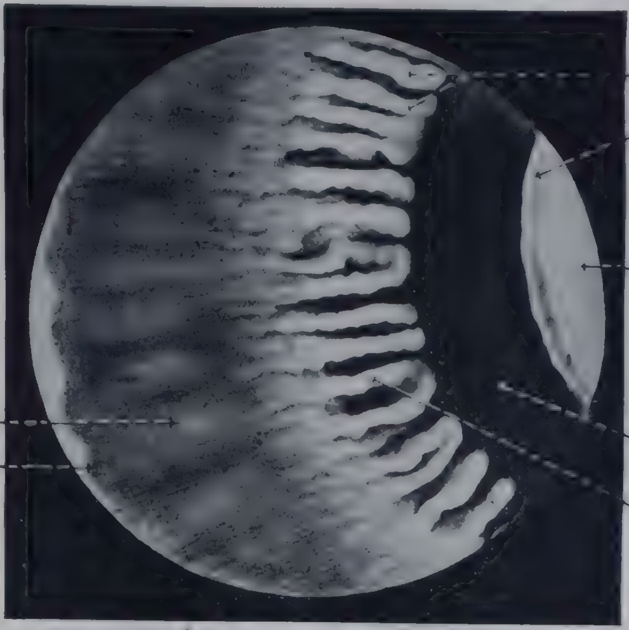

FIG. 986.—ANTERIOR PART OF EYEBALL SEEN FROM WITHIN.

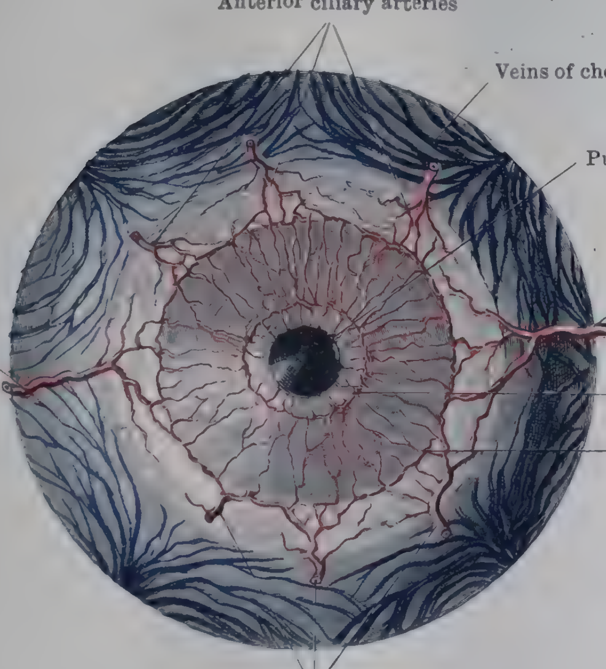

FIG. 987.—BLOOD-VESSELS OF IRIS AND ANTERIOR PART OF CHOROID VIEWED FROM THE FRONT. (Arnold.)

Iris.—The iris is a contractile diaphragm situated in front of the lens, and it presents, a little to the nasal side of its centre, an almost circular aperture — the **pupil**—which, during waking hours, is continually varying in size in order to regulate the amount of light admitted into the eyeball. The iris partially divides the space between the cornea and lens into two portions which are filled with the aqueous humour, and are named the **anterior** and **posterior chambers** of the eye. It is of almost equal thickness throughout, though it is rather thinner in the middle and thickens towards its pupillary margin; the peripheral margin is continuous with the ciliary body, and, through the pectinate ligament, with the posterior elastic lamina of the cornea: the pupillary margin rests on the front of the capsule of the lens.

The colour of the eye depends on the arrangement of the pigment in the iris; in the blue eye the pigment is limited to the posterior surface of the iris, but in the brown eye it is also scattered throughout its stroma; in the albino the pigment is absent.

The pupil is covered, during the greater part of intra-uterine life, by the **pupillary membrane.** This is a thin, highly vascular membrane, the vessels of which are derived primarily from the hyaloid artery and later from the long posterior ciliary arteries. The membrane is situated on the superficial surface of the iris, and its vessels form a series of arcades converging towards the centre of the pupil. At about the seventh month of intra-uterine life, atrophy begins in the central vessels and proceeds towards the circumference, more and more peripheral vessels becoming involved until the lesser arterial circle is reached; here the process of atrophy ceases, and this circle comes therefore to be the most central part of the vascular arcades of the iris. At birth, atrophy of the membrane is usually complete, though fragments of it may remain into adult life.

Structure.—The main mass of the iris is known as the *stroma* and is composed of delicate white and elastic fibres, mingled with pigmented cells, blood-vessels, nerves, and plain muscle-fibres.

The anterior surface of the stroma is covered with a layer of mesothelium continuous with that on the posterior surface of the cornea. Its posterior surface is covered with a double layer of epithelium continuous with that on the inner surface of the ciliary ring and processes; the epithelium of the iris differs, however, from that of the ciliary processes in that the posterior layer, as well as the anterior, is pigmented. This epithelium is the remains of the original edge of the optic cup and is thus homologous with the retina. It is from these layers that the sphincter and dilator muscles of the pupil are developed, the sphincter from the inner layer just where it turns round to become continuous with the outer layer, and the dilator from the anterior surface of the outer layer. The sphincter muscle is arranged in a circular manner round the pupil and by its contraction it reduces the size of that aperture; the dilator consists of fibres which radiate from the pupil to the periphery of the iris.

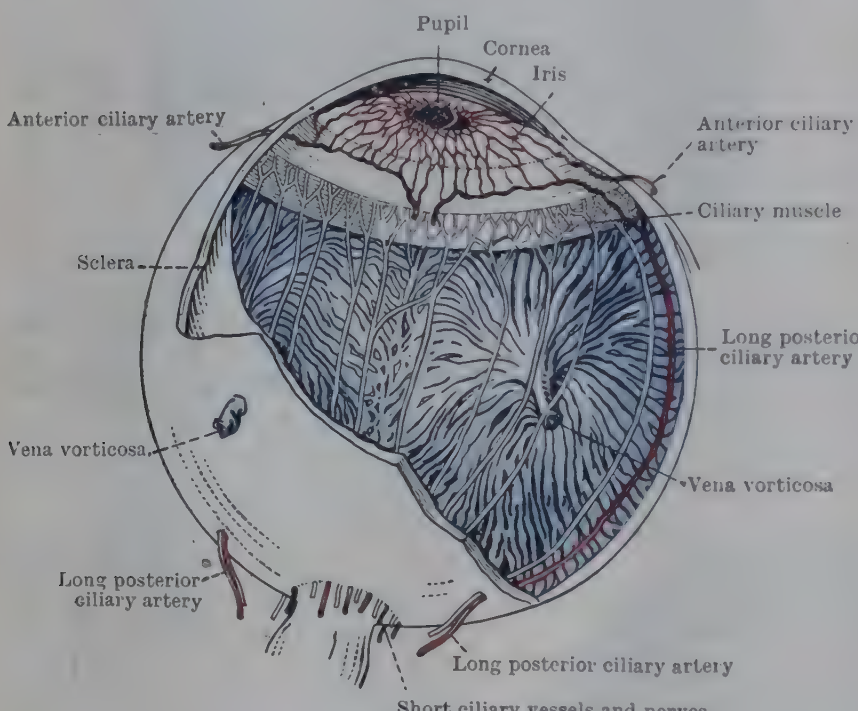

FIG. 988.—DISSECTION OF EYEBALL SHOWING VASCULAR COAT AND ARRANGEMENT OF CILIARY NERVES AND VESSELS.

Vessels and Nerves.—The **arteries** of the iris come from the *long posterior ciliary* and the *anterior ciliary* branches of the ophthalmic artery. There are two long posterior ciliary arteries, a medial and a lateral; they pierce the sclera by the sides of the optic nerve and run forwards between the sclera and the choroid as far as the periphery of the iris, where they are joined by the anterior ciliary arteries, which are usually arranged as two or three superior and two or three inferior branches; by the union of all these vessels a vascular circle is formed round the margin of the iris and is known as the *greater arterial circle* of the iris. From this circle branches pass forwards towards the pupil, round which a second circle is formed, called the *lesser arterial circle* of the iris. The **veins** of the iris proceed towards its periphery, and communicate with the veins of the ciliary processes and with the sinus venosus scleræ. The convergence of the blood-vessels towards the pupil gives a striated appearance to the anterior surface of the iris.

The **nerves** of the choroid and iris (Fig. 988) are derived from the *long* and *short ciliary* nerves. The former, two or three in number, are branches of the naso-ciliary nerve; the latter, from eight to fourteen in number, are derived from the ciliary ganglion. Piercing the sclera around the entrance of the optic nerve, the ciliary nerves run forward between the sclera and the choroid to the ciliary muscle, where they form a plexus from which fibres are distributed to the ciliary body, iris, and cornea. Ganglion-cells have been described along the course of the short ciliary nerves (Wolff, 1948). The sphincter of the pupil and the ciliary muscle are supplied by the oculomotor nerve, the dilator of the pupil by the sympathetic.

The **retina**, or nervous coat of the eyeball, is a soft, delicate membrane in which the fibres of the optic nerve are spread out. It is composed of two layers—an outer, pigmented layer, attached to the choroid; and an inner, nervous layer—the retina proper—in contact with the vitreous body. Expanding from the entrance of the optic nerve, the retina appears to end at the posterior edge of the ciliary body in a wavy border, called the **ora serrata** of the retina. But it is, in reality, only the nervous elements of the retina which come to an end at this line; the non-nervous elements, *i.e.*, the original two layers of the optic cup, are prolonged over the posterior surface of the ciliary body and iris (Fig. 985). The portion of the retina behind the ora serrata is termed the **optic part of the retina**, and its continuation over the ciliary body is called the *ciliary part of the retina*. The thickness of the retina gradually diminishes from 0·4 mm. near the entrance of the optic nerve, to 0·1 mm. at the ora serrata. It presents, just lateral to the posterior pole of the eye, a small, oval yellowish spot, called the **macula lutea**, of which the central part is depressed and named the **fovea centralis**. About 3 mm. to the nasal side and slightly above the level of the posterior pole there is a whitish disc which corresponds with the point of entrance of the optic nerve, and has a diameter of about 1·5 mm.; this is known as the *optic disc*, and its circumference is slightly raised to surround a central depression. The optic disc consists merely of nerve-fibres; it is insensitive to light, and is named the "blind spot". Around the optic disc and at the ora serrata the retina is more firmly adherent to the choroid than elsewhere.

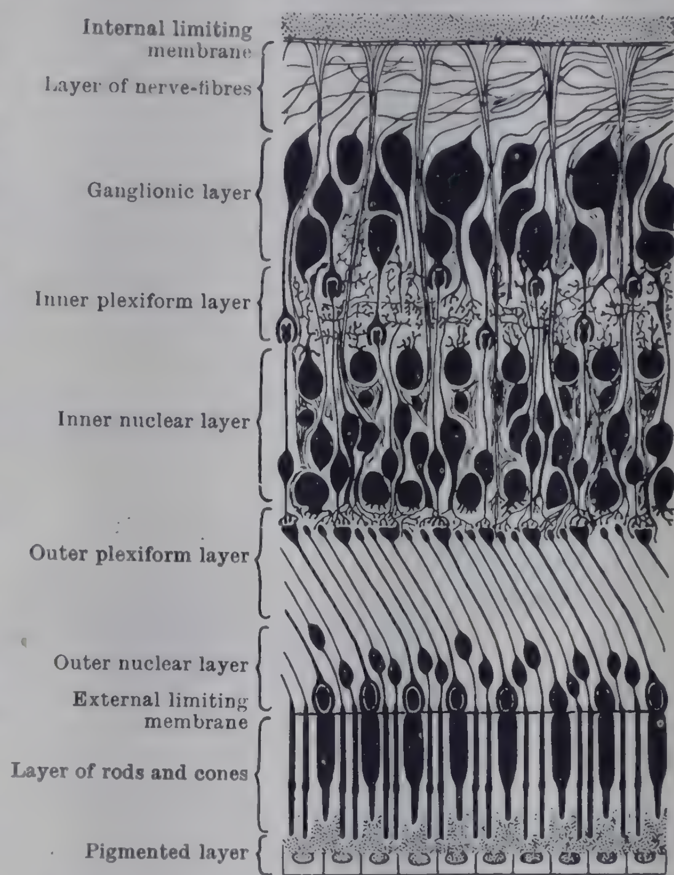

FIG. 989.—SCHEMATIC RECONSTRUCTION OF HUMAN RETINA. (After Polyak, 1941.)

The nervous layer of the retina is transparent during life, but becomes opaque and of a greyish colour soon after death. If an animal is kept in the dark before the removal of its eyeball, the retina presents a purple tinge owing to the presence of a colouring matter, named **rhodopsin** or **visual purple**, which is rapidly bleached on exposure to sunlight. The visual purple is absent from the macula lutea, and over a narrow zone, 3-4 mm. in width, near the ora serrata.

Structure (Figs. 989, 990).—The nervous elements of the retina are supported by non-nervous or **sustentacular fibres**, and are arranged in the following seven layers from within outwards, *i.e.*, from the vitreous body to the choroid :—

1. Layer of nerve-fibres.
2. Ganglionic or nerve-cell layer.
3. Inner plexiform layer.
4. Inner nuclear layer.
5. Outer plexiform layer.
6. Outer nuclear layer.
7. Layer of rods and cones.

An internal limiting membrane separates the layer of nerve-fibres from the vitreous body, and an external limiting membrane separates the layer of rods and cones from the outer nuclear layer; to the outer side of the layer of rods and cones is the pigmented layer of the retina.

1. **Layer of Nerve-Fibres.**—Most of these fibres are centripetal and are the axons of cells in the ganglionic layer; they reach the brain by means of the optic nerve, of

which they constitute the greater part. A few are centrifugal and are the axons of cells situated in the brain; they reach the retina by means of the optic nerve and ultimately ramify in the inner plexiform layer.

2. **Ganglionic or Nerve-Cell Layer.**—The cells of the ganglionic layer vary in size; they are oval or piriform in shape, and form a single layer, except near the macula lutea, where several strata are present and where the cells are smaller than towards the periphery of the retina. The axons of these nerve-cells pass into the nerve-fibre layer; the dendrites form arborizations in the inner plexiform layer with the axons of cells in the inner nuclear layer.

3. **Inner Plexiform Layer.**—This is constituted chiefly by the interlacement of the dendrites of the cells of the ganglionic layer with the axons of those of the inner nuclear layer.

4. **Inner Nuclear Layer.**—This consists of numerous cells which may be divided into (*a*) bipolar cells, (*b*) horizontal cells, and (*c*) amacrine cells. The nuclei of the sustentacular fibres also are present in this layer.

(*a*) The **bipolar cells** are by far the most numerous; they are fusiform in shape and are divided into rod-bipolars and cone-bipolars. The axons of each type arborize in

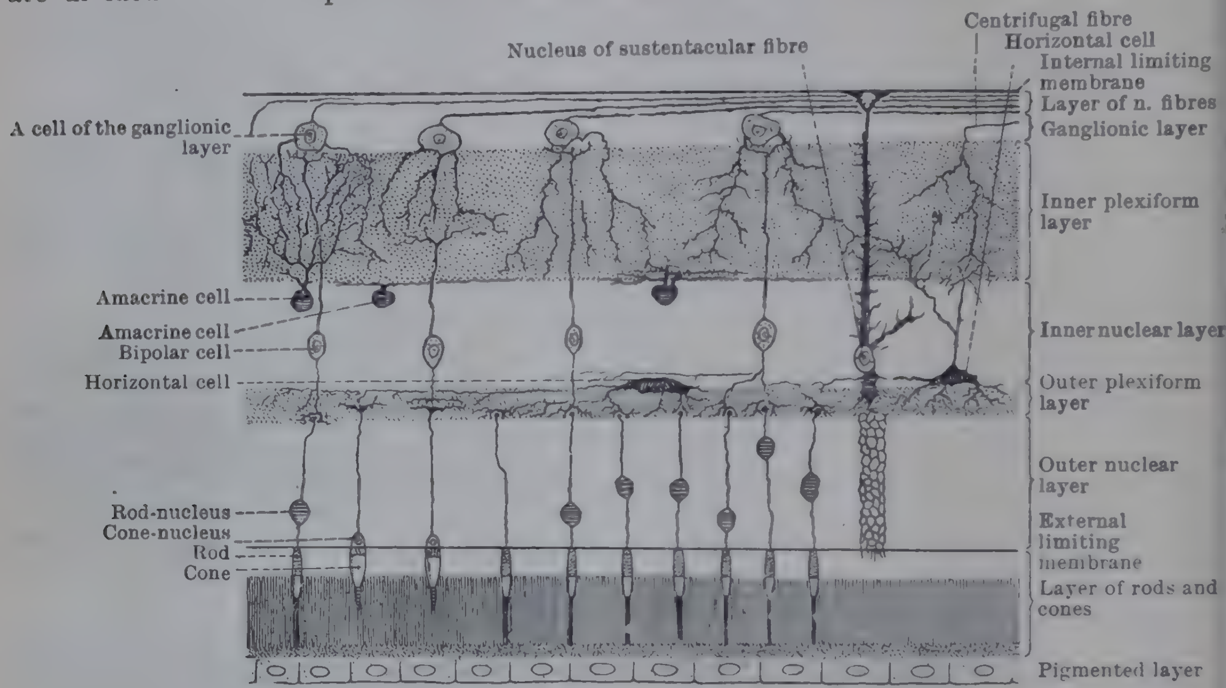

Fig. 990.—Plan of the Retinal Neurones. (After Cajal.)

the inner plexiform layer with the dendrites of the ganglion-cells; the dendrites of the rod-bipolars arborize around the ends of the rod-fibres, and those of the cone-bipolars around the ends of the cone-fibres.

(*b*) The **horizontal cells** serve to connect various rod-fibres or cone-fibres to each other. There are small and large horizontal cells: the small cells are flattened and star-like and lie on the borderline between the outer plexiform and the inner nuclear layers; they send a tuft of dendrites outwards, towards the bases of the cone-fibres; their axons are directed horizontally for a variable distance, and end around the bases of other cone-fibres. The large cells are irregular in shape and are placed to the inner side of the small cells; their processes make connexion between various rod-fibres. A third variety of horizontal cell sends short processes into the outer plexiform layer and a long process into the inner plexiform layer, where it arborizes around the end of a centrifugal fibre.

(*c*) The **amacrine cells** are so called on account of the absence of an axon. They are situated in the innermost part of the inner nuclear layer; their processes ramify in the inner plexiform layer, it may be in one stratum (stratified cells) or in several strata (diffuse cells).

5. **Outer Plexiform Layer.**—This is constituted by the interlacement of the dendrites of the bipolar and horizontal cells, just described, with the spherules of the rod-fibres and the ramifications of the foot-plates of the cone-fibres.

6. **Outer Nuclear Layer.**—This is chiefly made up of the nuclei of the rod-fibres and cone-fibres; the nuclei of the rod-fibres lie at different levels in the layer, but those of the cone-fibres are all situated close against the external limiting membrane of the retina. The rod-nuclei send a process into the outer plexiform layer where it ends in

a small rounded knob or spherule in association with the dendrites of rod-bipolar or of horizontal cells; the cone-nuclei send out processes which are similarly arranged but end in an expanded foot plate instead of in a spherule. From their opposite ends the rod-nuclei send outwards processes which pass through the external limiting membrane into the inner ends of the rods, whereas the cone-nuclei, since they are placed close alongside the external limiting membrane, become directly continuous through the membrane with the inner ends of the cones.

7. **Layer of Rods and Cones.**—The rods and cones are the special receptive endings of the **rod-cells** and **cone-cells**, each of which is thus composed of a cell-body, a nucleus, in the outer nuclear layer, an axon—the rod-fibre or cone-fibre—which ends in the outer plexiform layer and a dendrite, or receptor, the definitive rod or cone. At the fovea centralis, cones alone are present, and in this situation they are more slender and elongated than elsewhere; as one passes forwards over the retina from the macula the rods appear and gradually outnumber the cones; near the ora serrata cones are again the more numerous; over the retina as a whole the rods are nearly twenty times as many as the cones. The rods are slender, cylindrical, and of almost uniform diameter throughout their length; the cones are spindle-shaped and taper to a fine point at the outer end. Each rod and cone has an outer and an inner segment; the outer segment of a rod is slightly more slender than the inner and it contains the rhodopsin; the outer segment of a cone is far smaller than the inner and it rapidly tapers to a fine point. The inner segments of both rods and cones have an affinity for staining reagents, and each shows a homogeneous basal portion and a longitudinally striated outer part.

Pigmented Layer.—This consists of a single layer of cells which, on surface view, are hexagonal (Fig. 991), their outer flattened surfaces being firmly attached to the choroid. When seen in section the outer part of each cell shows a large oval nucleus which rests on the basal lamina of the choroid. When the eye is in the dark the pigment accumulates near the outer part of the cell, but when the eye is exposed to light the pigment streams in between the rods and cones.

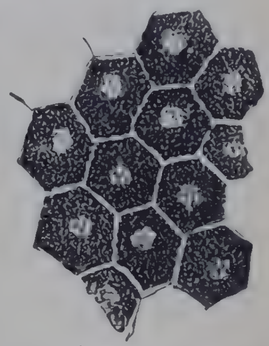

Fig. 991.—Pigmented Layer of Human Retina (viewed from the surface).

Sustentacular Fibres of Retina.—The cell-bodies of these fibres lie in the inner nuclear layer, and the fibres extend from the cell-body inwards and outwards through the whole thickness of the retina from the internal to the external limiting membrane; these two membranes are, in fact, formed by the fusion of the expanded inner and outer ends of the fibres. In the inner nuclear and inner plexiform layers the inwardly directed fibres give off numerous side-branches, and in the outer nuclear layer the outwardly directed fibres form a delicate network which lodges the rod- and cone-nuclei.

Structure of Macula Lutea and Fovea Centralis.—At the fovea centralis there are no rods; the cones are closely packed, and are narrower and more elongated in their outer segments than they are elsewhere in the retina. Since the macula lutea, and especially the fovea centralis, are the regions of distinct vision, the cones are here almost bare, and the light has to pass through only a comparatively thin layer of retinal tissue—the cone-fibres and cone-nuclei—on its way to the receptor cells. At the periphery of the macula there is a great increase in the thickness of the ganglionic layer and in that of the inner nuclear layer, but these layers rapidly come to an end as the fovea is approached. It thus happens that the cone-fibres must pass obliquely from the fovea centralis to reach the cone bipolars in the inner nuclear layer which are nearer the periphery of the macula, and the cone-nuclei and fibres thus form an obliquely directed stratum covering the cones in the region of the fovea. Furthermore, since the fovea is almost devoid of nerve-fibres, those fibres from other regions of the retina which, on their way to the disc, approach the fovea, must skirt round it and are thus found to be arranged in a series of arcs around the fovea as a centre. As the ora serrata of the retina is approached, there can be seen, in the adult, a series of cystic cavities in the plane of the ganglionic layer (Fig. 985); they cause this part of the retina to bulge in towards the vitreous body. The transition at the ora serrata from the pars optica retinæ to the pars ciliaris is a very sudden one, the thickness of the pars optica rapidly diminishing by a disappearance first of the rod and cone layer, then of the other nervous elements, so that in the pars ciliaris there is nothing left except a pigmented layer and a layer of undifferentiated columnar epithelium—in fact, the two original undifferentiated layers of the optic cup.

Vessels (Fig. 992).—The retina is supplied by the **arteria retinæ centralis**—a branch of the ophthalmic artery. It pierces the sheath of the optic nerve obliquely from below and appears at the centre of the optic disc. It then divides into an upper and a lower branch, each of which divides into a nasal branch and a temporal branch; the resulting four branches are named the *superior* and *inferior temporal arteries* and the *superior* and *inferior nasal arteries*. The temporal arteries pass laterally above and below the macula lutea, to which they give small branches;

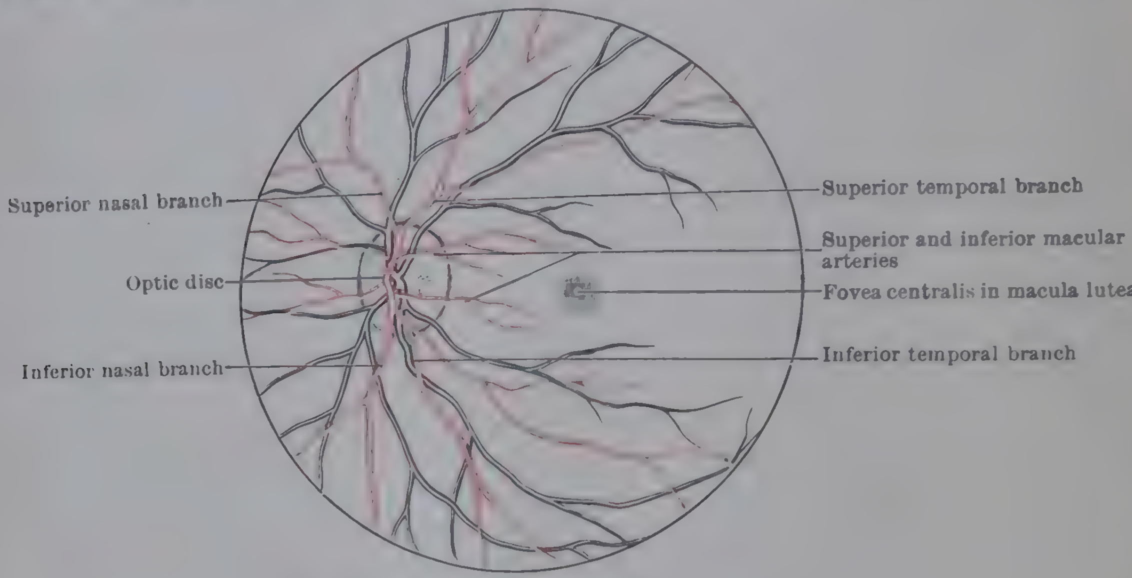

Fig. 992.—Blood-Vessels of Left Retina.

these do not, however, extend as far as the fovea centralis, which is devoid of blood-vessels. The macula receives also two small arteries (*superior* and *inferior macular*) directly from the stem of the arteria centralis. The larger vessels run in the layer of nerve-fibres; they do not anastomose with each other except through the capillary plexuses, which extend as far as the inner nuclear layer. The **veins** follow the course of the arteries; they have no muscular coats, but consist merely of a layer of endothelial cells outside which there is a perivascular lymph-sheath surrounded by delicate reticular tissue. The *central vein of the retina* joins the superior ophthalmic vein or may run direct to the cavernous sinus.

REFRACTING MEDIA

The light waves, on their way to the retina, must pass through a number of structures of different densities, *i.e.*, the cornea (already described), the aqueous humour, the lens, and the vitreous body. These constitute the **refracting media** of the eye.

Aqueous Humour and Chambers of Eye.—The **aqueous humour** is a fluid with a refractive index of 1·336, and consists of about 98 per cent of water, with 1·4 per cent of sodium chloride, and traces of albumin. It fills the **anterior** and the **posterior chambers** of the eye, which are the spaces in front of the lens, separated from each other by the iris and communicating with each other through the pupil. The anterior chamber communicates also with the spaces of the iridocorneal angle, and the posterior chamber with the zonular spaces.

Lens.—The lens lies in front of the vitreous body and behind the iris. It is a biconvex, transparent body (Fig. 980), enclosed in a thin, transparent, homogeneous *capsule*. The central points of its anterior and posterior surfaces are termed the **anterior** and **posterior poles**, and a line joining the poles is known as the **axis**; the peripheral circumference is named the **equator**. The axial measurement of the lens is 4 mm., and the transverse diameter from 9 to 10 mm. The anterior surface is in contact with the pupillary margin of the iris; the central part of that surface corresponds with the pupil; the peripheral part is separated from the iris by the aqueous humour of the posterior chamber. The posterior surface of the lens is more convex than the anterior, and occupies the hyaloid fossa of the vitreous body. The curvatures of the surfaces of the lens, especially that of the anterior surface, are constantly varying, during life, for the purpose of focusing near or distant objects on the retina.

substance of each tarsus there is a row of from 20 to 30 modified sebaceous glands named the **tarsal glands,** of which the openings have already been noticed. The lateral ends of the tarsi unite to form the *lateral palpebral ligament,* which fixes them to a small tubercle on the orbital surface of the zygomatic bone; their medial ends join to form the *medial palpebral ligament,* which is attached to the frontal process of the maxilla immediately in front of the lacrimal fossa.

The eyelids are further strengthened by a membranous sheet, named the **palpebral fascia,** which extends into them from the orbital margin, along which it is continuous with the periosteum. In the upper eyelid the fascia fuses with the superficial lamella of the aponeurosis of the levator palpebræ superioris; in the lower eyelid it is thin, and blends with the anterior surface of the inferior tarsus.

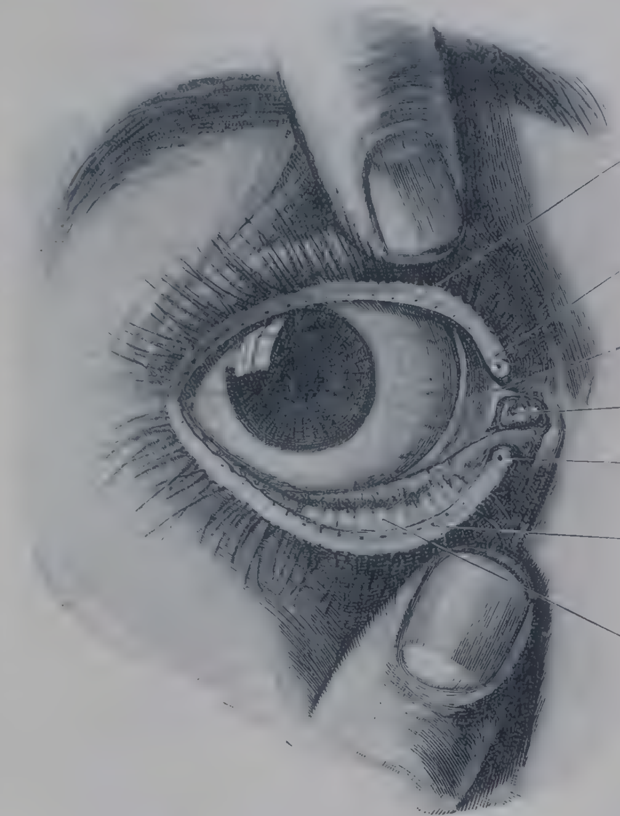

FIG. 996.—EYE WITH LIDS SLIGHTLY EVERTED TO SHOW STRUCTURES AT THE MEDIAL ANGLE.

The skin of the eyelids is thin, and is continuous, at their free margins, with the palpebral conjunctiva. The subcutaneous tissue is loose and devoid of fat, and in it are found the fibres of the orbicularis oculi muscle—a small separate slip of which occupies the margin of the lids behind the eyelashes.

Behind and between the roots of the eyelashes there are two or three rows of modified sweat-glands termed the **ciliary glands** (p. 1157).

H. Müller (1859) described a layer of plain muscle in each eyelid: in the upper lid it extends from the deep lamella of the aponeurosis of the levator palpebræ superioris to the superior tarsus; in the lower lid it arises from the fascial sheath of the inferior oblique and divides into two lamellæ, one ending in the ocular part of the conjunctiva, the other in the lower eyelid.

The **eyelashes** are short curved hairs, three or four rows deep, which project from the free margins of the eyelids. In the upper eyelid they are longer and more numerous than in the lower lid.

Conjunctiva.—The conjunctiva is the membrane which clothes the deep surfaces of the eyelids and is reflected from them on to the front of the eyeball; the lines of reflexion are known as the *superior* and *inferior* **conjunctival fornices.** The palpebral part of the conjunctiva is highly vascular, is covered with a stratified columnar epithelium and is closely adherent to the tarsi. The ocular part is thinner and is transparent, so that the sclera and cornea can be seen through it. It is covered with a stratified squamous epithelium. It covers the sclera but is not adherent to it, for the two are separated by the thinned-out fascial sheath of the eyeball; at the sclero-corneal junction the sheath comes to an end and the conjunctiva is continued forwards over the cornea, to which it is firmly adherent, and, in fact, is represented merely by the epithelium of the cornea.

Vessels and Nerves.—The chief **arteries** of the eyelids are the superior and inferior palpebral branches of the ophthalmic artery; they pierce the palpebral fascia above and below the medial palpebral ligament and turn laterally in the corresponding lid near its free margin. The upper lid receives branches from the supra-orbital and supratrochlear arteries also, and the lower lid from the facial artery. The **veins** are arranged in two sets: (*a*) *subconjunctival,* which open into the muscular tributaries of the ophthalmic veins, and (*b*) *pretarsal,* which open into the anterior facial and superficial temporal veins. The **lymph-vessels** form networks in front of and behind the tarsal plates. There are at least four main vessels in each eyelid, two coursing medially, and two laterally. Those directed medially ultimately join to form a vessel that accompanies the anterior facial vein and drains into the submandibular glands. The lateral vessels join to

form a trunk directed to the superficial parotid lymph-glands (Burch, 1939). The lymph is drained chiefly into the parotid lymph-glands, but partly, by vessels which accompany the anterior facial vein, into the submandibular lymph-glands. The **sensory nerves of the eyelids** are the supra-orbital and supratrochlear for the upper lid, and the infra-orbital for the lower lid. The region of the lateral angle is supplied by the lacrimal nerve, and that of the medial angle

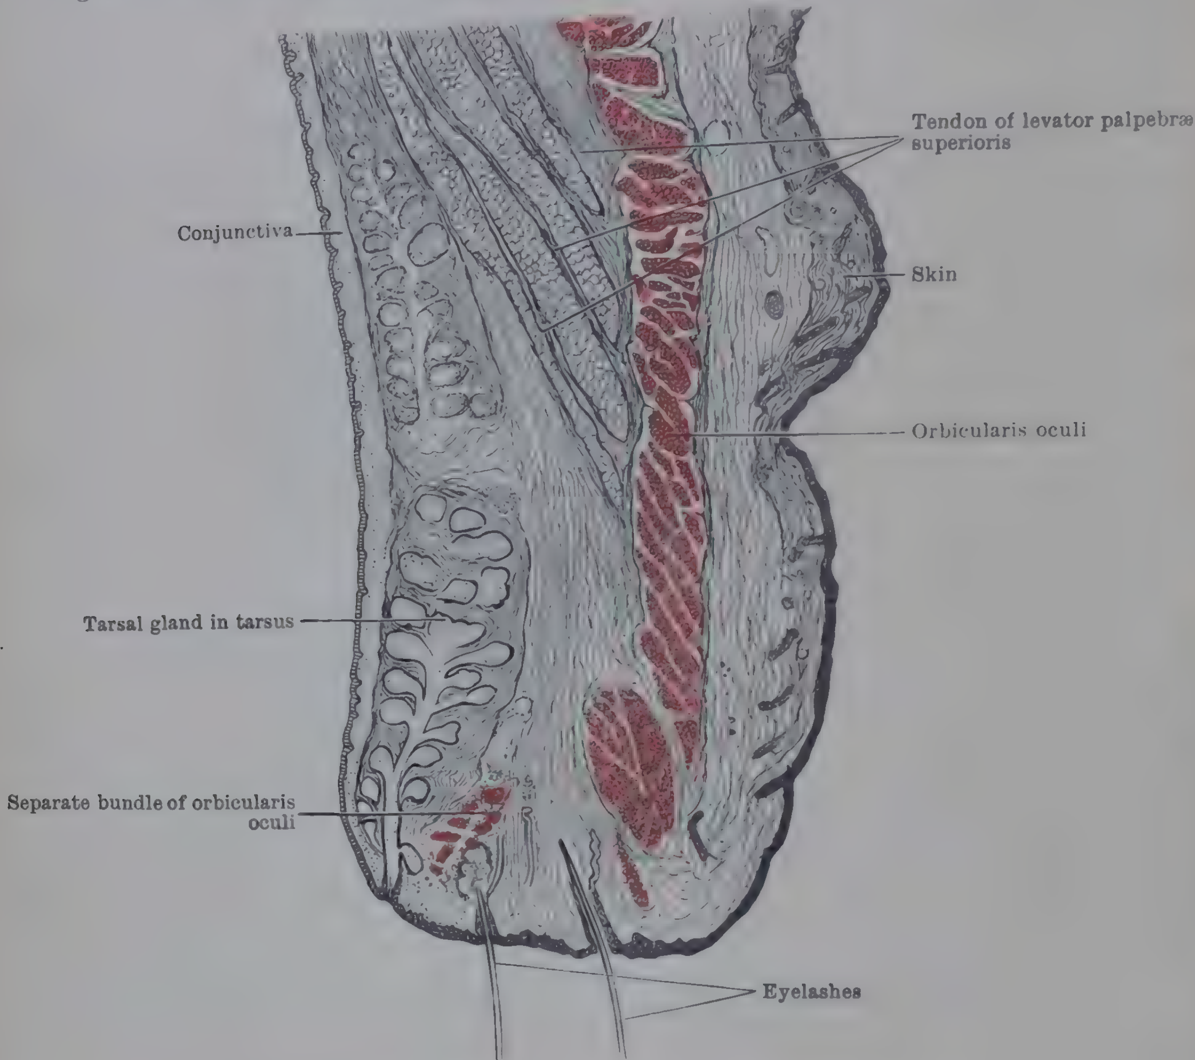

FIG. 997.—DIAGRAMMATIC SAGITTAL SECTION THROUGH UPPER EYELID.

by the infratrochlear. The levator palpebræ superioris muscle is supplied by the oculomotor nerve, and the plain muscle-fibres of the eyelids by the sympathetic.

S.N. LACRIMAL APPARATUS

The **lacrimal apparatus** consists of: (1) the lacrimal gland, which secretes the lacrimal fluid; and (2) the lacrimal canaliculi, lacrimal sac, and naso-lacrimal duct, through which the fluid is conveyed to the nasal cavity. When the secretion of lacrimal fluid is excessive, it overflows as *tears*.

The **lacrimal gland** (Fig. 999) is about the size and form of an almond, and is situated in the upper and lateral part of the orbit. It occupies the fossa on the medial surface of the zygomatic process of the frontal bone, and extends down almost as far as the lateral angle of the eye; from this point a continuation of the gland, called the **palpebral process**, projects upwards, backwards, and medially in the root of the upper eyelid and along the line of the superior conjunctival fornix. Occasionally the palpebral process projects also in a downward and medial direction beyond the lateral angle of the eye, and for a considerable distance along the root of the lower lid. It is only at its lateral end that the palpebral process is connected with the main gland, and the two are separated from each other by the expanded insertion of the levator palpebræ superioris, which, until it is turned aside, completely hides the process. The **ducts** of the gland vary in number from three to nine, and open at the upper and lateral part

of the superior fornix of the conjunctiva. In close relation with the conjunctival fornices (especially the superior fornix) there are numerous small *accessory*

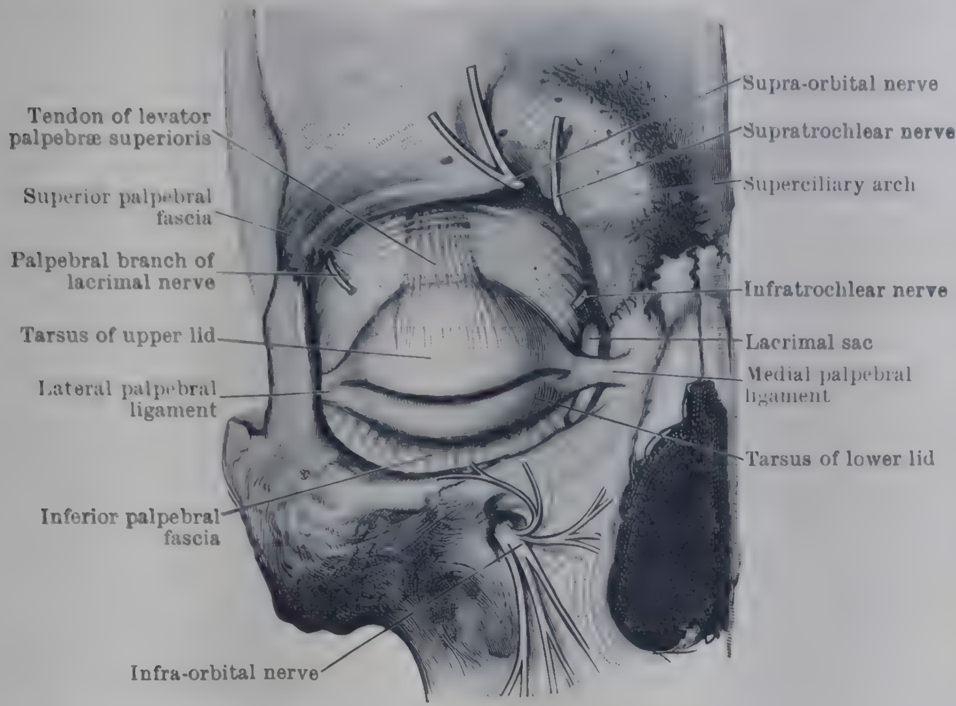

FIG. 998.—DISSECTION OF RIGHT EYELID. The orbicularis oculi has been removed.

lacrimal glands, the secretion from which may serve to moisten the conjunctiva after the extirpation of the principal gland and its process.

Structure, Vessels, and Nerves.—The structure of the lacrimal gland resembles that of the parotid gland. It is supplied by the sympathetic, lacrimal, and facial **nerves**, and by the lacrimal **artery**; its **veins** open into the ophthalmic vein.

The **lacrimal canaliculi** (Fig. 999), one in each eyelid, begin in minute orifices, termed *puncta lacrimalia*, situated on the summit of the lacrimal papillæ; each

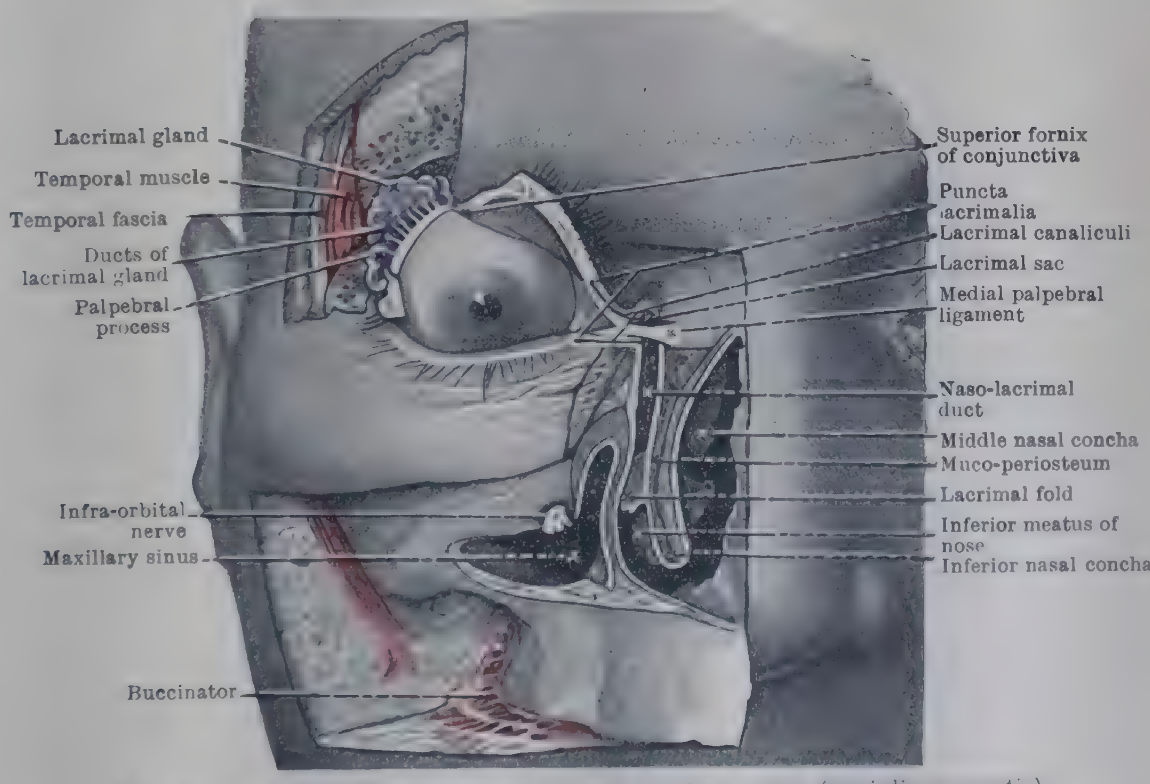

FIG. 999.—DISSECTION TO SHOW THE LACRIMAL APPARATUS (semi-diagrammatic).

canaliculus is about 10 mm. long. From the puncta lacrimalia they pass medially above and below the lacus lacrimalis; the superior at first ascends for a short distance and then inclines downwards; the inferior descends for a short distance

and then runs horizontally; where the canaliculi change their direction they are dilated into *ampullæ*. The two canaliculi open close together into the lateral and front part of the lacrimal sac, a little above its middle; sometimes they open into a pouch-like dilatation of the sac. The canaliculi are lined with stratified epithelium, and are surrounded by the lacrimal part of the orbicularis oculi muscle.

The lacrimal sac and naso-lacrimal duct together form the passage by which the lacrimal fluid is conveyed from the lacrimal canaliculi to the nasal cavity.

The **lacrimal sac** (Figs. 998, 999) is the upper, blind part of the naso-lacrimal duct, and it occupies the lacrimal fossa on the medial wall of the orbit. A sheet of fascia, continuous with the orbital periosteum, stretches from the anterior to the posterior edge of the lacrimal fossa and thus covers the lateral side of the lacrimal sac. The medial palpebral ligament and some of the fibres of the orbicularis oculi muscle lie in front of the upper half of the lacrimal sac; the lacrimal part of this muscle lies behind and to the lateral side of the sac; the lower half of the sac is below these two structures.

The **naso-lacrimal duct** (Fig. 999) is about 18 mm. long, and has a diameter of from 3 to 4 mm. Rather narrower in the middle than at its ends, it is directed downwards and slightly backwards and laterally. It opens into the inferior meatus of the nose towards its anterior end, about 30 mm. behind the nostril. The opening is very variable in form and position, and is frequently guarded by a fold of mucous membrane termed the *lacrimal fold* (Fig. 999). The duct is lined with columnar epithelium.

Vessels and Nerves.—The arteries are derived from the palpebral arteries, from the terminal branch of the facial artery, and from the infra-orbital artery. The **veins** of the naso-lacrimal duct are large, and form a well-marked plexus. The **nerves** of the lacrimal canaliculi and sac are derived from the infratrochlear nerve; the lower part of the naso-lacrimal duct receives a branch from the anterior superior dental nerve.

Development of Eye

The *retina* and *optic nerve* are developed from a hollow outgrowth of the fore-brain termed the **optic vesicle**. The vesicle extends towards the side of the head, and its connexion with the brain is gradually elongated to form the **optic stalk**. The ectoderm towards which the optic vesicle is growing becomes thickened, invaginated, and finally cut off as a hollow island of cells named the **lens-vesicle**. The lens-vesicle indents the lateral and lower part of the optic vesicle, converting it into a cup (**optic cup**), which thus consists of two layers of cells continuous with each other at the margin of the cup. The inner layer is the thicker, and it becomes the nervous layer of the retina, while the outer forms the pigmented layer. The rim of the optic cup grows forwards in front of the equator of the lens to become the pigmented part of the iris, which is thus in reality composed of two layers, and it bounds the future pupil. The indentation that forms the optic cup extends also along the postero-inferior aspect of the optic stalk in the form of a groove termed the **choroidal fissure** (Fig. 1001). Through this fissure mesoderm passes inwards between the lens and the retina to form a part of the vitreous body, and the *arteria retinæ centralis* also becomes enclosed in it and so gains its future position in the optic nerve. This artery is prolonged forwards from the optic disc through the vitreous body, as a cone of branches, as far as the back of the lens. By the fifth or sixth month all these branches have disappeared except one—the **hyaloid artery**—which persists until the last month of intra-uterine life, when it also atrophies, leaving only the **hyaloid canal** (and its corkscrew-like anterior end adherent to the back of the lens) to indicate its position.

The *vitreous body* is developed between the optic cup and the lens, and is derived partly from ectoderm and partly from mesoderm. It consists primarily of a series of fine protoplasmic

fibres which project from the cells of the retinal layer of the cup and from the back of the lens and form a delicate reticular tissue. At first the fibres are seen in relation to the whole of the optic cup, but later they become more condensed where they form the *ciliary zonule* and the walls of the *hyaloid canal*, though they can still be seen throughout the whole of the vitreous in the adult. The mesodermal element of the vitreous body is derived from the mesoderm which enters the optic cup through the choroidal fissure.

The *lens*, at first in contact with the ectoderm from which it is derived, is soon separated from it by mesoderm, and is then a rounded vesicle with epithelial walls. The outer or superficial wall remains as a single layer of cells—the anterior epithelium of the adult lens. The cells of the inner or deep wall become elongated into lens-fibres, and at the same time they grow forward into the cavity of the lens-vesicle, which thus becomes obliterated. The elongation of the cells into lens-fibres is greatest at the centre of the lens, while near the equator the fibres are shorter, and here the gradual transition between the anterior epithelium and the lens-fibres is seen (Fig. 993). The lens becomes enveloped in a vascular tunic which receives its vessels from

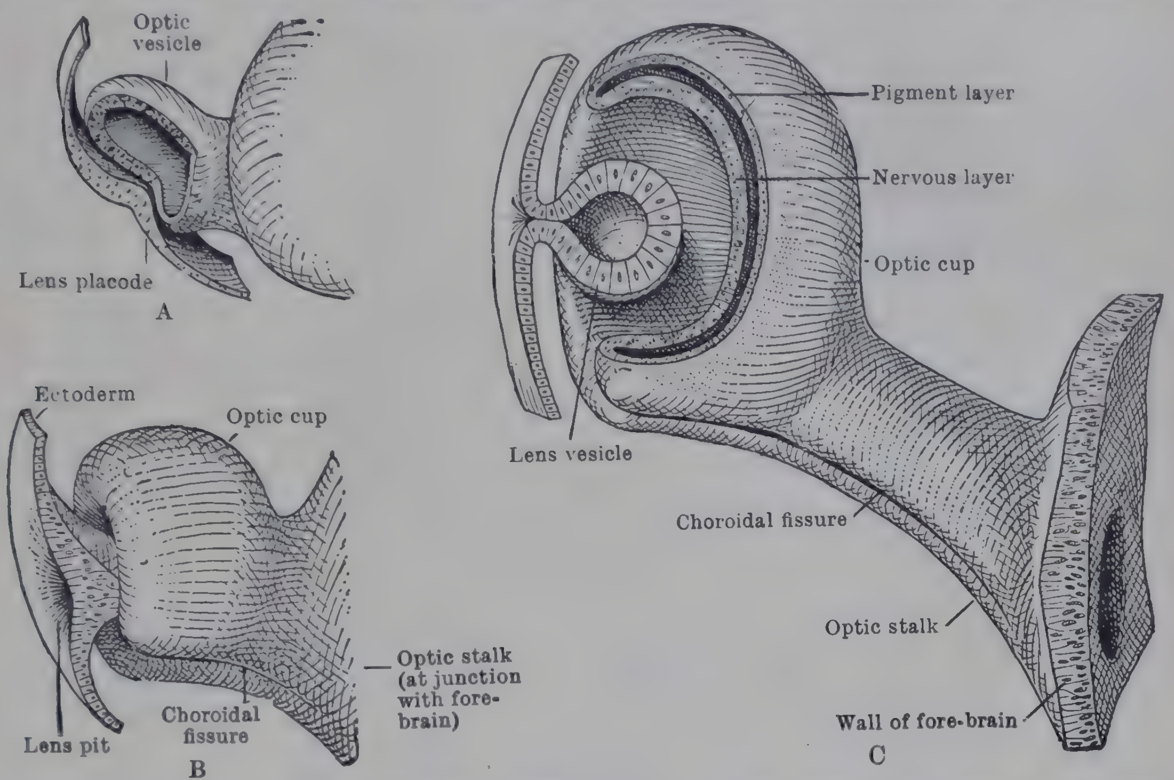

FIG. 1001.—MODELS OF DEVELOPING HUMAN EYE. ×100. (From Arey's *Developmental Anatomy*, after Ida Mann, 1928.) The lens has been sectioned, and the optic vesicle has been partly cut away in A and C.

A, 4·5 mm. embryo ; B, 5·5 mm. ; C, 7·5 mm.

the arteria retinæ centralis and from the vessels of the iris. The front part of this tunic forms the pupillary membrane which disappears before birth (p. 1168).

The optic stalk, at first hollow, becomes solid by the thickening of its walls, and, acquiring nerve-fibres, is transformed into the *optic nerve*. The further development of the retina resembles, in certain respects, that of the spinal cord.

In the first stage in the development of the retina there are present an inner marginal layer and an outer neuro-epithelial layer ; that is followed by the formation of an inner and outer neuroblastic layer owing to a migration of cells from the primitive neuro-epithelial layer to the marginal layer. The new inner neuroblastic layer ultimately gives rise to the ganglion-cells, the amacrine cells, and the cells of the sustentacular fibres, while the outer neuroblastic layer furnishes the bipolar and the horizontal cells of the inner nuclear layer, and the nuclei of the rods and cones. It will thus be seen that the inner nuclear layer of the fully formed eye, comprising amacrine, sustentacular, bipolar, and horizontal cells, is a composite structure derived in part from the inner primitive neuroblastic layer and in part from the outer layer (Mann, 1928).

The condensed mesoderm around the optic cup becomes the *sclera* and *choroid*. The mesoderm in front of the lens becomes divided by a cleft into a thick anterior layer and a thin posterior layer. The cleft becomes the *anterior chamber* of the eye ; the anterior mesodermal layer becomes the substantia propria of the *cornea* ; the posterior mesodermal layer forms the stroma of the *iris* and anterior part of the temporary vascular tunic of the lens. The deep surface of the iris is ectodermal in origin and is derived from the forward growth of the edge of the optic cup ; from this ectodermal source the muscular tissue also of the iris is derived.

The **eyelids** arise as folds above and below the cornea, each being covered on both surfaces with ectoderm. By the third month the edges of the folds meet and unite, the eyelids being only permanently opened shortly before birth ; in many animals they are not opened until after birth. The ectoderm forms the epithelium of the *conjunctiva* and the *epithelium of the cornea*. It is also invaginated at the margins of the eyelids to form the *hair-follicles* and the lining cells of the

tarsal and *ciliary glands*, and at the superior conjunctival fornix to form the lining cells of the ducts and alveoli of the *lacrimal gland*.

The **lacrimal sac** and **naso-lacrimal duct** are developed along the line of the furrow which separates the maxillary process from the lateral nasal process. The furrow is lined with ectodermal cells, and these cells, after the meeting and fusion of the lips of the furrow, proliferate and form a solid rod which is embedded in the mesoderm. By the breaking down and disintegration of its central cells, the rod becomes hollowed out to form the lacrimal sac and the naso-lacrimal duct—the lower end of the duct remaining closed until near the end of intra-uterine life. The **lacrimal canaliculi** develop as secondary buds of cells which extend sidewards from the upper end of the solid rod, and subsequently undergo canalization. The **lacrimal caruncle** is formed from a small part of the margin of the lower eyelid which is cut off by the growth of the inferior lacrimal canaliculus.

For further information, consult Ida Mann's *Development of the Human Eye* (1928).

ORGANS OF HEARING AND EQUILIBRATION

The **ear** or **auditory organ** (Fig. 1002) consists of three portions—external, middle, and internal—and it is customary to speak of these as the external, middle, and internal ear. The peripheral terminations of the cochlear and vestibular divisions of the auditory nerve are distributed within the internal ear, which contains not only the essential peripheral organ of hearing but also the peripheral organs of equilibration. The monograph of Bast & Anson (1949) gives the most recent detailed account of these organs, including their development.

EXTERNAL EAR

The **external ear** includes—(*a*) the auricle, attached to and projecting from the side of the head; and (*b*) the external auditory meatus, leading inwards from the most depressed part of the auricle to the tympanic membrane.

Auricle

The **auricle** (Fig. 1003) forms an angle of about 30° with the side of the head, though this varies considerably in different persons. Its lateral surface is irregularly concave, but has several well-marked elevations and depressions. The deepest of the depressions — the **concha** — is situated near the middle of the auricle; it is divided by a ridge, called the **crus of the helix**, into an upper and a lower portion; the lower portion is the larger and leads into the external auditory meatus. Anteriorly, the crus helicis is continuous with the **helix** or margin of the auricle, which is incurved in the greater part of its extent, and is directed at first upwards, and then backwards and downwards, to become gradually lost in the upper part of the lobule. Near the point where the helix begins to descend, a small **tubercle** is often seen. In front of the descending part of the helix there is a second elevation, called the **antihelix**, which bifurcates at its upper end into two **crura** that enclose a

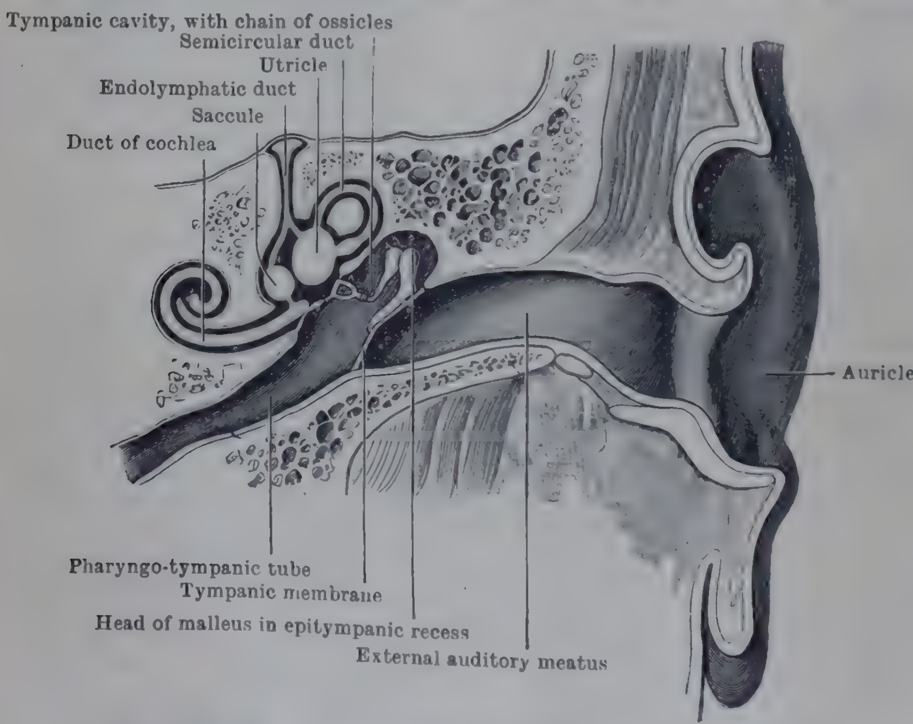

Fig. 1002.—Diagrammatic Section of Organ of Hearing.

depression called the **triangular fossa**. The elongated furrow between the helix and antihelix is named the **scaphoid fossa**. The concha is overlapped in front by a tongue-like process called the **tragus**, and below and behind by a triangular projection called the **antitragus**; the notch, directed downwards and forwards between those two processes, is named the **incisura intertragica**. The tragus is often partially divided into two small tubercles, and it is separated from the crus of the helix by the **anterior notch of the auricle**. The **lobule** is situated below the incisura intertragica, and is the most dependent part of the auricle; its shape and degree of development are subject to much variation.

The medial or cranial surface of the auricle presents elevations corresponding to the depressions on its lateral surface, *e.g.*, the **eminence of the concha**, the **eminence of the scaphoid fossa**, the **eminence of the triangular fossa**, etc.

The auricle, usually smaller and more finely modelled in women than in men, presents great variations in size and shape in different persons. In the new-born child its length is about one-third of that of the adult; in old age it increases both in length and breadth.

The **tubercle of the ear** is a triangular prominence which projects usually forwards from the helix. It is more often present in men than in women. Its significance, which was recognized by Charles Darwin, is that it probably represents the point of the ear of lower animals; it is well seen in the macaque monkey, the ear of which closely resembles that of a human fœtus of the sixth month.

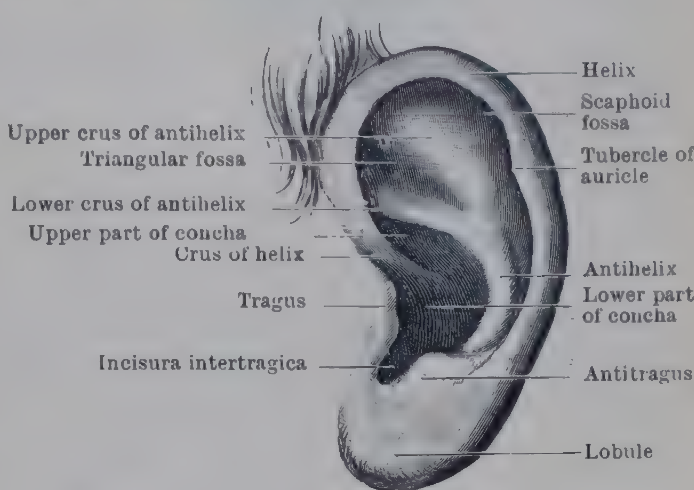

Fig. 1003.—Lateral Surface of Left Auricle.

Structure of Auricle.—The skin of the auricle is thin and smooth, and is prolonged, in the form of a tube, as a lining to the external auditory meatus. On the lateral surface of the auricle, it adheres firmly to the subjacent perichondrium. Strong hairs, named **tragi**, are often present in men on the tragus and antitragus, and also in the incisura intertragica; soft downy hairs are found over the greater part of the auricle and point towards the tubercle. Sebaceous glands, present on both surfaces of the auricle, are most numerous in the concha and triangular fossa. Sweat-glands are found on the medial surface; few or none on the lateral surface.

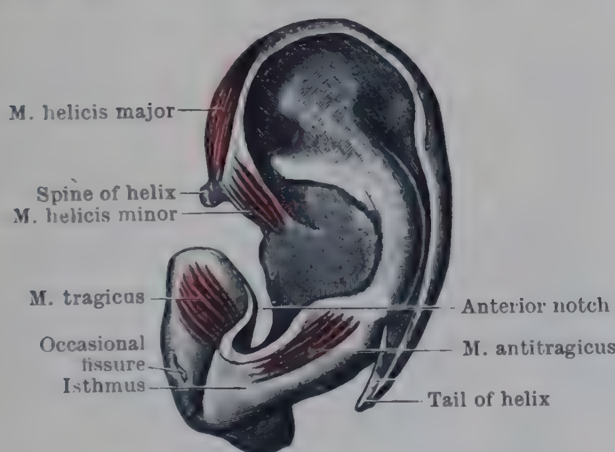

Fig. 1004.—Lateral Surface of Cartilage of Left Auricle, with Muscles.

The greater part of the auricle is supported by yellow fibro-cartilage; the cartilage is, however, absent from the lobule, which is composed of fat and fibro-areolar tissue. When laid bare, the cartilage (Figs. 1004, 1005) presents, in an exaggerated form, all the inequalities of the auricle. It is continuous medially with the cartilaginous part of the external auditory meatus through a narrow **isthmus**, 8 or 9 mm. in breadth, which corresponds laterally with the deepest part of the incisura intertragica. The most anterior part of the cartilage of the helix projects forwards as the **spine**, and the most inferior part is called the **tail** of the helix. Small clefts are found here and there in the cartilage, and one of these is shown in Fig. 1004.

Ligaments of Auricle.—The cartilage of the auricle is fixed to the temporal bone by two extrinsic ligaments—an *anterior*, stretching from the spine of the helix and the tragus to the zygomatic process, and a *posterior*, stretching from the eminence of the concha to the mastoid part of the bone. Small intrinsic ligaments pass between individual parts of the auricle.

Muscles of Auricle.—The muscles of the auricle are divisible into two groups, *extrinsic* and *intrinsic*. The extrinsic muscles connect the auricle to the skull and scalp, and are described in the Section on Myology. The intrinsic muscles are confined to the auricle and are six in number, four on its lateral surface and two on its cranial or medial surface. They are mere vestiges and have little or no action.

(*a*) *On the lateral surface* (Fig. 1004)—

1. The **helicis major** muscle passes upwards from the spine of the helix along the ascending part of the helix. 2. The **helicis minor** muscle covers the crus of the helix. 3. The **tragicus** muscle runs vertically over the greater part of the tragus. Some of its fibres may be prolonged upwards to the spine of the helix and constitute the **pyramidalis** muscle. 4. The **antitragicus** muscle covers the antitragus and runs obliquely upwards and backwards to the antihelix and tail of the helix.

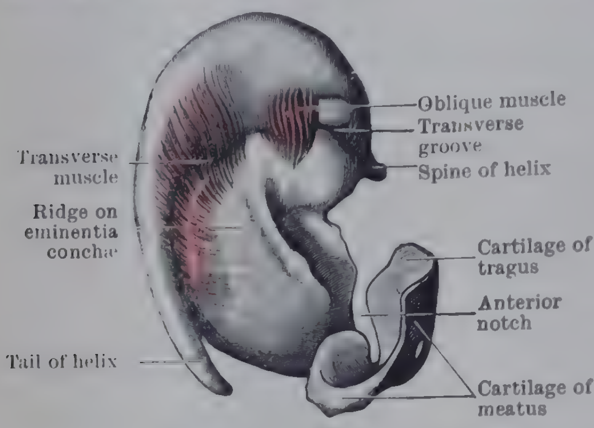

Fig. 1005.—Medial Surface of Cartilage of Left Auricle, with Muscles.

(*b*) *On the medial surface* (Fig. 1005)—

1. The **transverse muscle of the auricle** consists of scattered fibres which stretch from the eminence of the lower part of the concha to the eminence of the scaphoid fossa. 2. The **oblique muscle of the auricle** comprises a few fasciculi which run obliquely or vertically from the eminence of the triangular fossa to the eminence of the upper part of the concha.

Vessels and Nerves.—The **arteries** are derived—(*a*) from the superficial temporal artery, which sends two or three branches to the lateral surface; and (*b*) from the posterior auricular artery, which gives three or four branches to the medial surface. From the branches of the posterior auricular artery two sets of twigs pass to the lateral surface, one turning round the free margin of the helix, and the other passing through small fissures in the cartilage. The **veins** from the lateral surface open into the superficial temporal vein; those from the medial surface chiefly join the posterior auricular vein, but some communicate with the mastoid emissary vein. The **lymph-vessels** take three directions, viz.: (*a*) forwards to the parotid lymph-glands, and especially to the gland in front of the tragus; (*b*) downwards to the lymph-glands that lie alongside the external jugular vein, and to the lymph-glands under the sterno-mastoid muscle; and (*c*) backwards to the mastoid lymph-glands.

The **nerves** are motor and sensory. The muscles are supplied by the facial nerve. The skin receives its sensory nerves from—(*a*) the great auricular nerve, which supplies nearly the whole of the medial surface, and sends filaments in company with the branches of the posterior auricular artery to the lateral surface; (*b*) the auriculo-temporal nerve, which supplies the tragus and ascending part of the helix; (*c*) the lesser occipital nerve, which sends a branch to the upper part of the medial surface.

External Auditory Meatus

The **external auditory meatus** (Figs. 1002, 1006) is the passage that leads from the concha to the tympanic membrane. Its length, measured from the bottom of the concha, is 24 mm.; from the margin of the tragus it is 35 mm. On account of the obliquity of the tympanic membrane the anterior and inferior walls of the meatus are longer than the posterior and superior walls. The meatus consists of a lateral, cartilaginous part, about 8 mm. in length; and a medial, bony part about 16 mm. in length. The entire meatus makes a sinuous bend (Fig. 1002) and may be divided into three portions—lateral, intermediate, and medial; each is directed medialwards, but, in addition, the lateral part is inclined forwards and slightly upwards; the intermediate, backwards; and the medial—the longest—forwards

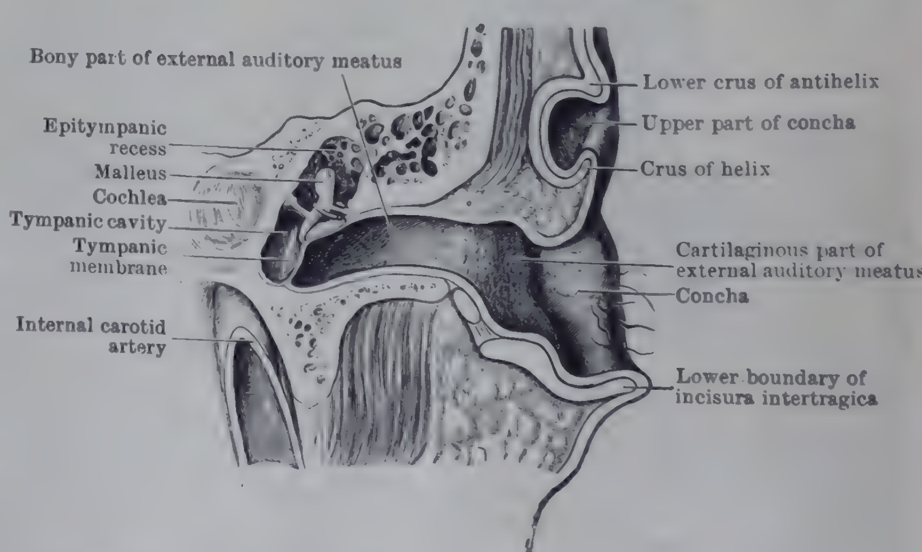

Fig. 1006.—Coronal Section of Right Ear: Anterior Half of Section, viewed from behind.

and slightly downwards. The passage is not circular in transverse section but elliptical—its greatest diameter being directed from above downwards and backwards. It is widest at its lateral end and becomes slightly narrower at the medial end of the cartilaginous part; it is expanded in the lateral portion of the bony part, and constricted near its medial end; this, the narrowest part, is named the **isthmus**, and its outer end is 20 mm. distant from the bottom of the concha. The medial end of the meatus is the most nearly circular part and is closed by the tympanic membrane.

The lumen of the cartilaginous part is influenced by the movements of the mandible, being widened when the mouth is opened. A large part of the head of the mandible lies in front of the bony part of the meatus, and a small portion lies in front of the cartilaginous part also; between this part of the meatus and the mandible there is lodged a process of the parotid gland. Posteriorly the bony portion of the meatus is related to the mastoid process.

Structure of Meatus.—The cartilage of the meatus does not form a complete tube but is folded to form a groove, opening upwards and backwards, the margins of the groove being connected with each other by fibrous tissue. The medial end of the cartilaginous part of the meatus is firmly fixed to the lateral margin of the bony part; its lateral end is continuous with the cartilage of the tragus. Two fissures exist in the anterior portion of the cartilaginous part, and are filled with fibrous tissue. In the lateral part of the meatus the cartilage forms about three-fourths of the circumference of the tube; but near the medial end it forms only a part of the anterior and lower boundaries.

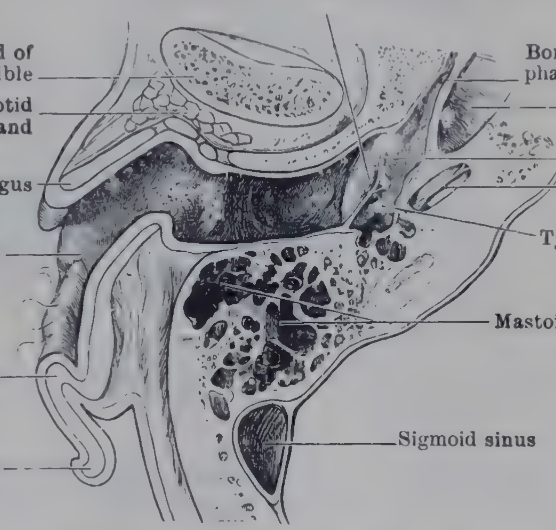

Fig. 1007.—Horizontal Section through Right Ear; Upper Half of Section, viewed from below.

The bony part is described on pp. 164, 165. In the new-born child it is represented only by an incomplete ring of bone—the **tympanic ring**—together with a small portion of the squamous part of the temporal bone, which articulates with the ring and completes it superiorly (Fig. 188, p. 224). Along the concavity of the ring there is a groove, called the **tympanic groove**, in which the circumference of the tympanic membrane is fixed. On the medial surface of the anterior part of the ring, a little below its free end, a groove, called the **malleolar sulcus**, is directed downwards and forwards. It transmits the anterior process and the anterior ligament of the malleus, the tympanic artery, and the chorda tympani nerve. A **fibrous tympanic plate** (Symington, 1885) intervenes between the tympanic ring and the cartilage of the meatus, and into that plate the bony ring extends. The bony outgrowth does not, however, proceed uniformly from the whole circumference of the ring but occurs most rapidly from its anterior and posterior parts, with the result that when the two outgrowths fuse, at about the end of the second year of life, a gap is left between them in the floor of the meatus; this gap is usually closed by the fifth year, but may persist in the adult skull.

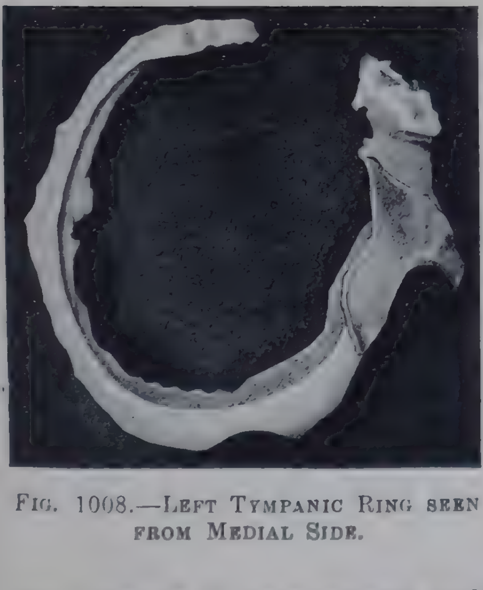

Fig. 1008.—Left Tympanic Ring seen from Medial Side.

The lumen of the meatus in the new-born child is extremely small: its lateral part is funnel-shaped; its medial part is a mere slit, bounded below by the fibrous tympanic plate and above by the tympanic membrane. Since there is no bony external auditory meatus the tympanic membrane is close to the surface, and is on the inferior rather than the lateral surface of the skull.

The meatus is lined with skin which covers also the lateral surface of the tympanic membrane. The skin is thick in the cartilaginous part, and contains fine hairs and sebaceous glands; the

glands extend for some distance along the postero-superior wall of the bony part of the meatus. In the subcutaneous tissue of the cartilaginous part there are numerous enlarged sweat-glands (p. 1157); they are named **ceruminous glands** because they secrete the ear-wax or cerumen.

Vessels and Nerves.—The **arteries** of the external auditory meatus are branches of the posterior auricular and superficial temporal arteries, and of the deep auricular artery, which distributes some minute twigs to the tympanic membrane also. The **veins** open into the maxillary and external jugular veins, and into the pterygoid venous plexus. The **lymph-vessels** end like those of the auricle. **Sensory nerves** are supplied to the meatus by the auriculo-temporal nerve and by the auricular branch of the vagus nerve.

MIDDLE EAR OR TYMPANUM

The **tympanic cavity** is a small air-chamber in the temporal bone, between the tympanic membrane and the lateral wall of the internal ear or labyrinth (Figs. 1002, 1006). It is lined with mucous membrane, and it contains a chain of ossicles—malleus, incus, and stapes—which reaches from its lateral wall to its medial wall, and transmits the vibrations of the tympanic membrane across the cavity to the internal ear. Several ligaments and two small muscles are attached to the ossicles.

The larger part of the tympanic cavity is opposite the tympanic membrane and is the true **tympanum**, but the cavity extends also above the level of the

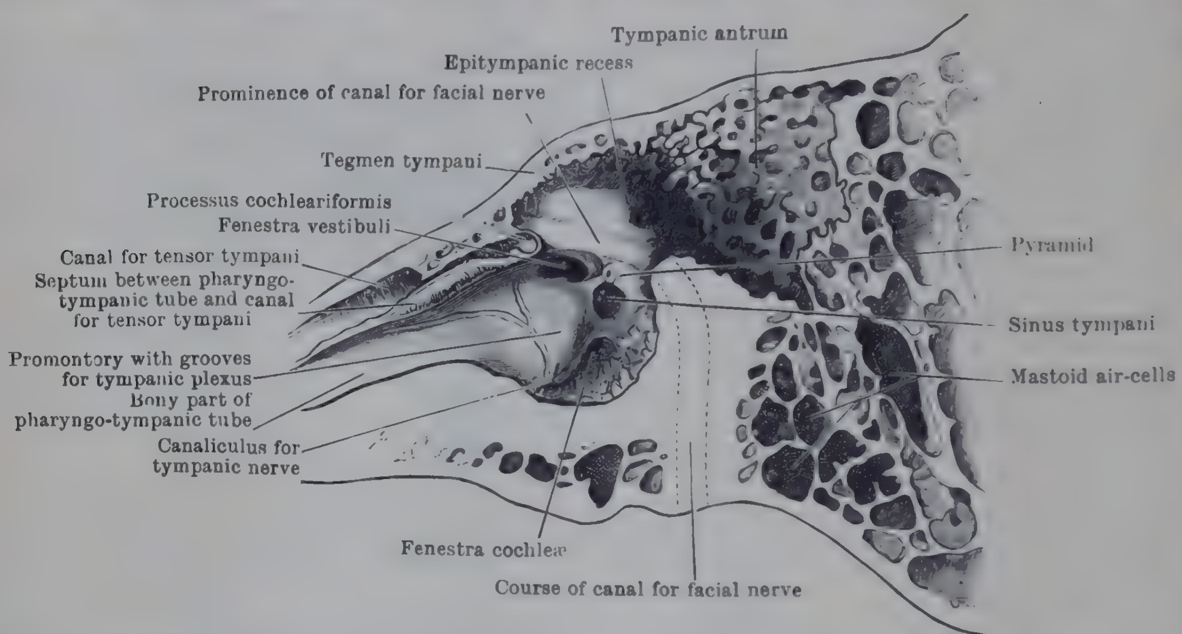

FIG. 1009.—SECTION THROUGH LEFT TEMPORAL BONE, SHOWING MEDIAL WALL OF TYMPANIC CAVITY.

membrane and this part is named the **epitympanic recess**; it contains the greater part of the incus and the upper half of the malleus. Including the recess, the vertical and antero-posterior diameters of the cavity are each about 15 mm. The distance between its lateral and medial walls is about 6 mm. in the upper part and 4 mm. in the lower, while at its central part, owing to the bulging of the two walls towards the cavity, it is only 1·5 or 2 mm.

The tympanic cavity communicates, behind, with the tympanic antrum (see p. 1187), and through that with the mastoid air-cells; in front, with the nasal part of the pharynx through the pharyngo-tympanic tube. It is enclosed by a roof, a floor, and four walls—anterior, posterior, medial, and lateral.

The **roof** of the tympanic cavity (Fig. 1009) is a thin plate of bone—the **tegmen tympani**—which forms a portion of the anterior surface of the petrous part of the temporal bone. It extends backwards to cover the tympanic antrum, and forwards to form a roof for the canal for the tensor tympani muscle. It separates the tympanic cavity and antrum from the middle cranial fossa; it may contain a few air-cells, and occasionally it is partly deficient. In the child its lateral edge corresponds with the petro-squamous suture, traces of which can generally be seen in the adult bone.

The **floor** is narrower than the roof, and consists of a thin plate of bone which separates the tympanic cavity from the jugular fossa; anteriorly, it slopes upwards

and is continuous with the posterior wall of the carotid canal (Fig. 159, p. 185). The inner orifice of the canaliculus which transmits the tympanic nerve—a branch of the glosso-pharyngeal—is placed near the junction of the floor and medial wall.

The **medial wall** of the middle ear (Fig. 1009) is also the lateral wall of the internal ear. It presents:—(1) A rounded eminence, called the **promontory**, caused by the bulging of the first coil of the cochlea; its surface is marked by small grooves which lodge the tympanic plexus of nerves. (2) An oval or kidney-shaped opening, named the **fenestra vestibuli**, situated above and behind the promontory, with its long axis directed antero-posteriorly and its concavity directed downwards. It measures 3 mm. in length and 1·5 mm. in breadth and, in the macerated bone, leads into the vestibule of the bony labyrinth, but, in the recent state, is closed by the base of the stapes surrounded by its **annular ligament**. (3) An elevation—the **prominence of the canal for the facial nerve**—situated above the fenestra vestibuli, in the epitympanic recess. (4) The **processus cochleariformis**—a thin, narrow bony shelf which extends backwards above the anterior end of the fenestra vestibuli, where it makes a sharp lateral curve and forms a pulley over which the tendon of the tensor tympani muscle plays. (5) A funnel-shaped recess, situated behind and below the promontory, and almost hidden by its overhanging edge, and which leads to an irregularly oval opening, termed the **fenestra cochleæ**; in the macerated bone the fenestra opens into the cochlea, but in the recent state is closed by the **secondary tympanic membrane**. This membrane consists of three layers: (*a*) a *lateral* layer, continuous with the mucous lining of the tympanic cavity and containing a network of capillaries; (*b*) an *intermediate* fibrous layer; (*c*) a *medial* layer, continuous with the epithelial lining of the labyrinth. (6) A small depression named the **sinus tympani**, situated behind the promontory and between the fenestra vestibuli and the fenestra cochleæ; it indicates the position of the ampullated end of the posterior semicircular canal, but of course is not caused by this.

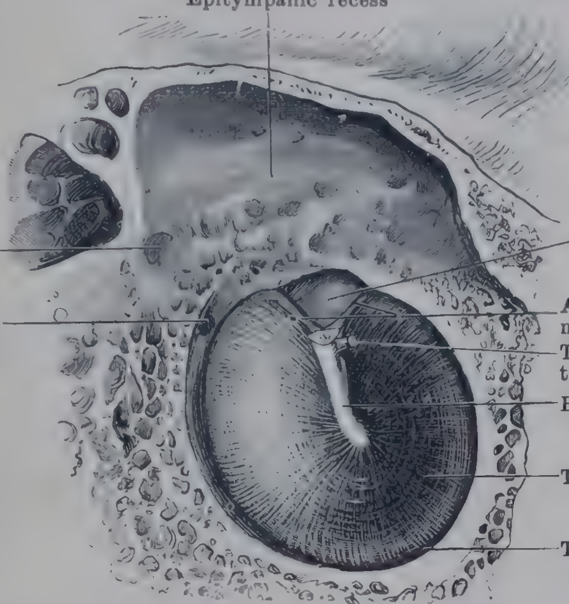

Fig. 1010.—Left Tympanic Membrane and Epitympanic Recess, viewed from Within. The head and neck of the malleus have been removed to show the flaccid part of the membrane and the malleolar folds.

The **posterior wall** of the tympanic cavity (Figs. 1009, 1010), presents, from above downwards:—(1) A round or triangular opening, called the **aditus**, which leads from the epitympanic recess into the **tympanic antrum**; (2) a depression—the **fossa for the incus**—situated in the postero-inferior part of the epitympanic recess, for the reception of the end of the short process of the incus; (3) a minute, conical, bony projection called the **pyramid**, the summit of which is perforated by the tendon of the stapedius muscle. From the interior of the pyramid a small canal passes downwards and backwards in front of the facial canal, into which it usually opens; its walls give attachment to the stapedius, and it transmits the vascular and nervous supply to that muscle. This small canal sometimes opens independently on the base of the skull, immediately in front of the stylo-mastoid foramen; (4) a small aperture—the **posterior canaliculus for the chorda tympani**—situated close to the posterior edge of the tympanic membrane nearly on a level with the upper end of the handle of the malleus.

The **anterior wall is** narrowed in its transverse diameter by the approximation

of the lateral and medial walls of the tympanic cavity, and in its vertical diameter by the descent of the tegmen tympani and the ascent of the floor (Fig. 1009). It presents the openings of two parallel canals, one above the other, separated by a thin lamella of bone, the posterior end of which is the processus cochleariformis. The two canals run forwards on the lateral side of the carotid canal and open in the angle between the squamous and the petrous parts of the temporal bone. The upper and smaller canal is the **canal for the tensor tympani**, and lies immediately below the tegmen tympani. It has a diameter of about 2 mm., and extends on to the medial wall of the tympanic cavity above the anterior part of the fenestra vestibuli. The lower and larger canal is the **bony part** of the **pharyngo-tympanic tube**, and it gradually increases in diameter from before backwards. Below the orifice of the tube the anterior part of the tympanic cavity is separated from the ascending portion of the carotid canal by a thin plate of bone in which sometimes there are gaps. The plate is perforated by the carotico-tympanic nerves as they pass from the sympathetic plexus on the carotid artery to join the tympanic plexus.

The **lateral wall** is formed almost entirely by the tympanic membrane (Fig. 1010). The tympanic groove, in which the membrane is attached, is deficient superiorly, and the gap is called the **tympanic notch**. On a level with the upper edge of the membrane, and in front of the tympanic ring, there is the medial end of the **squamo-tympanic fissure**. It transmits the tympanic branch of the maxillary artery, and lodges the anterior process and anterior ligament of the malleus. Close to the medial end of the fissure is the **anterior canaliculus for the chorda tympani**.

The **tympanic membrane** is an almost circular sheet of fibrous tissue, with a diameter of about 10 mm. It is placed very obliquely, and forms an angle of about 55° with both the lower and anterior walls of the external auditory meatus.

At its attachment to the tympanic groove the membrane is considerably thickened. This thickened portion is named the **fibro-cartilaginous ring** and is prolonged from the anterior and posterior ends of the tympanic notch to the lateral process of the malleus as two ligamentous bands which raise up ridges, called the **anterior** and **posterior malleolar folds**, on the medial surface of the membrane. The small, triangular portion of the membrane (Fig. 1010) between the malleolar folds is thin and lax, and is its **flaccid part**, whilst the main portion of the membrane is tightly stretched and is termed the **tense part**. The handle of the malleus is firmly fixed to the tympanic membrane, the central portion of which is drawn in towards the tympanic cavity. The point of greatest convexity of the membrane corresponds with the lower end of the handle of the malleus, and is named the **umbo of the tympanic membrane**.

Structure.—The tympanic membrane is composed of three layers—cuticular, fibrous, and mucous.

The **cuticular layer** is continuous with the skin of the external auditory meatus.

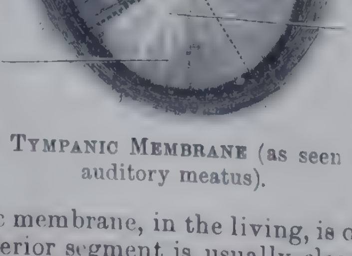

FIG. 1011.—LEFT TYMPANIC MEMBRANE (as seen from the external auditory meatus).

The **fibrous layer** is composed of radial and circular fibres. The radial fibres pass from the handle of the malleus to the fibro-cartilaginous ring; the circular fibres are numerous near the circumference of the membrane, but scattered and few in number near its centre (Fig. 1010). Both radial and circular fibres are absent from the flaccid part, which thus consists only of the cuticular and mucous layers.

The **mucous layer** is part of the mucous lining of the tympanic cavity and is thickest at the upper part of the membrane.

Otoscopic Examination of Tympanic Membrane (Fig. 1011).—The tympanic membrane, in the living, is of a "pearl-grey" colour, but may have a red or yellow tinge; the posterior segment is usually clearer than the anterior. At the antero-superior part, close to its periphery, a whitish point appears as if projecting towards the meatus; this is the lateral process of the malleus. Passing downwards and backwards from that point to the umbo

there is a ridge caused by the handle of the malleus, the lower end of which appears rounded. Two ridges, corresponding with the malleolar folds, extend from the lateral process of the malleus, one forwards and upwards, the other backwards and upwards. Behind and near the lower end of the handle of the malleus there is a rather red or yellow spot, due to the promontory of the medial wall shining through the membrane. If the membrane is very transparent, the long process of the incus may be visible behind the upper part of the handle of the malleus, reaching downwards as far as its middle. From the lower end of the handle, a bright area termed the "cone of light" radiates in a downward and forward direction.

For the purpose of precise localization of any point on the membrane, its surface is divided into quadrants by the handle of the malleus and a line continued from it to the circumference and by a line drawn at right angles to this through the lower end of the handle.

Vessels and Nerves.—The **arteries** are arranged in two sets—one on the outer surface and the other on the inner; they anastomose by means of small branches which pierce the membrane, especially near its periphery. The branches to the outer surface are derived chiefly from the deep auricular branch of the maxillary artery; those to the inner surface from its anterior tympanic branch and from the stylo-mastoid branch of the occipital artery. The **veins** from the outer surface open into the external jugular vein; those from the inner surface end partly in the venous plexus on the pharyngo-tympanic tube, and partly in the sigmoid sinus and in the veins of the dura mater. The **lymph-vessels**, like the blood-vessels, are arranged in two sets which communicate freely with each other. The lateral surface of the membrane receives its **nerves** from the auriculo-temporal nerve and from the auricular branch of the vagus nerve; the medial surface, from the tympanic branch of the glosso-pharyngeal nerve.

Tympanic Antrum and Mastoid Air-Cells

The **tympanic antrum** is an air-space situated behind the epitympanic recess. In the adult its average length is from 12 to 15 mm., its height from

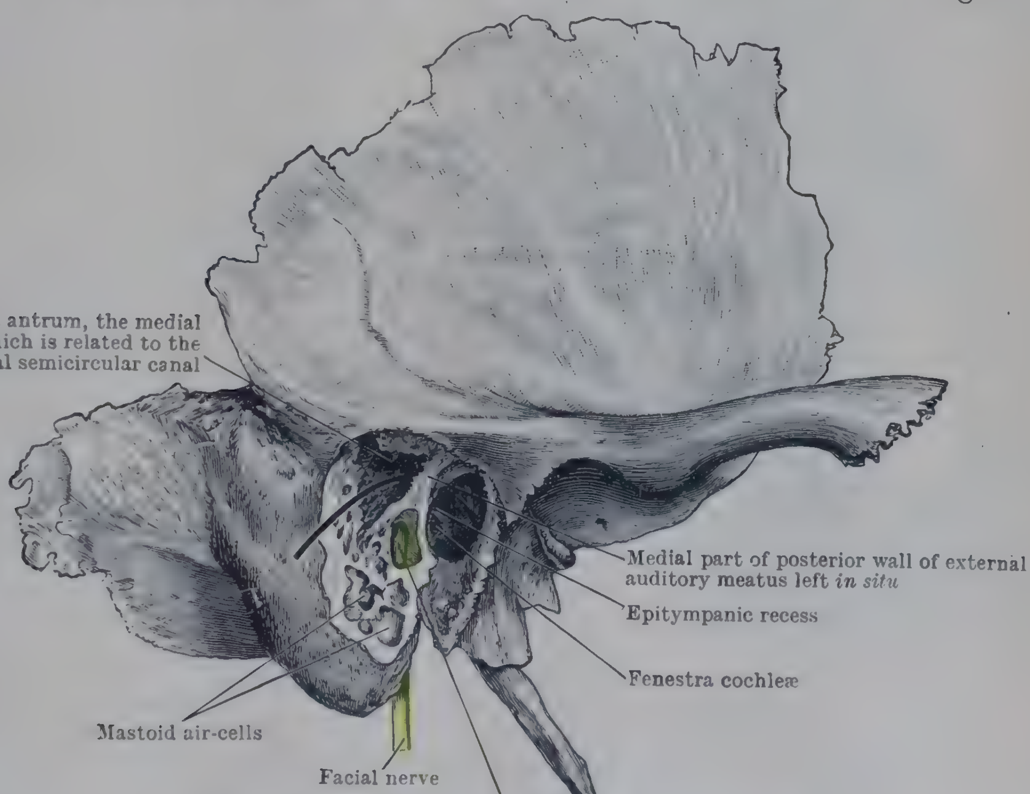

Fig. 1012.—Preparation displaying Position and Relations of Right Tympanic Antrum. The greater part of the posterior wall of the external meatus has been removed, leaving only a bridge of bone at its medial end; under this a bristle passes from the tympanic antrum to the tympanic cavity.

8 to 10 mm., and its width from 6 to 8 mm. Its roof is a backward extension of the tegmen tympani and its floor and medial wall are the mastoid and petrous parts of the temporal bone; laterally it is closed by the portion of the squamous part of the temporal bone which lies below the supramastoid crest. It communicates with the epitympanic recess through the aditus, on the medial wall of which, immediately above and behind the canal for the facial nerve, there is a smooth convexity that indicates the position of the ampullated end of the lateral semicircular canal.

At birth the lateral wall of the antrum has a thickness of only 1 or 2 mm., but it increases to about 10 mm. by the ninth year and to about 15 mm. in the adult. Coincident

with the growth of the mastoid process the mastoid air-cells are developed as downward and backward diverticula from the antrum, and present great variation in different skulls.

The **mastoid air-cells** may be large or small, numerous or few, and may involve all the mastoid part of the temporal bone or may not extend at all deeply into it; when the cells are large and numerous the compact bone around them is thin, and the inner cells are separated from the posterior cranial fossa and the sigmoid sinus only by a thin sheet of bone which sometimes is perforated. The air-cells are not always limited to the mastoid part of the temporal bone, but may extend upwards towards the squamous part, forwards into the roof of the meatus, and medially towards the temporo-occipital suture; occasionally they invade the jugular process of the occipital bone. The tympanic antrum and the mastoid air-cells are lined with thin mucous membrane continuous with that of the tympanic cavity; it is firmly adherent to the endosteum, and its free surface is covered with a layer of flattened, non-ciliated epithelium.

Pharyngo-Tympanic Tube

The **pharyngo-tympanic tube** is the passage through which air may pass from the pharynx to the tympanic cavity in order that the pressure of air on each side of the tympanic membrane may be equal. The tube is about 3·5 cm. ($1\frac{3}{8}$ inches) long and is partly bony and partly cartilaginous. The lower and medial part is cartilaginous and is twice as long as the upper and lateral bony part. From the **pharyngeal opening** the tube is directed upwards and laterally, making an angle with the horizontal plane of about 40° and with the sagittal plane an angle of about 45°; the bony part of the tube is rather more horizontal than the cartilaginous part and makes with it a wide angle —about 160°. The cartilaginous part of the tube is composed of a triangular plate of cartilage folded along its long axis so as to form a gutter, open in a downward and lateral direction. The two sides of the gutter are unequal, the medial being much the deeper. The gap between the sides of the gutter is bridged over by fibrous tissue, thus converting the gutter into a tube. The base of this triangular cartilage impinges on the wall of the pharynx and partially surrounds the *pharyngeal opening* of the tube; the apex is firmly fixed to the bony part of the tube; the amount of cartilage thus becomes gradually less as the bony part of the tube is approached. As can be easily demonstrated by a triangular piece of paper folded in the manner indicated above, it is only the medial and upper walls of the gutter that impinge on the pharyngeal wall; in that situation they give rise to a hook-like ridge, named the **tubal elevation**, from the posterior edge of which there is prolonged down the pharyngeal wall a fold of mucous membrane called the **salpingo-pharyngeal fold**; this fold overlies the salpingo-pharyngeus muscle (Fig. 504, p. 588).

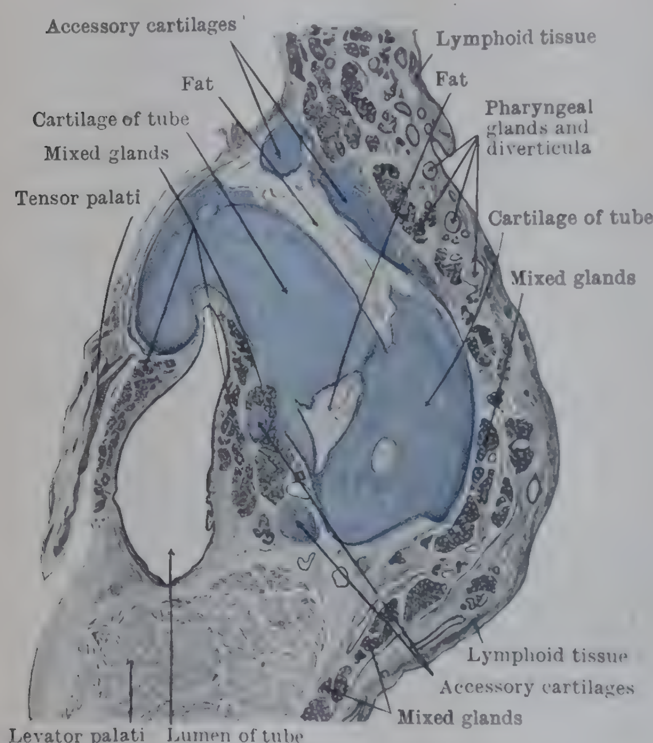

Fig. 1013.—Cross-Section through Pharyngo-Tympanic Tube near its Pharyngeal End.

The cartilaginous part of the tube is firmly fixed to the under surface of the skull in the groove between the greater wing of the sphenoid and the petrous part of the temporal bone. Close to its medial end it is supported by a small tubercle on the posterior edge of the medial pterygoid plate. The tensor palati muscle,

which receives some fibres of origin from the cartilage, lies on the lateral side of the tube and separates it from the middle meningeal artery and the mandibular division of the trigeminal nerve; the levator palati and the mucous membrane of the pharynx are on its medial side. The bony part of the tube occupies the angle between the tympanic and petrous parts of the temporal bone, and it opens into the tympanic cavity below the canal for the tensor tympani muscle; the internal carotid artery ascends across its medial side.

The tube is opened, during deglutition, by the tensor palati and salpingo-pharyngeus muscles. When the tensor contracts, the lateral wall of the tube is drawn laterally and forwards. The salpingo-pharyngeus draws the medial part of the cartilage downwards and backwards, thus increasing the angle between it and the lateral part.

Mucous Membrane.—The mucous lining of the tube is continuous behind with that of the tympanic cavity, and in front with that of the nasal part of the pharynx. In the bony part it is thin and firmly fixed to the bony wall; in the cartilaginous part it is loose and thrown into longitudinal folds. Numerous mucous glands open into the tube near its pharyngeal end, and there also there is a considerable amount of lymphoid tissue. The lymphoid tissue is continuous with that of the nasal part of the pharynx, and, like it, is especially well developed in children. The mucous membrane is lined with ciliated columnar epithelium.

Vessels and Nerves.—The **arteries** of the tube come from the ascending pharyngeal and middle meningeal arteries and from the artery of the pterygoid canal. Its **veins** drain into the pterygoid venous plexus. Its sensory **nerves** are derived from the tympanic plexus and from the pharyngeal branch of the spheno-palatine ganglion.

The tube of the child differs considerably from that of the adult; its lumen is wider, its direction more horizontal, and its bony part relatively shorter. The pharyngeal opening is below the level of the hard palate in the fœtus; at birth it is level with the palate; at the fourth year it is 3 to 4 mm. above it, and in the adult 10 mm. above it; in the child it is a narrow fissure, and the tubal elevation is less prominent.

Auditory Ossicles

The auditory ossicles, three in number, form an articulated column that connects the lateral wall of the tympanic cavity with the medial wall; they are

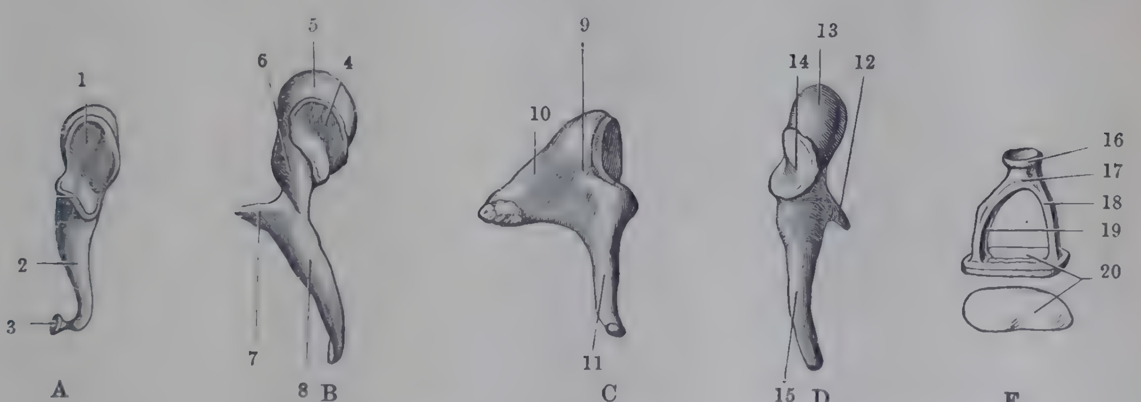

Fig. 1014.—Auditory Ossicles of Left Ear (enlarged about three times).

A, Incus, seen from the front; B, Malleus, seen from behind; C, Incus, and D, Malleus, seen from medial side; E, Stapes, seen from above and from the medial side.

15. Handle of malleus.
16. Head of stapes.
17. Neck of stapes.
18. Anterior limb of stapes.
19. Posterior limb of stapes.
20. Base of stapes.

named the malleus, the incus, and the stapes. The malleus is attached to the medial surface of the tympanic membrane; the stapes fits against the fenestra vestibuli; and the incus is between the other two.

The **malleus** (Fig. 1014, B, D)—the largest of the three—is from 8 to 9 mm. long; it bears some resemblance to a club, or small hammer [*malleus* = a hammer], and has a head, a neck, a handle, and two processes—anterior and lateral.

The head and neck are situated in the epitympanic recess; the lateral process and the handle are fixed to the medial surface of the tympanic membrane; the anterior process is directed forwards towards the squamo-tympanic fissure, to the margin of which, in the adult, it is connected by ligamentous fibres. The **head** is smooth and convex above and in front; on its posterior surface there is a facet for articulation with the body of the incus. The facet is more or less elliptical, but is constricted near the middle; an oblique ridge, corresponding with the constriction, divides the facet into two parts—an upper and larger, directed backwards, and a lower and smaller, directed medialwards. Opposite the lower part of the constriction the inferior edge of the facet is very prominent, and is continued upwards into the oblique ridge just referred to and forms a tooth-like spur. On the back of the head, below this spur, there is an oblique crest, to which the lateral ligament of the malleus is attached. The **neck** is the slightly constricted portion immediately below the head. Its lateral surface is directed towards the flaccid part of the tympanic membrane; its medial surface is crossed by the chorda

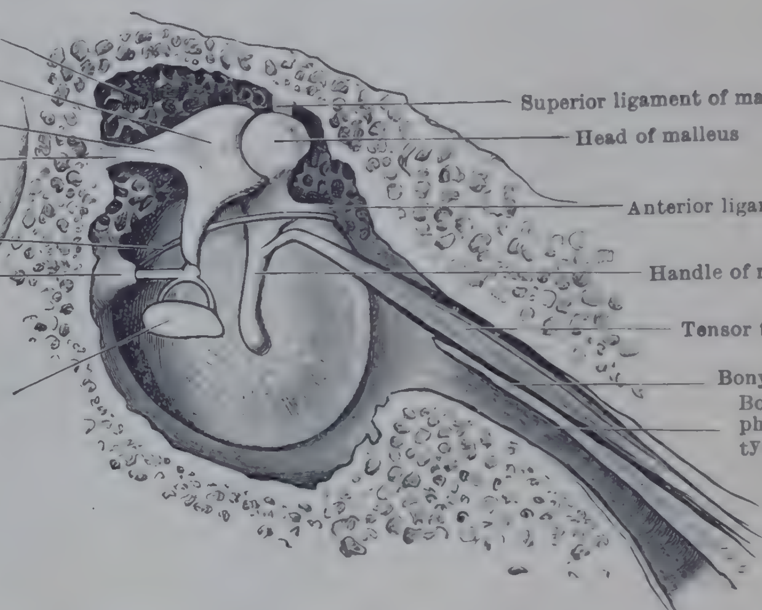

FIG. 1015.—LEFT TYMPANIC MEMBRANE AND CHAIN OF AUDITORY OSSICLES (seen from medial side).

tympani nerve. The **handle** projects downwards, backwards, and medialwards from the neck, and forms with the long axis of the head an angle of 126° to 150°; the lower end is slightly curved, the concavity being directed forwards and sidewards. The handle is fixed by its periosteum and by a layer of cartilage to the fibrous layer of the tympanic membrane. On the medial surface of the handle, near its upper end, there is a slight projection for the attachment of the tendon of the tensor tympani muscle. The **anterior process** is a slender spicule that springs from the front of the neck and is directed forwards towards the squamo-tympanic fissure. The **lateral process** is a conical eminence, and it may be looked upon as the upper end of the handle projected laterally; it is fixed to the upper part of the tympanic membrane by a layer of cartilage, and to the ends of the tympanic notch by the anterior and posterior malleolar folds.

The **incus** (Fig. 1014, A, C) is so named from its fancied likeness to an anvil. It has a body, a long process, and a short process; the processes form with each other an angle of 90° to 100°. The body and the short process are situated in the epitympanic recess. On the **body** there is a saddle-shaped surface for articulation with the head of the malleus. That surface is directed forwards, and its lower part is hollowed out for the accommodation of the spur of the malleus, and it ends below and medially in a prominent edge. The long process projects downwards into the tympanic cavity, where it lies parallel with the handle of the malleus, but slightly posterior and medial to it. Its lower end is bent medialwards and narrowed to form a short neck, on the end of which there is a

small knob of bone, called the **lentiform nodule**, for articulation with the head of the stapes. The short process is thick, pyramidal in shape, and projects horizontally backwards; its apex, covered with cartilage, is received into the fossa for the incus.

The **stapes** (Fig. 1014, E) is like a stirrup and has a head, a neck, two limbs, and a base. The **head**, directed laterally, is concave for articulation with the lentiform nodule of the incus. The **neck** is slightly constricted, and from it the two limbs spring; the tendon of the stapedius is inserted into the posterior surface of the neck. The **anterior limb** is shorter and less curved than the **posterior limb**. Diverging from each other, the limbs are directed medialwards and are attached—one near the anterior end of the base, the other near its posterior end. The **base** is oval or kidney-shaped when seen from the medial side, and it fits against the fenestra vestibuli. In the recent condition an *obturator membrane* fills the arch formed by the limbs and the base, the limbs being grooved for its reception.

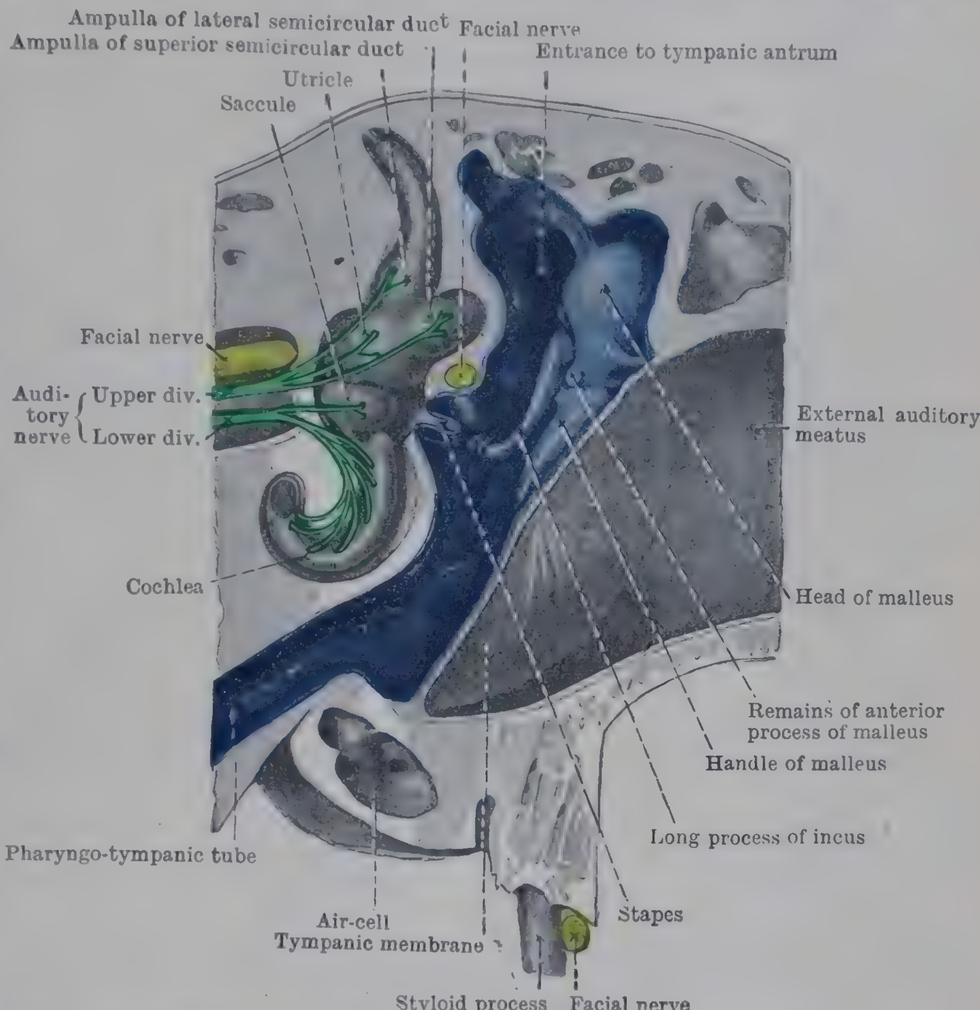

FIG. 1016.—SECTION OF LEFT TYMPANIC CAVITY AND ADJACENT PARTS VIEWED FROM THE FRONT (semi-diagrammatic).

Joints of Auditory Ossicles.—The joint between the head of the malleus and the body of the incus is synovial, and may be described as a saddle-shaped joint. It is surrounded by an articular capsule, from the inner surface of which a wedge-shaped *disc* projects into the joint-cavity and incompletely divides it. The joint between the lentiform nodule and the head of the stapes is of the nature of a ball-and-socket joint, but some observers deny the presence of a synovial cavity and regard the articulation as a syndesmosis.

Ligaments of Auditory Ossicles.—The malleus is attached to the walls of the tympanic cavity by anterior, superior, and lateral ligaments (Fig. 1015). The **anterior ligament** consists of two portions: one passes forwards from the anterior process through the squamo-tympanic fissure, to reach the spine of the sphenoid, from which it is continued to the spheno-mandibular ligament; the other extends from the anterior process to the anterior margin of the tympanic notch. The former of these two parts may contain muscle-fibres and was described by Soemmerring (1806) as the *musculus externus mallei* (Walls, 1946). The **superior ligament** stretches from the head of the malleus to the roof of the epitympanic recess. The **lateral ligament** is short and fan-shaped; its fibres radiate from the oblique crest of the malleus to the posterior edge of the tympanic notch. It is strong, and, with the anterior ligament, it forms the axis around which the

malleus rotates; and the two constitute what Helmholtz (1868) termed the "axis-ligament" of the malleus.

The posterior end of the short process of the incus is tipped with cartilage and fixed by means of a ligament to the floor of the fossa for the incus (Fig. 1015).

The medial surface and the circumference of the base of the stapes are covered with hyaline cartilage; the cartilage encircling the base is joined to the circumference of the fenestra vestibuli by a ring of elastic fibres named the **annular ligament of the base of the stapes.**

Muscles of Auditory Ossicles.—These are the tensor tympani and the stapedius.

The **tensor tympani**, the larger of the two, takes origin from the upper surface of the cartilage of the pharyngo-tympanic tube, from the adjacent part of the greater wing of the sphenoid and from the walls of the bony canal in which the muscle lies. It ends in a tendon which turns laterally round the processus cochleariformis, and passes across the tympanic cavity to be inserted into the medial edge and anterior surface of the handle of the malleus near its upper end. When the muscle contracts, it draws the handle towards the tympanic cavity, and so makes the tympanic membrane more tense. It receives its nerve-supply from the motor root of the trigeminal nerve, through the otic ganglion.

The **stapedius** arises from the walls of a canal that leads downwards from the interior of the pyramid. Its tendon emerges from the apex of the pyramid and is inserted into the posterior surface of the neck of the stapes. On contraction it draws back the head of the stapes, and so tilts the anterior part of the base towards the tympanic cavity. It is supplied by a branch of the facial nerve.

Movements of Auditory Ossicles.—The handle of the malleus follows all the movements of the tympanic membrane; and the malleus and incus move together around an axis that extends forwards through the short process of the incus and the anterior process of the malleus. When the tympanic membrane moves medialwards it carries the handle of the malleus with it; the long process of the incus, moving medialwards at the same time, forces the base of the stapes towards the labyrinth. The movement is communicated to the fluid (perilymph) in the bony labyrinth, and causes a lateral bulging of the secondary tympanic membrane, which closes the fenestra cochleæ. The movements are reversed when the tympanic membrane is relaxed, unless the lateral movement of the membrane is excessive. When that occurs, the incus does not follow the full movement of the malleus, but merely glides on that bone at the incudo-malleolar joint, and thus the forcible dragging of the base of the stapes out of the fenestra vestibuli is prevented. The spur arrangement, already described, on the head of the malleus and body of the incus, causes the incudo-malleolar joint to become locked during the medial movement of the handle of the malleus, the joint becoming unlocked during its lateral movement.

Mucous Membrane of Tympanic Cavity.—The **mucous lining** is continuous, through the pharyngo-tympanic tube, with that of the nasal part of the pharynx; it extends backwards also and lines the tympanic antrum and the mastoid air-cells. Thin and transparent, it follows closely all the irregularities of the walls of the cavity, and is reflected over the ossicles, their ligaments and muscles, and the chorda tympani; there is thus formed a number of folds that enclose pouches in which pus may collect in inflammatory conditions of the middle ear.

Vessels and Nerves of Tympanic Cavity.—The **arteries** are: (1) the anterior tympanic artery, which reaches the cavity by way of the squamo-tympanic fissure; (2) the stylo-mastoid artery, which passes through the stylo-mastoid foramen; (3) a branch from the middle meningeal artery which accompanies the greater superficial petrosal nerve. The **veins** drain into the pterygoid plexus and superior petrosal sinus. The **lymph-vessels** form a network in the mucous membrane and end mainly in the retropharyngeal and parotid lymph-glands. The **nerves** to the muscles have been referred to above. The mucous membrane receives its nerves from the tympanic plexus. The chorda tympani branch of the facial nerve passes from behind, upwards and forwards through the tympanic cavity; its course is described on p. 1032.

Early Condition of Tympanic Cavity.—During the greater part of intra-uterine life the tympanic cavity is almost completely filled with a soft, jelly-like embryonic tissue in which there is a slit-like space lined with epithelium. By the time of birth that tissue has disappeared, and at birth the cavity is filled with fluid which becomes absorbed after the entrance of air from the nasal part of the pharynx through the pharyngo-tympanic tube. All the parts of the middle and internal ear are relatively large and show little if any difference from the adult condition.

INTERNAL EAR

The **internal ear** is lodged within the petrous part of the temporal bone, and is composed of a series of delicate membranous chambers and passages—the *membranous labyrinth*—enclosed within corresponding cavities which are hollowed out of the bone and constitute the *bony labyrinth*. The component parts of the membranous labyrinth are, from before backwards, the **duct of the cochlea** (which contains the essential organ of hearing), the **saccule** and the **utricle**, and the three **semicircular ducts**; the corresponding parts of the bony labyrinth are the **cochlea**, the **vestibule**, and the three **semicircular canals**. The utricle and the saccule are both contained in the vestibule; and all the parts of the bony labyrinth are considerably larger than the corresponding parts of the membranous labyrinth.

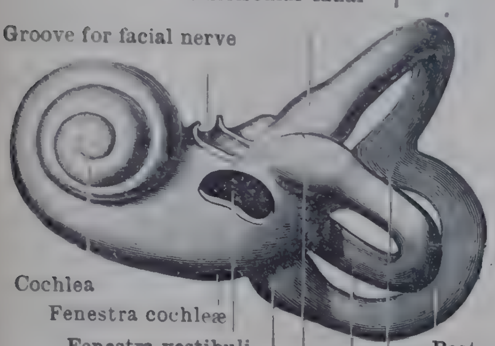

FIG. 1017.—LEFT BONY LABYRINTH (seen from lateral side).

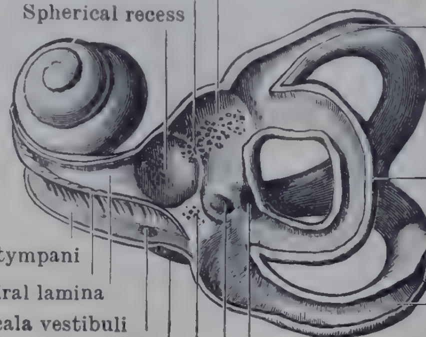

FIG. 1018.—INTERIOR OF LEFT BONY LABYRINTH (seen from below and lateral side).

For the comparative anatomy of the membranous labyrinth, with stereoscopic illustrations, consult Gray (1907-8).

BONY LABYRINTH

Vestibule.—The vestibule is the middle portion of the bony labyrinth, and communicates behind with the semicircular canals and in front with the cochlea. It is an oval cavity with its long axis directed forwards and medially, and it measures about 6 mm. antero-posteriorly, 4 or 5 mm. vertically, and about 3 mm. transversely. Its lateral wall is directed towards the tympanic cavity, and in it is the fenestra vestibuli, which is closed by the base of the stapes. Its medial wall corresponds with the bottom of the internal auditory meatus, and presents, at its antero-inferior part, a circular depression called the **spherical recess**, which lodges the saccule. In the recess there are twelve or fifteen very small foramina (**macula cribrosa media**) which transmit the filaments of the auditory nerve to the saccule. The spherical recess is limited above and behind by an oblique ridge, called the **vestibular crest**, the anterior end of which is triangular in shape and named the **pyramid of the vestibule**. Posteriorly the crest divides into two limbs that enclose a small depression called the **cochlear recess**, in which there are several minute foramina for the passage of the nerves to the vestibular end of the duct of the cochlea. Above and behind the vestibular crest, in the roof and medial wall of the vestibule, there is an oval depression, called the **elliptical recess**, which lodges the utricle. The pyramid of the vestibule and adjacent part of the elliptical recess show twenty-five or thirty very small foramina (**macula cribrosa superior**) for the passage of the nerves to the utricle and to the ampullæ of the superior and lateral semicircular ducts. Behind and below the elliptical recess there is a furrow that gradually deepens to form a canal, called the **aqueduct of the vestibule**, which

passes backwards through the petrous part of the temporal bone and opens into the posterior cranial fossa as a slit-like fissure about midway between the internal auditory meatus and the groove for the sigmoid sinus. This aqueduct is from 8 to 10 mm. long, and gives passage to the endolymphatic duct and a small vein. At the posterior part of the vestibule there are five circular openings which lead into the semicircular canals; at its anterior part there is an elliptical opening that leads from the spherical recess into the scala vestibuli of the cochlea. This opening is bounded below by a thin bony plate, called the **osseous spiral lamina**, which springs from the floor of the vestibule immediately lateral to the spherical recess and forms, in the cochlea, the bony part of the septum between the scala tympani and the scala vestibuli.

Semicircular Canals.—The three semicircular canals are situated above and behind the vestibule (Figs. 1017, 1018). They are distinguished from one another by their positions, and are named superior, posterior, and lateral. Each forms about two-thirds of a circle, one end of which is dilated and termed the **ampulla.** They are slightly compressed from side to side, and their diameter is from 1 to 1·5 mm., whilst that of the ampullæ is about 2 mm. They open into the vestibule by five apertures only, since the medial end of the superior canal joins the upper end of the posterior canal to form a common canal termed the *crus commune.*

The **superior semicircular canal**, 15 to 20 mm. long, is vertical and placed across the long axis of the petrous part of the temporal bone. Its convexity is directed upwards, and its position is indicated by the arcuate eminence. Its ampullated end is the antero-lateral end, and it opens into the vestibule immediately above the ampullated end of the lateral canal. Its opposite end joins the non-ampullated end of the posterior canal to form the **crus commune**, which is about 4 mm. long, and which opens into the upper and medial part of the vestibule. The **posterior semicircular canal**, from 18 to 22 mm. long, also is vertical. Its ampulla is placed inferiorly and opens into the lower and posterior part of the vestibule, where there are six or eight small apertures (**macula cribrosa inferior**) for the transmission of the nerves to this ampulla. Its upper end joins the crus commune. The **lateral canal**, from 12 to 15 mm. long, arches nearly horizontally. Its lateral end is ampullated and opens into the vestibule immediately above the fenestra vestibuli, close to the ampullated end of the superior canal, and causes an elevation on the medial wall of the aditus to the tympanic antrum above the canal for the facial nerve (Fig. 1016). The lateral canal of one ear is very nearly in the same plane as that of the other; the superior canal of one ear is nearly parallel to the posterior canal of the other (Crum Brown, 1874).

Cochlea.—When freed from its surroundings the **cochlea** has the form of a short cone (Fig. 1019). The central part of its **base** corresponds with the bottom of the internal auditory meatus; and its apex or **cupola**, directed laterally, is in close relation with the canal for the tensor tympani muscle, and thus the whole structure lies across the long axis of the petrous temporal bone. (In the following description the cochlea is supposed to be placed on its base.) It measures about 9 mm. across the base and about 5 mm. from base to apex, and consists of a spirally arranged tube which forms from $2\frac{1}{2}$ to $2\frac{3}{4}$ coils around a central pillar termed the **modiolus.** The length of the tube is 32 mm., and its diameter, near the base of the cochlea, is 2 mm. Its coils are distinguished by the terms basal, middle, and apical; the basal coil bulges into the tympanic cavity, giving rise to the promontory on its medial wall.

The modiolus is about 3 mm. long, and its diameter diminishes rapidly from the base to the apex; it ends about 1 mm. from the cupola. Its **base** corresponds with the **cochlear area** on the fundus of the internal auditory meatus, and exhibits (Fig. 1020): (1) the **tractus spiralis foraminosus**, which transmits the nerves to the basal and middle coils of the cochlea; and (2) a **central foramen**, which gives passage to the nerves to the apical coil. From the free edge of the osseous spiral lamina numerous small canals, for the transmission of vessels and nerves, pass to its attached edge, where they unite to form the **spiral canal** of the cochlea, which lodges the **spiral ganglion**. From the spiral canal other small canals pass down the modiolus and open by the holes along the tractus spiralis foraminosus.

The **osseous spiral lamina** is a thin, flat shelf of bone which winds round the modiolus like the thread of a screw, and, projecting about half-way into the cochlear tube, incompletely divides it into two passages—an upper, the **scala vestibuli**, and a lower, the **scala tympani**. It begins at the floor of the vestibule, near the fenestra cochleæ, and ends near the cupola of the cochlea in a sickle-shaped process, called

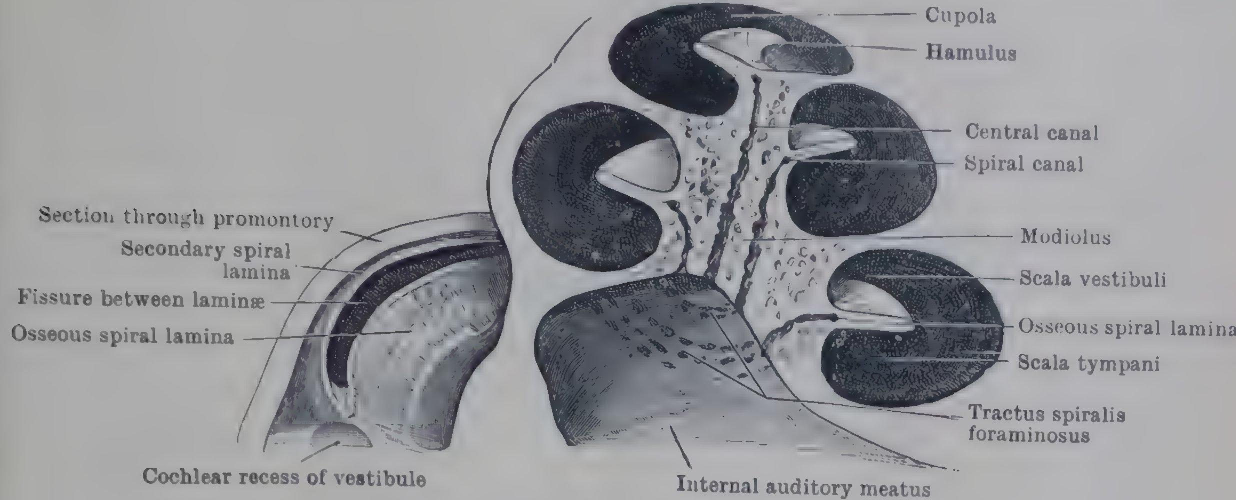

FIG. 1019.—SECTION OF BONY COCHLEA.

the **hamulus of the spiral lamina**, which helps to bound an aperture named the **helicotrema**, through which the scala tympani and scala vestibuli communicate with each other. In the basal coil the upper surface of the lamina forms almost a right angle with the modiolus, but the angle becomes more and more acute on ascending the tube. In the lower half of the basal coil a second smaller bony plate, called the **secondary spiral lamina**, projects from the outer wall of the cochlea towards the osseous spiral lamina, without, however, reaching it, so that a slit-like fissure is seen between the two laminæ, which are continuous with each other round the posterior end of the fissure. A membrane, called the **basilar lamina**, stretches from the free edge of the osseous spiral lamina to the outer wall of the cochlea, and completes the division of the cochlear tube into scala vestibuli and scala tympani; the two, however, communicate with each other through the helicotrema at the cupola of the cochlea. The **scala tympani** begins at the fenestra cochleæ, which is closed by the secondary tympanic membrane. Close to the beginning of the scala tympani and on its medial wall there is seen the inner orifice of the **aqueduct of the cochlea**; this is a canal, 10 to 12 mm. in length, which opens on the under surface of the petrous part of the temporal bone in the upper border of the jugular fossa. This aqueduct establishes a communication between the scala tympani and the subarachnoid space. The **scala vestibuli**, the upper of the two passages, begins in the vestibule; in the basal coil its diameter is less than that of the scala tympani, but in the upper coils it is greater.

FIG. 1020.—FUNDUS OF LEFT INTERNAL AUDITORY MEATUS DIVIDED INTO UPPER AND LOWER AREAS BY TRANSVERSE CREST.

The **fundus** of the **internal auditory meatus** has been referred to as corresponding to the medial wall of the vestibule and the base of the modiolus. It is divided by a transverse crest into an upper and a lower area. In the anterior part of the upper area there is a single large opening for the transmission of the facial nerve; the posterior part is named the **superior vestibular area**, and is perforated by the nerves of the utricle and of the ampullæ of the superior and lateral semicircular ducts. The anterior part of the lower area is the **cochlear area**,

already referred to, and the posterior part is named the **inferior vestibular area** and is pierced by the nerves of the saccule; behind that area is the **foramen singulare**, which gives passage to the nerves of the ampulla of the posterior semicircular duct.

MEMBRANOUS LABYRINTH

The membranous labyrinth (Figs. 1021, 1027) repeats fairly accurately the form of the bony labyrinth, except that there are two membranous sacs in the vestibule, and only one membranous canal in the cochlea. The two sacs in the vestibule are the **utricle** behind and the **saccule** in front. The membranous labyrinth is a closed system and contains a fluid called **endolymph**; the membranous labyrinth does not completely fill the bony labyrinth, and the resulting space is occupied by a fluid termed **perilymph**. Neither of these fluids has any connexion with the fluid of the lymphatic system. The perilymphatic space is closed except for the communication with the subarachnoid space through the aqueduct of the cochlea.

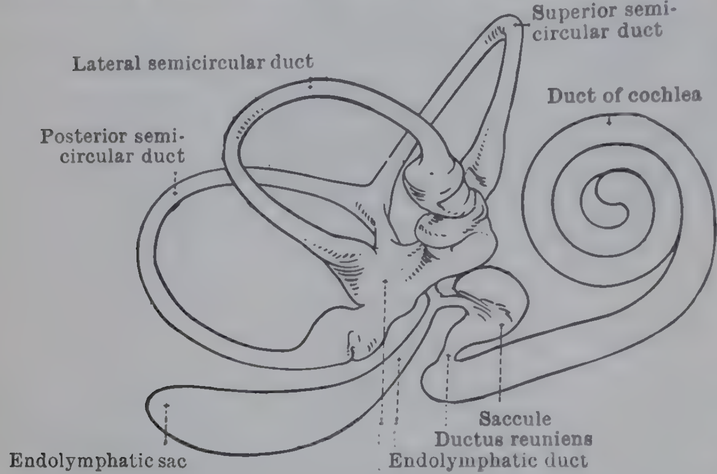

Fig. 1021.—Diagrammatic Representation of Model of Right Membranous Labyrinth. (From a model by J. K. Milne Dickie.)

The **utricle** is an elongated sac and occupies the posterosuperior portion of the vestibule. Its highest part lies in the elliptical recess, and the ampullæ of the superior and lateral semicircular ducts open into this part. The non-ampullated end of the lateral semicircular duct and the crus commune of the superior and posterior semicircular ducts open into its central part. The ampulla of the posterior semicircular duct opens into its lower and medial part. The floor and anterior wall of the highest part are thickened to form the **macula of the utricle**, to which the utricular fibres of the auditory nerve

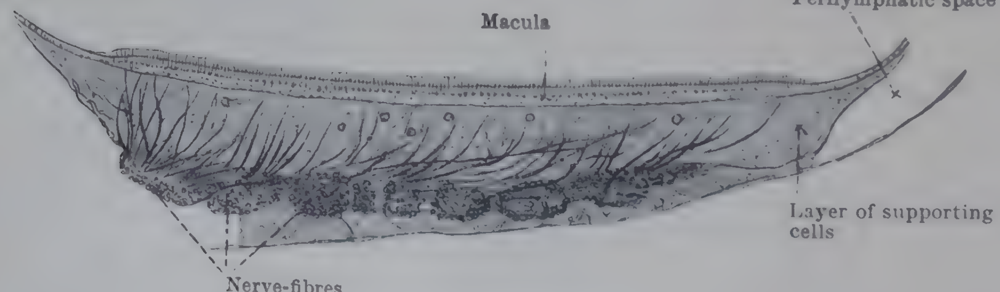

Fig. 1022.—Vertical Section of Wall of Highest Part of Utricle with the Macula and Bundles of Nerve-Fibres.

are transmitted through the foramina in the pyramid of the vestibule. The macula is pale in colour and of an oval or nearly rhombic shape; it measures 3 mm. in length and 2·3 mm. in its greatest breadth.

The **saccule** is smaller than the utricle, and occupies the spherical recess in the lower and anterior part of the vestibule. It is of an oval shape and measures 3 mm. in its longest diameter, and about 2 mm. in its shortest. It presents anteriorly a pale, oval thickening, called the **macula of the saccule**, which has a breadth of about 1·5 mm., and to which the saccular fibres of the auditory nerve are distributed. The upper end of the saccule is directed upwards and backwards and comes into contact with the utricle, and there the utricle and saccule are separated by a common wall (Dickie, 1920). From the lower

part of the saccule a short canal—the **ductus reuniens**—descends and gradually widens into the vestibular end of the duct of the cochlea. A second small channel, named the **endolymphatic duct**, is continued from the posterior part of the saccule, and is joined by a small canal, called the **utriculo-saccular duct**, which arises from the medial side of the utricle. The endolymphatic duct then enters and traverses the aqueduct of the vestibule and ends, under the dura mater on the posterior surface of the petrous part of the temporal bone, in a dilated blind pouch termed the **endolymphatic sac.**

Structure.—The walls of the utricle and saccule are composed of (*a*) an external layer of fibrous tissue which blends with the endosteal lining of the vestibule, (*b*) a middle, transparent layer and (*c*) an internal layer of epithelium. The walls are thickened at the maculæ; on them the epithelium is columnar, towards their periphery it is cubical, and elsewhere it is of the pavement type.

In the maculæ of the utricle and saccule two kinds of cells are found—(*a*) supporting cells, and (*b*) hair-cells. The **supporting cells** are fusiform, with the nucleus near the middle. Their deep ends are branched; their free ends lie between the hair-cells and form a thin, inner, limiting layer. The **hair-cells** are flask-shaped, their rounded ends lying between the supporting cells. Each hair-cell contains a large nucleus in its deepest part, the rest of the cell being granular and pigmented. From the free end of each there projects a stiff, hair-like process which, on the application of reagents, splits into several filaments. The nerve-fibres ramify around the deep ends of the hair-cells (Fig. 1022). A collection of small crystals of carbonate of lime, termed *otoliths*, adheres to each of the maculæ.

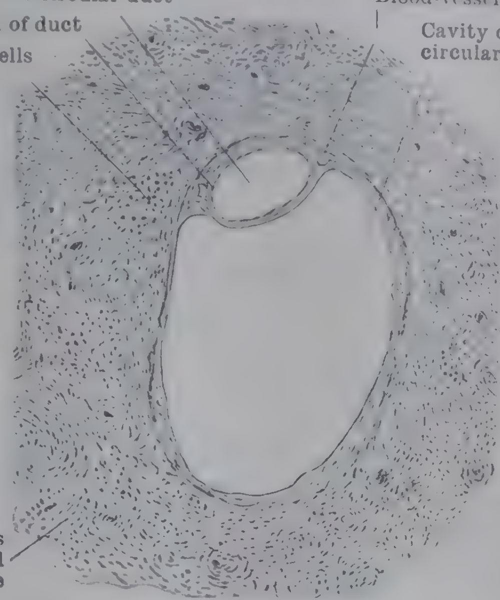

FIG. 1023.—SECTION OF A SEMICIRCULAR CANAL AND DUCT.

The **semicircular ducts** are elliptical on transverse section (Fig. 1023), and are very much smaller than the bony canals which contain them. Each duct is fixed by one of its walls to the endosteal lining of the canal, whilst the opposite wall bulges into the lumen of the canal. Like the bony canals, each of the semicircular ducts is dilated at one end into an ampulla, and the ampulla nearly fills the corresponding portion of the bony canal.

Structure.—Each semicircular duct has the same structure as the utricle and the saccule. In each ampulla the middle, transparent layer is thickened and projects into the cavity as a transverse elevation which, when seen from above, is fiddle-shaped; the most prominent part of the elevation is named the *ampullary crest*. The cells which cover the crest consist of **supporting cells** and **hair-cells**, and are similar in their arrangement to those in the maculæ of the utricle and saccule; the hairs of the hair-cells are, however, considerably longer, and project as far as the middle of the ampullary lumen.

The **duct of the cochlea** is a spirally arranged canal inside the bony cochlea. Its lower end occupies the cochlear recess of the vestibule and communicates with the saccule through the ductus reuniens; its upper end is closed and is named the **cæcum cupulare**; it is fixed to the cupola of the cochlea and partly bounds the helicotrema. As already stated (p. 1195), the basilar lamina stretches from the free edge of the osseous spiral lamina to the outer wall of the cochlea. A second more delicate membrane, called the **vestibular membrane**, stretches from the thickened endosteum of the upper surface of the osseous spiral lamina to the outer wall of the cochlea, some distance above the external attachment of the basilar lamina. A tunnel, triangular in transverse section, is thus enclosed between the basilar lamina below, the vestibular membrane above, and the wall of the scala vestibuli on the lateral side; this is the *duct of the cochlea*.

The **roof** of the duct is the vestibular membrane, which is an extremely delicate,

nearly homogeneous membrane, covered on both surfaces with a layer of epithelium. Its entire thickness is about 3 μ.

The **outer wall** is the endosteal lining of the bony cochlea, which is thickened and greatly modified to form the *spiral ligament of the cochlea*. This ligament

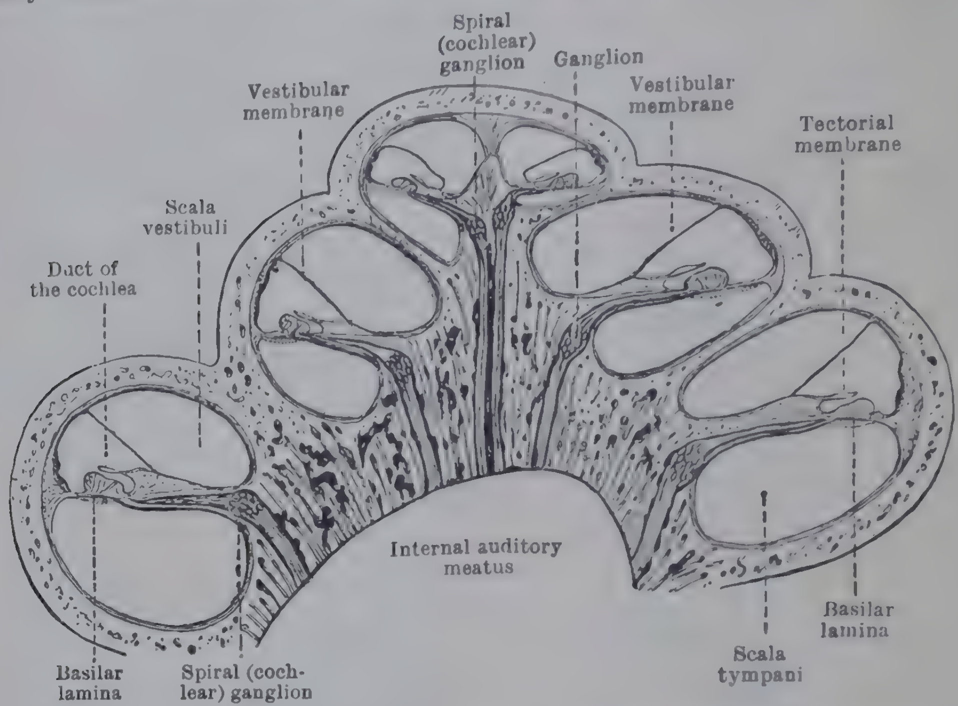

FIG. 1024.—AXIAL SECTION OF HUMAN COCHLEA. (Schafer's *Essentials of Histology.*)

projects inwards inferiorly as a triangular crest to which the outer edge of the basilar lamina is attached. The upper part of the spiral ligament contains, immediately under its epithelial lining, numerous small blood-vessels and capillary

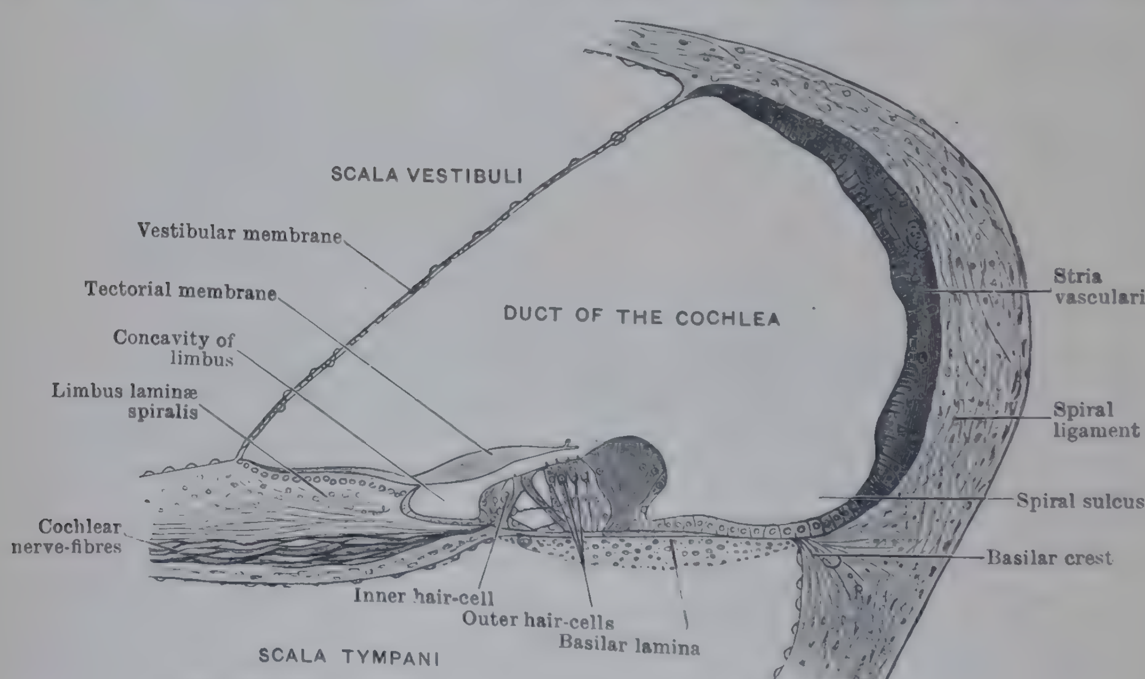

FIG. 1025.—SECTION ACROSS DUCT OF COCHLEA. (Retzius, 1881.)

loops, forming the **stria vascularis**. The lower limit of this stria is bounded by a prominence called the *spiral prominence*, in which a larger vessel—the **vas prominens** —is sometimes seen and below this prominence is a concavity, called the *spiral sulcus*. The height of the outer wall of the duct diminishes towards the apex of the cochlea.

The **floor** of the duct is formed by the lateral part of the osseous spiral lamina and by the basilar lamina. On the inner part of the basilar lamina the complicated

structure termed the *spiral organ* is situated. The osseous spiral lamina consists of two plates of bone between which the canals for the branches of the cochlear nerve are placed. On the upper plate the endosteum is thickened and modified to form the **limbus laminæ spiralis**, the outer border of which is concave, and appears, in radial sections, as a C-shaped indentation. The portions of the limbus which project above and below this concavity are termed respectively the *vestibular lip* and the *tympanic lip*. The tympanic lip is perforated by the branches of the cochlear nerves, and is continuous with the basilar lamina. The upper surface of the limbus and of its vestibular lip is divided into a series of blocks or segments by furrows that intersect each other at right angles; this gives to the free edge of the vestibular lip a dentated appearance, and here the segments are named the *auditory teeth.* The limbus is covered with a layer of apparently squamous epithelium; the deeper protoplasmic portions of the cells, however, with their contained nuclei, lie in the intervals between the blocks or segments just mentioned.

The **basilar lamina** stretches from the tympanic lip of the limbus to the crest of the spiral ligament. Its inner part is thin, and supports the spiral organ. Its

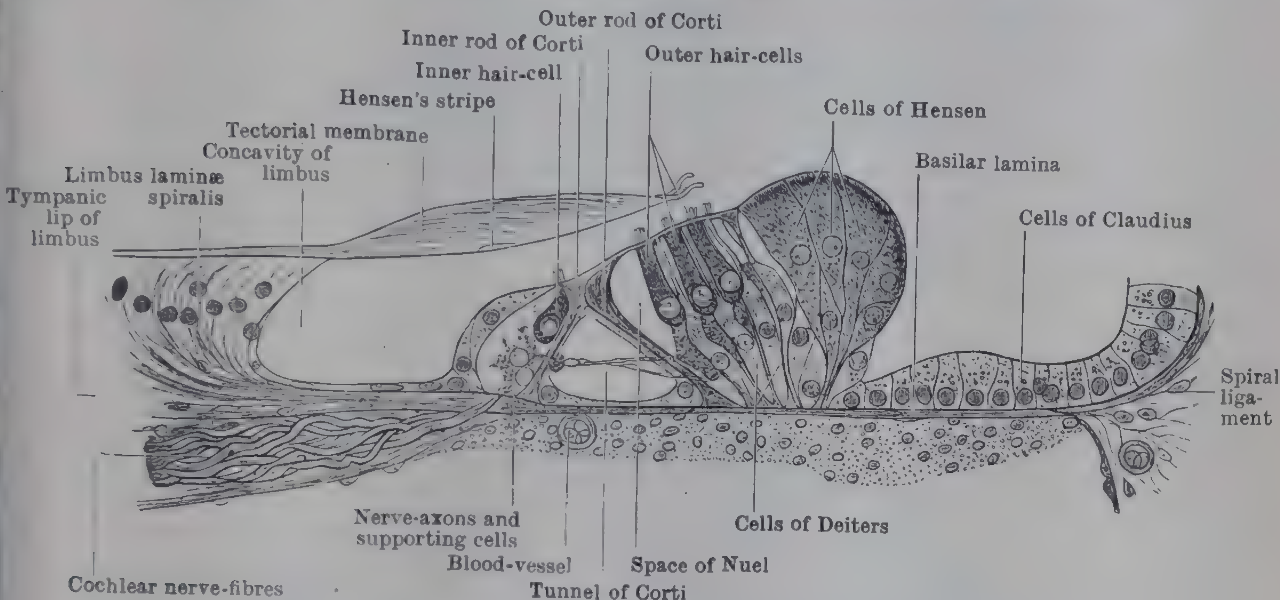

FIG. 1026.—TRANSVERSE SECTION OF SPIRAL ORGAN FROM CENTRAL COIL OF DUCT OF COCHLEA. (Retzius, 1881.)

outer part is thicker and striated. The under surface of the basilar lamina is covered with a layer of fibrous tissue which contains, in its inner part, small blood-vessels; one of them which lies below the more medial part of the spiral organ is considerably larger than any of the others. The width of the basilar lamina increases from 0·21 mm. in the basal coil to 0·36 mm. in the apical coil; its total length is 32 mm. (Hardy, 1938; Keen, 1940).

Spiral Organ.—This is an epithelial eminence of complicated structure, placed on the inner part of the basilar lamina. It extends throughout the entire length of the duct of the cochlea, and comprises the following structures: (1) Corti's rods or pillars, (2) hair-cells (inner and outer), (3) supporting cells of Deiters, (4) the cells of Hensen and Claudius, (5) the reticular lamina, and (6) the tectorial membrane (Fig. 1007).

The **rods of Corti** form two rows, **inner** and **outer**, of stiff, pillar-like structures, and each rod presents a base or foot-plate, an intermediate elongated portion, and an upper end or head. The bases of the rods are planted on the basilar lamina—those of the inner row at some little distance from those of the outer. The intermediate portions of the rods incline towards each other and the heads come into contact, so that the two rows and the basilar lamina enclose a triangular passage, called the **tunnel of Corti**; this tunnel increases both in height and width on passing towards the apex of the cochlea. The **inner rods** number nearly 6000, and the head of each resembles the upper end of the ulna—presenting externally a deep concavity for the reception of a corresponding convexity on the head of the outer rod. The part of the head which overhangs that concavity is prolonged outwards, under the name of the **head-plate**, and overlaps the head of the outer rod. The expanded bases of the inner rods are placed immediately on the outer side

of the foramina for the cochlear nerves in the tympanic lip of the limbus; the intermediate parts of these rods are sinuously curved, and form, with the basilar lamina, an angle of about 60°. The **outer rods** number about 4000, and are longer than the inner, especially in the upper turns of the cochlea. They are more inclined towards the basilar lamina, and form with it an angle of about 40°. The head of each is convex inwards, to fit the concavity on the head of the inner rod, and is prolonged outwards as a plate called the **phalangeal process**. The main part of each rod consists of a nearly homogeneous material which is finely striated. At the base of each rod, on the surface next Corti's tunnel, there is a nucleated mass of protoplasm which reaches as far as the head of the rod, and covers also a part of the floor of the tunnel; this protoplasm may be regarded as the undifferentiated part of the cell from which the rod was developed. Slit-like intervals, for the transmission of nerves, exist between the intermediate portions of adjacent rods.

Hair-Cells.—These, like Corti's rods, are arranged in two sets—**inner** and **outer**. The inner set is a single row lying immediately internal to the inner rods; the outer set is arranged in three or four rows placed to the outer side of the outer rods. The **inner hair-cells** are about 3500 in number; the diameter of each is greater than that of an inner rod, and so each inner hair-cell is supported by more than one rod. The free end of each hair-cell is surmounted by about twenty fine hair-like processes, arranged in the form of a crescent with its concavity directed inwards. The deep end of the cell contains a large nucleus and is rounded; it reaches only about half-way down the rod, and is in contact with the terminal arborizations of the nerves. To the inner side of this row of hair-cells there are two or three rows of elongated columnar cells which act as supporting cells, and are continuous with the low columnar cells that line the concavity of the limbus. The **outer hair-cells** number about 12,000, and are arranged in three rows in the basal coil and four rows in the upper two coils, although in the higher coils the rows are not so regularly arranged. The free, rounded end of each hair-cell supports about twenty hairlets arranged in the form of a crescent opening inwards; the deep end reaches about half-way to the basilar lamina and is in contact with the arborization of the nerves.

Deiters' supporting cells alternate with the rows of the outer hair-cells; their lower ends are expanded on the basilar lamina, and their upper ends are tapered. The nucleus is placed near the middle of each cell, and, in addition, each cell contains a bright, thread-like structure called the **supporting fibre**. That fibre is attached by a club-shaped base to the basilar lamina, and expands, at the free end of the cell, to form one of the phalanges of the reticular lamina, which is described below.

The **cells of Hensen**, or outer supporting cells, are arranged in about half a dozen rows immediately outside Deiters' cells, and are the most elevated part of the spiral organ. Their lower ends are narrow and attached to the basilar lamina, whilst their free ends are expanded. The columnar cells situated to the outer side of the cells of Hensen, and covering the outer part of the basilar lamina, are named the **cells of Claudius**. An interval exists between the outer rods of Corti and the neighbouring row of hair-cells and is termed the **space of Nuel**; it communicates with Corti's tunnel, and extends outwards between the outer hair-cells as far as Hensen's cells.

The **reticular lamina** is a thin sheet that extends from the heads of the outer rods to Hensen's cells, and is formed from expansions of these two structures. These expansions are termed the **phalanges** of the lamina, and are arranged in rows corresponding with the heads of the outer rods, the cells of Hensen, and the cells of Deiters, which also contribute to its formation. The free ends of the hair-cells occupy the intervals between the phalanges.

The **tectorial membrane** is a projecting shelf, composed of multitudes of delicate fibres in a matrix of jelly-like consistence, which overhangs the inner half of the spiral organ. Attached by its inner border to the limbus near the vestibular membrane, it reaches outwards as far as the outer row of hair-cells. Its inner portion is thin and overlies the auditory teeth of the limbus. Its outer part is thickened but becomes attenuated near its free border, which is fringed. The under surface rests on the inner and outer rows of hair-cells like a pad, and it shows, about half-way along its width, a clear spirally arranged band named **Hensen's stripe**.

Auditory Nerve (Fig. 1027).—This nerve divides in the internal auditory meatus into a cochlear nerve and a vestibular nerve.

The **cochlear nerve** is the nerve of hearing. Its fibres originate from the cells of the **spiral ganglion**. This ganglion is situated in the spiral canal of the modiolus; and from the ganglion the centrally directed fibres traverse the

modiolus—those from the apical coil emerging at the internal auditory meatus through the central foramen and those from the basal coils through the holes in the tractus spiralis foraminosus. The peripherally directed fibres extend outwards, at first in bundles, and then in a more or less continuous sheet; from the outer edge of the sheet they are again collected into bundles which pass through the foramina of the tympanic lip of the limbus laminæ spiralis. Beyond this point they appear as naked axis-cylinders, and turn in a spiral manner towards the inner row of hair-cells. Other fibrils run between individual inner rods and through Corti's tunnel, from which they enter Nuel's space, and pass towards the bases of the outer hair-cells. The hair-cells in the basal and middle coils of the cochlea are more richly supplied with nerves than those in the apical coil. The cochlear nerve also gives

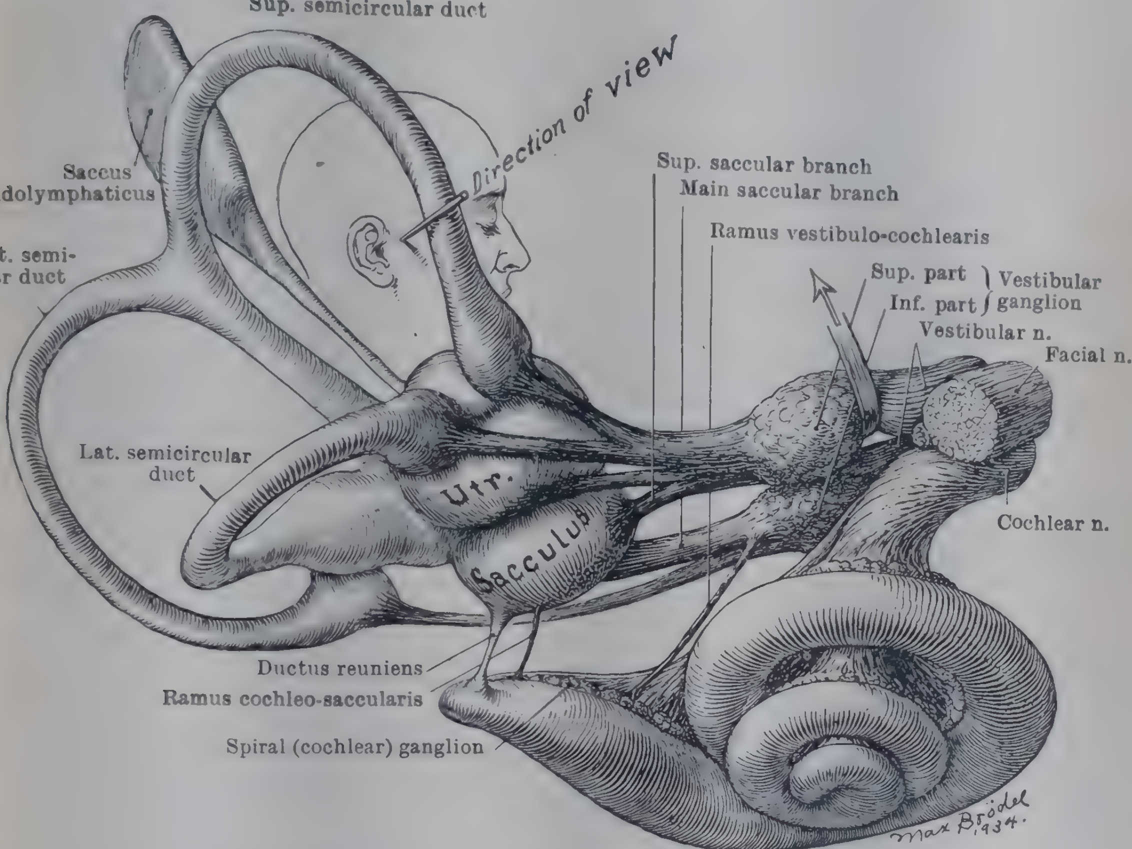

FIG. 1027.—DISTRIBUTION OF AUDITORY NERVE TO THE MEMBRANOUS LABYRINTH. (M. Hardy, *Anatomical Record*, 1934.)

off a branch whose terminal filaments go through the foramina in the cochlear recess to be distributed to the hair-cells of the vestibular end of the cochlear duct.

The **vestibular nerve** is the nerve of equilibration and is distributed to the utricle, the saccule, and the ampullæ of the semicircular ducts; its fibres are derived from cells in the **vestibular ganglion**, which is usually placed in the internal auditory meatus. From the ganglion, which may be split into two or even three parts, two main branches arise—a superior and an inferior. The filaments from the superior branch go through the foramina in the superior vestibular area of the internal auditory meatus and supply the macula of the utricle, the ampullary crests of the superior and lateral semicircular ducts, and the anterior end of the macula of the saccule; those from the inferior branch run through the foramina in the inferior vestibular area to supply the greater part of the macula of the saccule and, through the foramen singulare, to the ampulla of the posterior semicircular duct, which receives some six to eight filaments. In addition, there arises from the inferior division of the vestibular nerve a branch, the ramus vestibulo-cochlearis, which passes to the spiral ganglion of the cochlea at the beginning of its basal coil. Another branch has been described (Hardy, 1934) which passes from the beginning of the cochlear ganglion to the surface of the saccule running a course parallel to the ductus reuniens (Fig. 1027).

Vessels of Internal Ear.—The **arteries** are the internal auditory branch of the basilar artery and the stylo-mastoid branch of the posterior auricular artery. The internal auditory artery enters the internal meatus and divides into vestibular and cochlear branches which are distributed to the structures supplied by the corresponding nerves. The **veins** from the cochlea and vestibule unite, at the bottom of the internal meatus, with the veins from the semicircular canals to form the **internal auditory vein**, which may open either into the posterior part of the inferior petrosal sinus or into the sigmoid sinus. A small vein passes through the aqueduct of the cochlea and opens into the inferior petrosal sinus or into the internal jugular vein. Another small vein traverses the aqueduct of the vestibule and ends in the superior petrosal sinus.

Development of Ear

External Ear.—The development of the external ear is associated with the first and second (mandibular and hyoid) pharyngeal arches and the intervening (first) external pharyngeal groove.

In a 12 mm. embryo the dorsal end of each of these two arches is divided into three tubercles or "*hillocks*"; these are seen more clearly in some specimens than in others and they are always

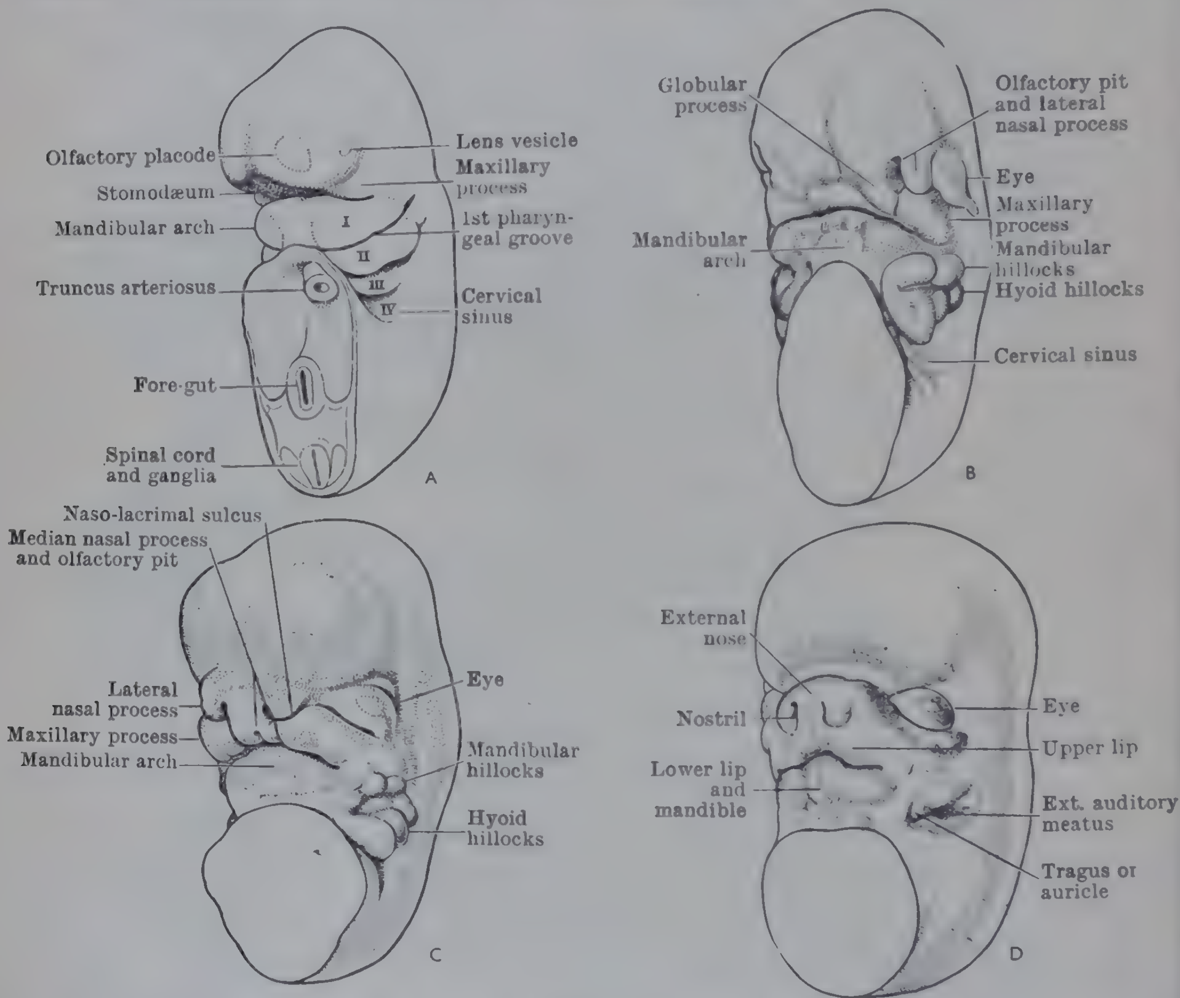

Fig. 1028.—Ventro-Lateral view of Head in series of Human Embryos showing Development of Face and External Ear. (After G. L. Streeter, 1922.) Note the lateral and dorsal migration of the auricle coincident with the formation of the lower lip and mandible.

A, 6 mm. embryo × 11; B, 12 mm. × 7·5; C, 14 mm. × 7·5; D, 18 mm. × 6.
I, II, III, IV, pharyngeal arches.

developed better on the hyoid arch than on the mandibular (Fig. 1028, B, C). In an 18 mm. embryo, the hillocks have disappeared as separate entities and are replaced by a general swelling of the dorsal end of each arch (Streeter, 1922). During the course of development, the mandibular arch grows in a ventral direction to meet the arch of the opposite side and form the basis of the lower jaw; and thus its auricular swelling is carried ventrally and only the most dorsal part remains in relationship to the future auricle, of which it forms the tragus. The auricular swelling of the hyoid arch undergoes greater development, and it grows round the dorsal end of the first external pharyngeal groove and on to its anterior border. It ultimately gives rise to the whole **auricle except the tragus** (Wood Jones & I-Chuan, 1934). It is clear from the descriptions given by Streeter and Wood Jones: (1) that the early development of hillocks on the margins of the first pharyngeal groove is merely an expression of exuberant local growth of mesoderm;

(2) that the hillocks do not give rise directly to the several parts of the auricle, as originally described by His; and (3) that the hyoid arch takes a much greater share than the mandibular in the formation of the auricle.

It will be understood that the first external pharyngeal groove therefore forms the greater part of the **external auditory meatus**, which is lined with the original ectoderm of the groove; but the external meatus has an additional origin.

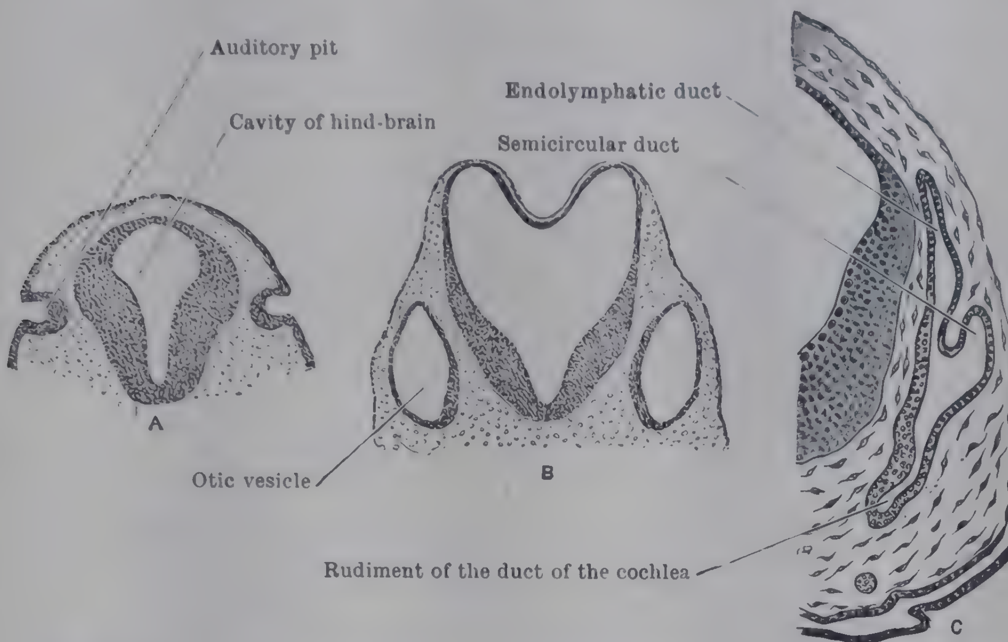

FIG. 1029.—SECTIONS THROUGH HIND-BRAIN OF FŒTAL RABBITS TO ILLUSTRATE DEVELOPMENT OF MEMBRANOUS LABYRINTH.

About the end of the second month of intra-uterine life, the ectoderm at the bottom of the groove grows in towards the future tympanic cavity as a solid mass of cells—the *meatal plate.* This ingrowth of ectoderm does not, however, come into contact with the entoderm of the tympanic cavity but is separated from it by mesoderm in which there occurs a condensation to form **the handle of the malleus**, which thus comes to be covered with entoderm on its inner surface and ectoderm on its outer. In the later months of fœtal life the deeper part of the external auditory meatus is formed by a breaking down of the central cells of the meatal plate—the cells at the bottom of the ingrowth forming the cuticular layer of the tympanic membrane, the mesoderm in which the condensation for the malleus occurs forming the fibrous layer of the membrane, and the entoderm of the tympanic cavity forming its mucous layer.

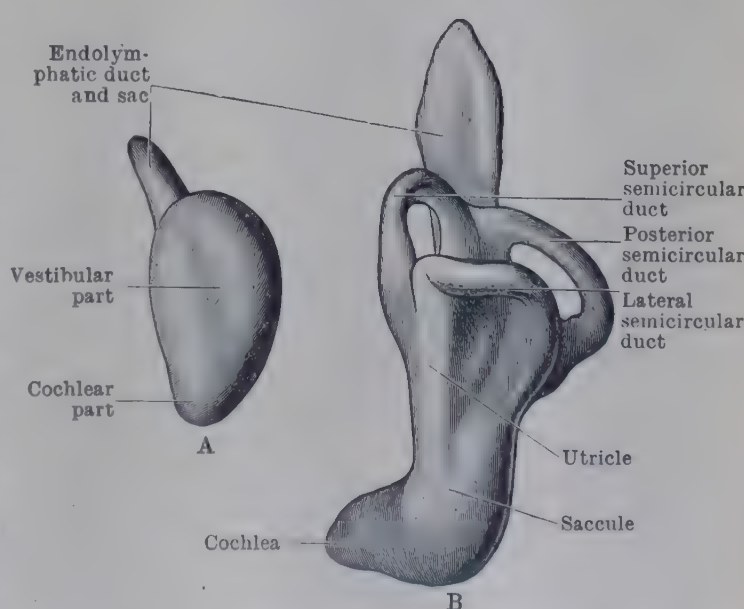

FIG. 1030.—THE LEFT MEMBRANOUS LABYRINTH SEEN FROM THE LATERAL SIDE, A, AT ABOUT THE FOURTH WEEK, AND B, AT ABOUT THE FIFTH WEEK. (W. His, Jr.)

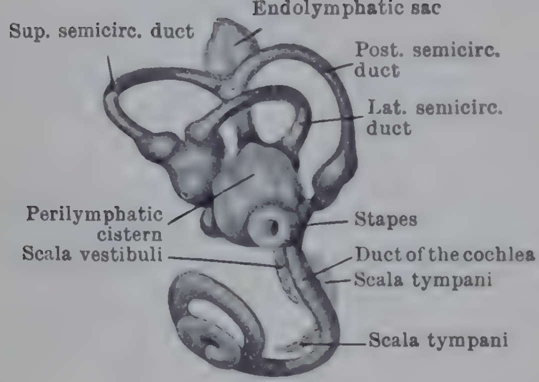
Middle Ear and Pharyngo-Tympanic Tube.—These are developed from the *tubo-tympanic recess* (Frazer, 1914), which is an upward and lateral outgrowth from the widest part of the pharynx involving the first and second internal pharyngeal pouches and the mandibular and hyoid arches. Its distal end is expanded and becomes partly constricted off to form the **tympanic cavity**; but it retains its connexion with the pharynx through a narrow channel which becomes the **pharyngo-tympanic tube**.

The tubo-tympanic recess grows in an oblique direction so that both its roof and floor are set obliquely; its roof becomes the medial wall of the tympanic cavity and its floor becomes the lateral wall. The floor is separated from the meatal plate by the mesoderm in which the malleus develops, and it comes to form the mucous lining of the tympanic membrane, the oblique position of this structure being due to the original oblique position of the floor of the recess. In relation to the roof of the recess there is the *otic vesicle*, from which the membranous labyrinth is developed, and which thus lies on the medial side of the tympanic cavity in the adult.

Just as the first external pharyngeal groove is not the only source of formation of the external auditory meatus, so the tubo-tympanic recess is not the sole origin of the tympanic cavity. The handle of the malleus has been described as being formed from a mesodermal condensation between the meatal plate and the tubo-tympanic recess; the remainder of the **malleus**, the **incus**, and the **stapes** are likewise formed from a condensation of mesoderm at the dorsal end of the mandibular and hyoid arches, the perforated condition of the stapes being due to the fact that the condensation occurs around the artery of the second pharyngeal arch—the *stapedial artery*—which later atrophies but leaves its original track as the foramen in the stapes. Ossification of all three bones begins in the third month of intra-uterine life. The malleus is ossified from two centres, one for the head and handle and one for the anterior process; the incus from one centre appearing in the upper part of the long process; and the stapes from one centre in the base of the bone.

The muscles of the ossicles—**tensor tympani** and **stapedius**—are similarly developed in association with the dorsal ends of the mandibular and hyoid arches and thus come to receive a supply from the nerves of these arches—the fifth and seventh cranial nerves. For many years it has been considered that the malleus and incus are derived from the end of Meckel's cartilage (the cartilage of the first arch), and that the stapes is derived from Reichert's cartilage (the cartilage of the second arch); the arrangement of the muscles of the ossicles and their nerve-supply was



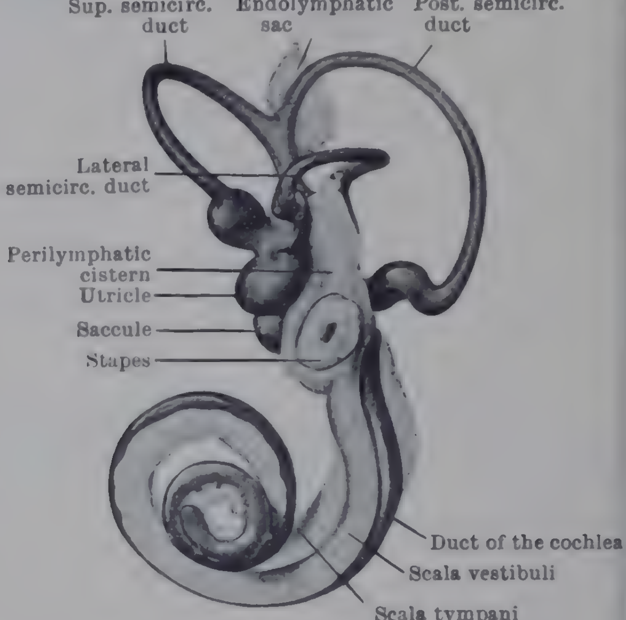


FIG. 1031.—MEMBRANOUS LABYRINTHS OF HUMAN EMBRYOS (Streeter, 1918). A, 50 mm. B, 85 mm.

considered to be evidence for this source of origin of the ossicles. It has, however, been suggested by Lightoller (1939) that the head of the malleus is the only part of any of the ossicles which is derived from the mandibular arch, and the rest of the malleus, the incus, and the stapes are all derivatives of the hyoid arch. Such a suggestion is not contrary to the arrangement of the muscles and their nerves, referred to above, for the tensor tympani is attached to that part of the malleus which is a derivative of the first arch. The ossicles at first do not lie in direct relationship to the tubo-tympanic recess but are placed dorsal and lateral to it, and are developed in a mass of mesoderm; a subsequent solution of this mesoderm around the ossicles gives rise to the formation of a series of cavities which come into communication with the cavity of the tubo-tympanic recess; and thus the ossicles appear to lie in the tympanic cavity whilst they are really separated from it by the entodermal lining of the recess and by a thin film of the mesoderm in which they were developed. They thus have the same sort of relationship to the tympanic cavity that the abdominal viscera have to the peritoneal cavity.

About the end of the sixth month of fœtal life the **tympanic antrum** begins to develop as an extension of the tympanic cavity, and from birth onwards further extensions produce the **mastoid cells**.

Internal Ear.—The epithelial lining of the labyrinth is derived from an ectodermal thickening, the **auditory placode**, which appears opposite the hind-brain immediately above the first pharyngeal groove in an embryo of 2 mm. CR length. An invagination of this placode gives rise to the **auditory pit**. The mouth of the pit is closed by the growing together of its margins, and the pit then assumes the form of a vesicle—the **otic vesicle**—which severs its connexion with the ectoderm and sinks into the mesoderm. The vesicle soon becomes pear-shaped; and its middle part gives off a diverticulum which later forms the **endolymphatic duct** and **sac**. About the fifth week the ventral part of the vesicle is prolonged medialwards and forwards as a diverticulum—the future **duct of the cochlea**. The diverticulum is at first short and straight, but it elongates and curves on itself, so that at the twelfth week all three coils of the cochlear duct are differentiated. From the upper part of the vesicle the three **semicircular ducts** are developed, and appear as hollow, disc-like evaginations; the central parts of the walls of each disc coalesce and disappear,

leaving only the peripheral ring or canal. The three ducts are free about the beginning of the second month, and are developed in the following order, viz.: superior, posterior, and lateral. The part of the otic vesicle from which the endolymphatic duct arises becomes divided by a constriction into an anterior part—the **saccule**—which communicates with the duct of the cochlea, and a posterior part—the **utricle**—which communicates with the semicircular ducts. The constriction extends for some distance into the endolymphatic duct, and thus the utricle and saccule are connected by a Y-shaped tube. Another constriction makes its appearance between the saccule and the vestibular end of the duct of the cochlea and forms the **ductus reuniens**. The epithelial lining is at first columnar, but becomes cubical throughout the whole labyrinth, except opposite the terminations of the auditory nerve, where it forms the columnar epithelium of the maculæ of the utricle and saccule, of the ampullary crests, and of the spiral organ. On the floor of the duct of the cochlea two ridges appear, of which the inner forms the limbus laminæ spiralis, whilst the cells of the outer become modified to form the rods of Corti, the hair-cells, and the supporting cells of Deiters and Hensen. (See Bast, Anson & Gardner, 1947.)

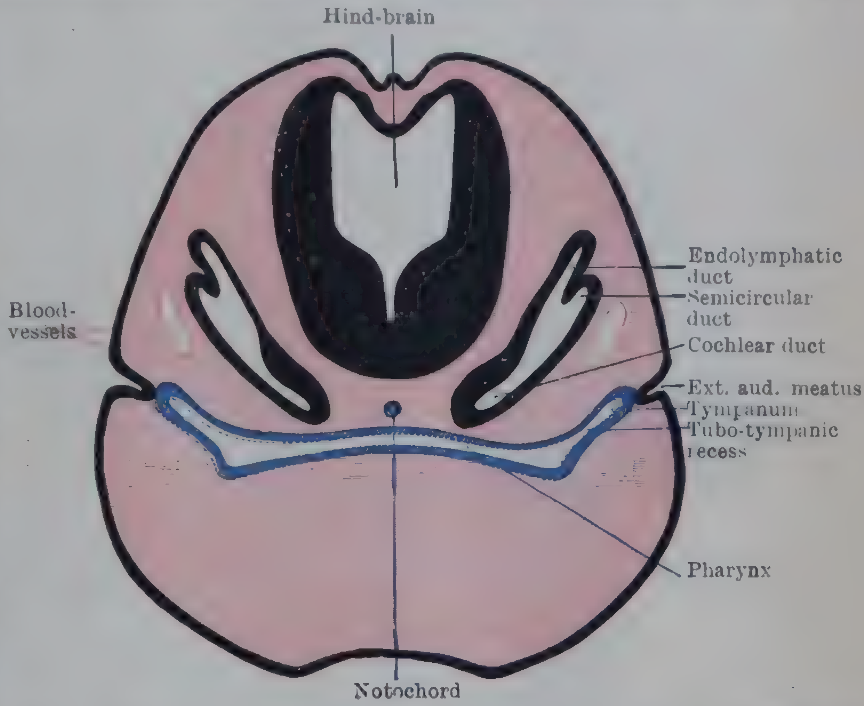

FIG. 1032.—DIAGRAM OF TRANSVERSE SECTION THROUGH THE HEAD OF AN EMBRYO. Showing the rudiments of the three parts of the ear and their relation to the tubo-tympanic recess and the first pharyngeal groove.

In the development of the perilymphatic spaces, the mesoderm surrounding the otic vesicle and its subsequent derivatives becomes differentiated into three layers—an inner reticular, a middle precartilaginous, and an outer cartilaginous. Room must be made in the enclosing cartilaginous labyrinth for the growing membranous portion, and this is brought about by a reversion of the precartilaginous layer next the membranous labyrinth into the more primitive type of reticular tissue; a breaking down of the fibrillæ of this tissue allows of a confluence between the enclosed spaces, which thus come to form the more or less completely open perilymphatic spaces that enclose the membranous labyrinth. The **scala vestibuli** appears as an outgrowth from the primitive cistern-like space which is developed in relation to the saccule and utricle, while the **scala tympani** appears independently a little earlier; these scalæ follow the turns of the cochlear duct and unite at the helicotrema about the sixteenth week.

For the development and ossification of the **auditory capsule**, see pp. 212, 224. Bast & Anson (1949) give a detailed account of the anatomy of the internal ear from the developmental point of view, with full bibliography.

ORGAN OF SMELL

The nose is the peripheral **organ of smell** and consists of: the external nose, which projects from the face; and the cavity of the nose, which is divided by a vertical septum into right and left chambers.

External Nose.—This resembles an irregular three-sided pyramid. Two sides of the pyramid are almost symmetrical and are the sides of the nose, which join the face at wide open angles and are separated from each other by a more or less sharp margin named the **dorsum** of the nose. The dorsum is continuous with the forehead at the **root** of the nose and ends below in the **apex** of the nose, beyond which the nose is continued into the upper lip. The third side of the pyramid is the smallest, is directed downwards, and has in it two orifices called the **nostrils**. These are usually elliptical in the adult but more circular in children; they are separated from each other by a median septum, and each is bounded on the lateral side by the **ala** of the nose, which is the expanded lower part of the side of the nose. The upper part of the nose is fixed in position, being supported

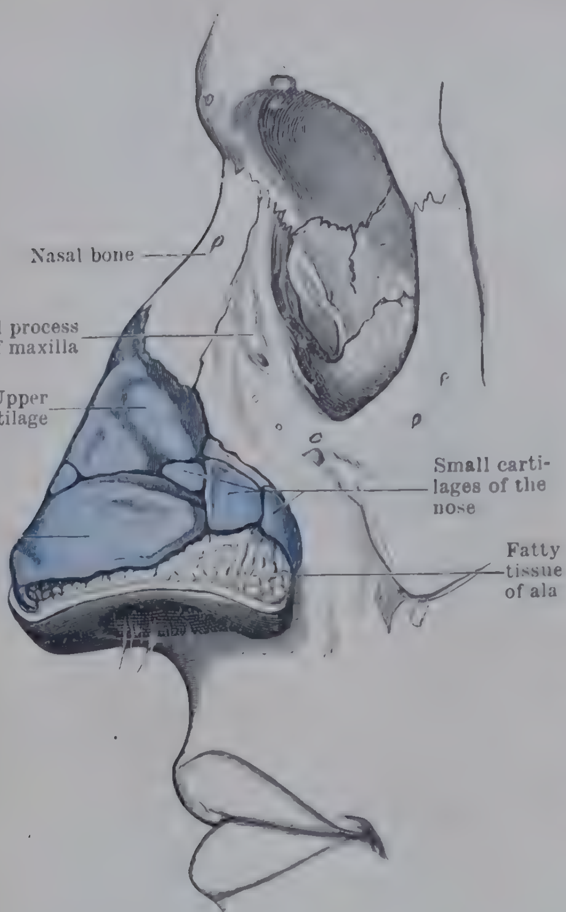

FIG. 1033.—PROFILE VIEW OF BONY AND CARTILAGINOUS SKELETON OF EXTERNAL NOSE.

by the nasal bones and the frontal processes of the maxillæ, and it is covered with thin and movable skin; the lower part, being supported only by pliable cartilages, is movable, and it is covered with thick and closely adherent skin in which there are many large sebaceous glands.

Vessels and Nerves.—The arteries are branches of the *facial artery* and of the *ophthalmic artery*. The **veins** open into the *anterior facial vein* and also communicate with the *ophthalmic vein*. The principal **lymph-vessels** follow the course of the anterior facial vein and open into the *submandibular lymph-glands*; but from the upper part of the nose a few vessels run sidewards in the upper and lower eyelids and end in the **superficial parotid lymph-glands**. The **nerves** to the muscles of the external nose come from the *facial nerve*, and to the skin from the infra-orbital branch of the *maxillary nerve* and from the infra-trochlear and external nasal nerves, which are derived from the naso-ciliary branch of the *ophthalmic nerve*.

CARTILAGES OF NOSE

Five chief cartilages are concerned in the formation of the nose; they are the upper and lower cartilages on each side, and the septal cartilage.

The **upper cartilage** (Figs. 1033, 1034) is triangular in shape and is situated immediately below the nasal bone. Its posterior edge is thin and is attached to the maxilla and to the nasal bone by fibrous tissue. The anterior edge is thick; its upper part is directly continuous with the cartilage of the septum, but its lower part is separated from that cartilage by a narrow fissure. The lower edge is joined by fibrous tissue to the lower cartilage.

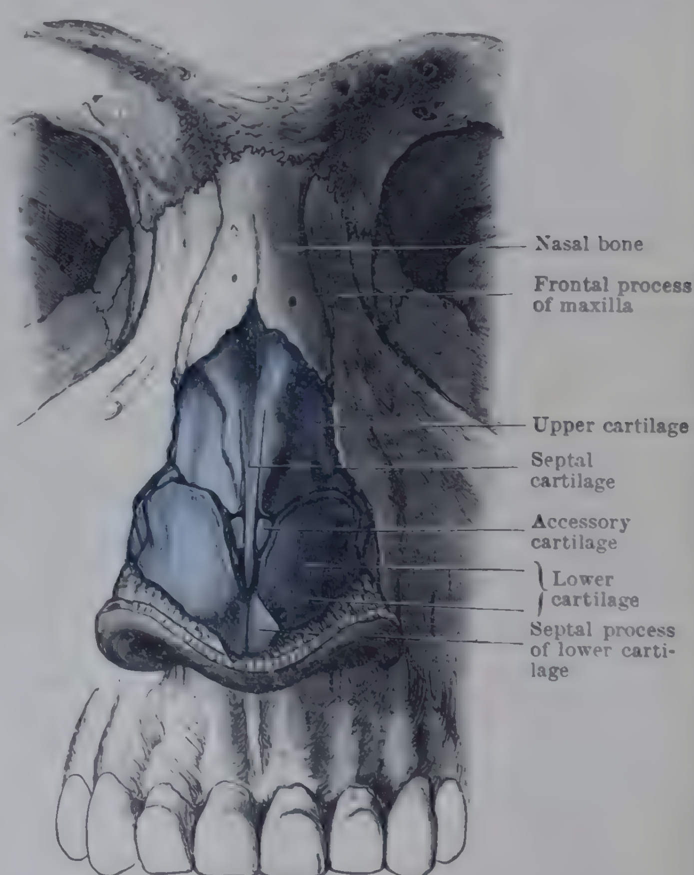

FIG. 1034.—FRONT VIEW OF BONY AND CARTILAGINOUS SKELETON OF EXTERNAL NOSE

The **lower cartilage of the nose** (Figs. 1033, 1034) is elliptical, with the long axis directed downwards and forwards. It forms a support for the lateral side and front of the nostril. Its anterior end is turned inwards as a small hook-like process called the **septal process**. The lower cartilage is connected above with the upper and septal cartilages, and behind with the maxilla by fibrous tissue, in which two or three *small cartilages of the nose* are embedded; in

front it is separated from its fellow by a gap, filled with fibrous tissue, which can easily be felt in the living subject.

The **septal cartilage** (Fig. 1035) is of an irregular quadrilateral form. Its postero-superior edge is attached to the perpendicular plate of the ethmoid bone; its postero-inferior margin to the vomer and to the nasal crests of the maxillæ. Its antero-superior border is thick and is fixed above to the back of the internasal suture; immediately below that suture it is directly continuous with the upper parts of the upper cartilages of the nose, which may be looked upon as its wing-like expansions. Its lower part is separated from the upper and lower cartilages of the nose by a narrow fissure filled with fibrous tissue in which a small accessory cartilage is usually seen. The antero-inferior border of the septal cartilage is short and is

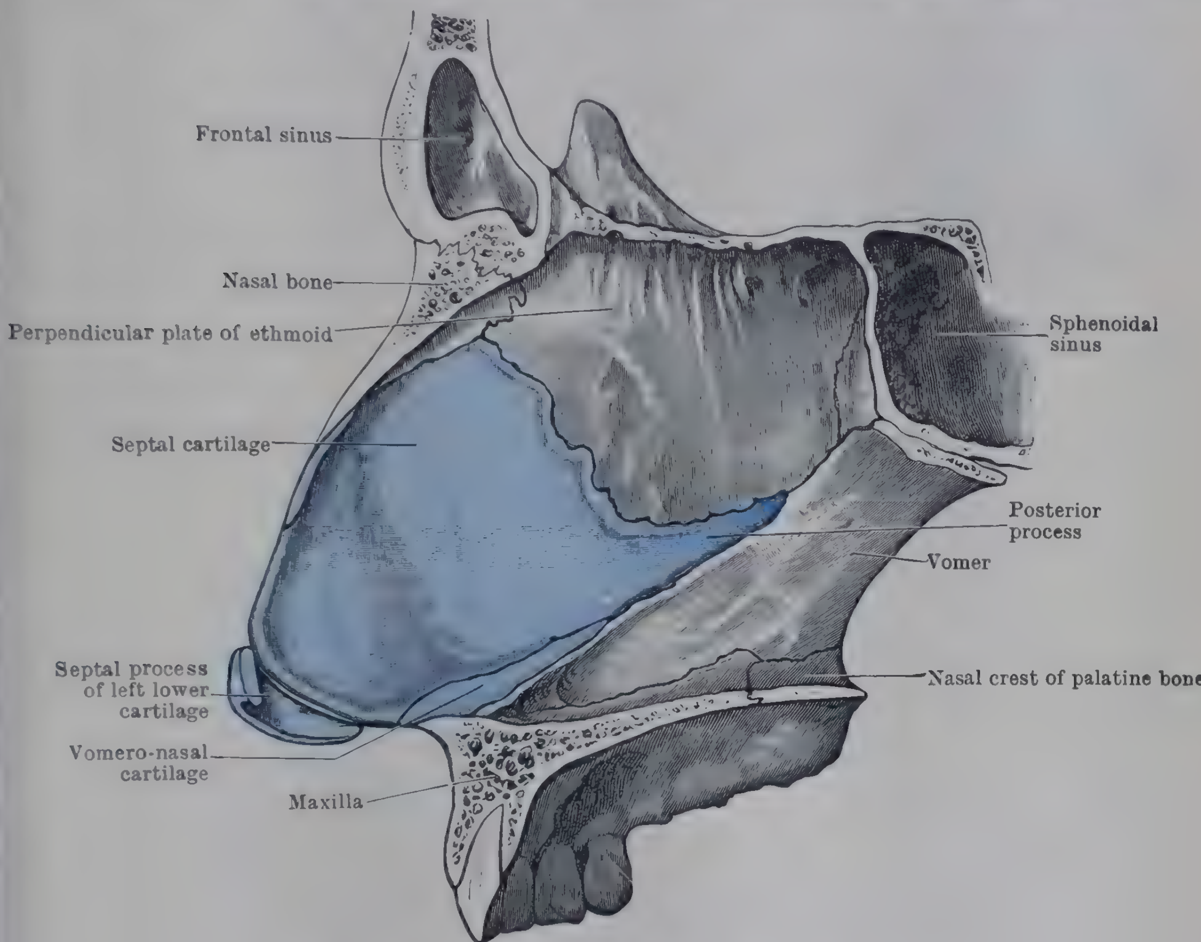

FIG. 1035.—VIEW OF NASAL SEPTUM FROM THE LEFT SIDE.

attached by fibrous tissue to the septal processes of the lower cartilages; its anterior angle is rounded and does not reach as far as the apex of the nose. The septal cartilage may be prolonged backwards (especially in children) as a narrow process into the angle between the vomer and the ethmoid bone.

On each side of the postero-inferior edge of the septal cartilage there is a narrow band of cartilage, called the **vomero-nasal cartilage** (Fig. 1035) since it lies below the rudimentary vomero-nasal organ (p. 1208).

The lowest part of the nasal septum is not formed by the septal cartilage but by the septal processes of the lower cartilages and by the skin; it is therefore double and, being freely movable, is termed the **movable part of the septum.**

CAVITY OF NOSE

The **cavity of the nose** extends from the *nostrils* in front to the *posterior apertures* of the nose behind; it is divided into right and left cavities by the *septum* of the nose, and it opens through the posterior apertures into the space known as the nasal part of the pharynx. The medial or septal wall of each nasal cavity is smooth and flat, while the lateral wall is irregular owing to the presence of the nasal conchæ.

Immediately above the nostril there is a slightly expanded portion, called the **vestibule**, which is bounded laterally by the lower cartilage of the nose, and medially by the lower part of the septum. It is lined with skin; and it is prolonged as a small recess towards the apex of the nose. The vestibule is partly divided by a curved ridge; in the lower part there are hairs and sebaceous glands, the hairs being curved downwards to guard the entrance to the nostril; the upper part is smooth, and is limited superiorly by a slight, arched prominence caused by the lower edge of the upper cartilage.

Each nasal cavity is divided into an upper or olfactory region and a lower or respiratory region. The **olfactory region**, to which alone the olfactory nerves are distributed, is the slit-like upper and posterior part of the cavity below the cribriform plate of the ethmoid bone; the remainder of the cavity is the **respiratory region**.

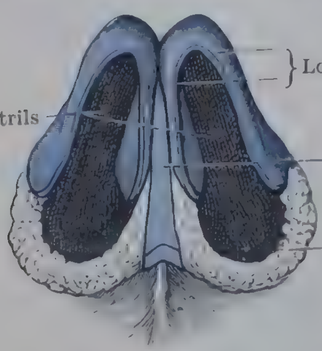

Fig. 1036.—Cartilages of Nose from below.

Septum of Nose.—The septum is partly bony and partly cartilaginous.

The upper part of the **bony septum** is formed chiefly by the perpendicular plate of the ethmoid, and slightly by the crest of the nasal bones in front and the crest of the sphenoid behind. The lower part is formed by the vomer and by the nasal crests of the maxillæ and of the palatine bones. The cartilaginous part of the septum is its antero-inferior part and is formed by the septal cartilage, which, as described on p. 1207, fills the gap between the ethmoidal and vomerine parts of the bony septum. In the septum, a little above and in front of the incisive canals, on each side of the median plane, there is a minute orifice, not always recognizable, from which a blind pouch—the **vomero-nasal organ**—extends upwards and backwards for a distance of from 2 to 9 mm.; it lies above the vomero-nasal cartilage. In Man the vomero-nasal organ is vestigial (Fig. 1039), but in many of the lower animals, *e.g.*, lizard, rabbit, it is well developed and is lined with epithelium similar to that of the olfactory region, and is supplied by branches of the olfactory nerve.

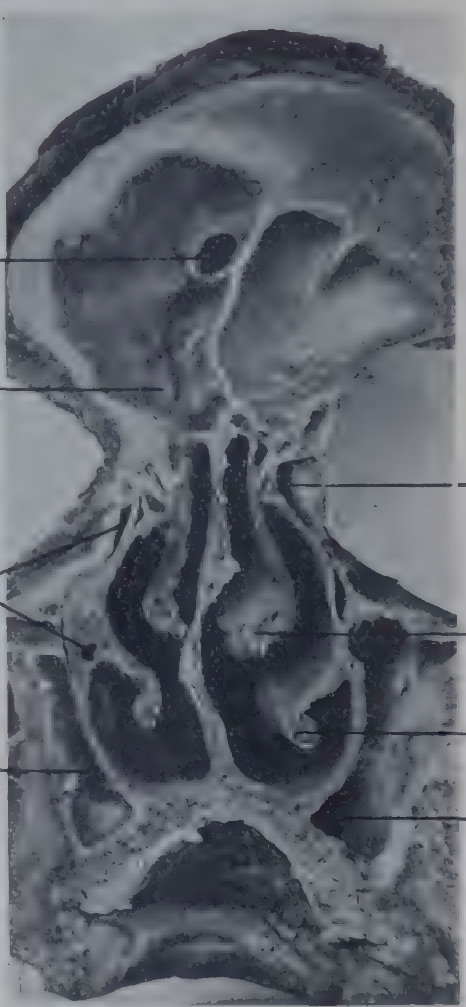

Fig. 1037.—Photograph of Coronal Section through the Nose; in Front of Section shown in Fig. 1038. Viewed from behind.

Until the seventh year of life the nasal septum is, as a rule, in the median plane, but after that age it is very often bent to one or other side—more frequently to the right—the deflexion being greatest usually along the line of junction of the vomer with the perpendicular plate of the ethmoid. Deflexion of the septum is more common in European than in non-European skulls—occurring in about

53 per cent of the former and in about 28 per cent of the latter (Zuckerkandl, 1893). Associated with that deviation, or apart from it, crests or spurs of bone are found projecting from the septum into one or other nasal cavity in about 20 per cent. of skulls.

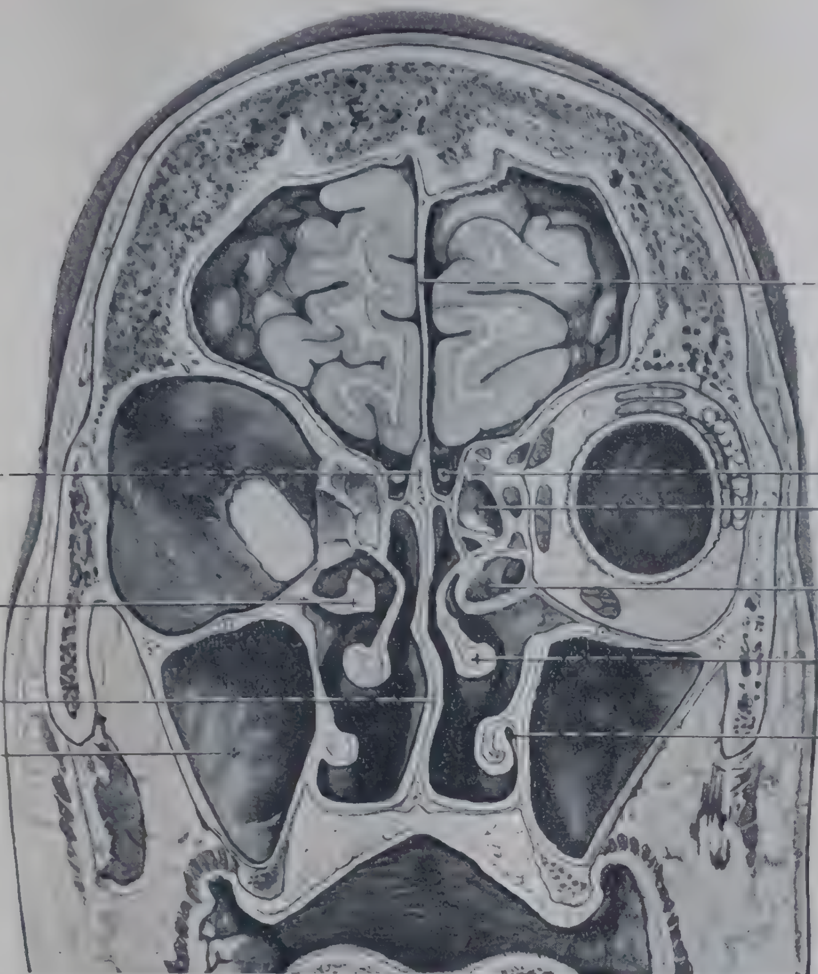

FIG. 1038.—CORONAL SECTION OF HEAD; BEHIND SECTION SHOWN IN FIG. 1037. VIEWED FROM THE FRONT. The contents of the right orbit have been removed.

Lateral Wall (Fig. 1040).—The lateral wall of the nasal cavity shows the three elevations caused by the superior, middle, and inferior conchæ and frequently a fourth due to a "highest" concha. Below and lateral to each concha there is a space or cleft—the superior, middle, and inferior meatus of the nose. Another small space may be present below the "highest" concha; and, above and behind the superior concha, there is a small space, called the **spheno-ethmoidal recess**, into which the sphenoidal sinus opens. Above and behind the vestibule and immediately in front of the middle meatus there is a slight concavity of the lateral wall known as the **atrium of the middle meatus**; the atrium is limited above by a ridge, called the **agger nasi**, which is the representative of the naso-turbinal found in many mammals. Above the agger nasi, a

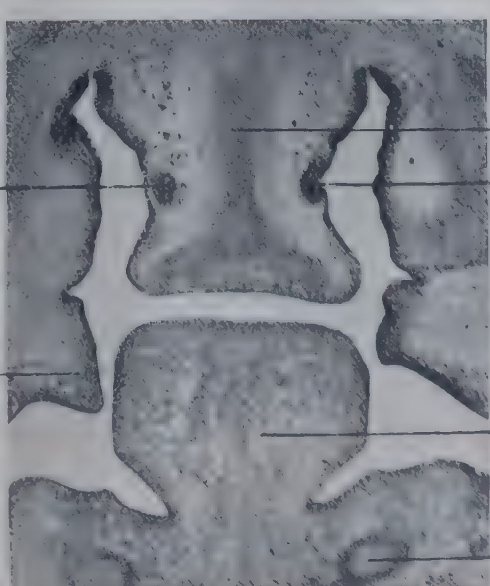

FIG. 1039.—SECTION THROUGH NOSE AND MOUTH OF 20 MM. HUMAN EMBRYO TO SHOW POSITION OF VOMERO-NASAL ORGAN (×28).

groove known as the **olfactory sulcus** leads to the olfactory portion of the nose. Certain of the paranasal sinuses open into the various meatuses of the nose: the

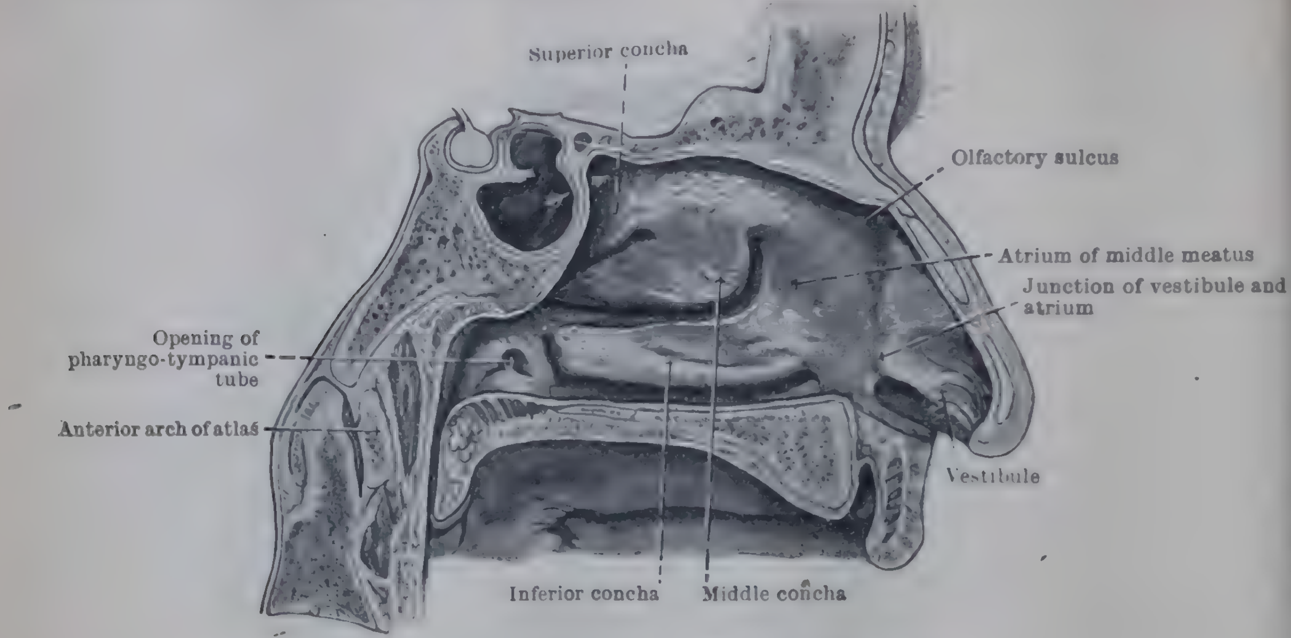

FIG. 1040.—LATERAL WALL OF LEFT NASAL CAVITY.
The arrow passes from the sphenoidal sinus to the spheno-ethmoidal recess.

sphenoidal sinus into the spheno-ethmoidal recess, the posterior ethmoidal sinuses into the superior meatus, the anterior and middle ethmoidal sinuses and the

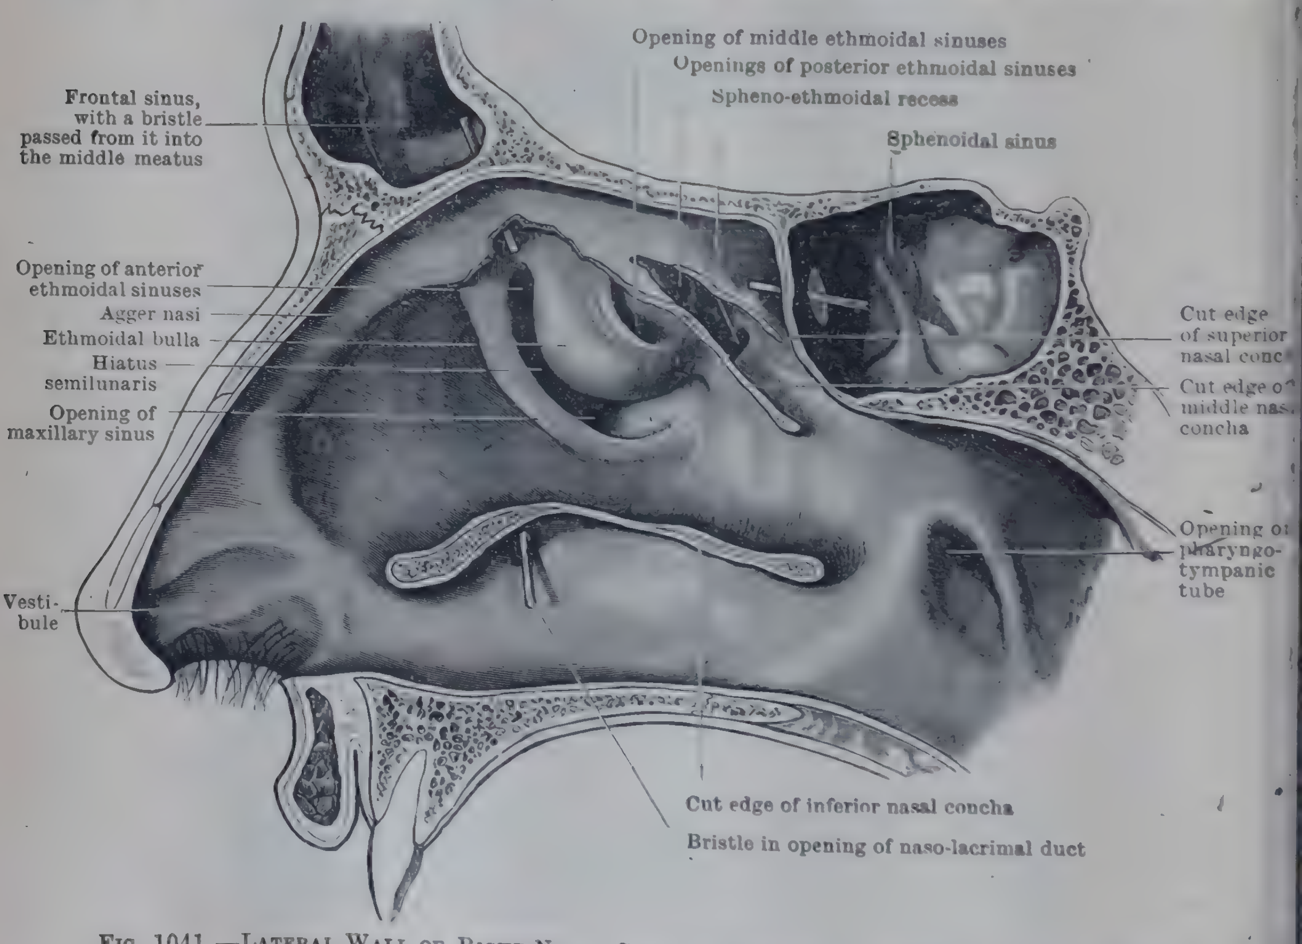

FIG. 1041.—LATERAL WALL OF RIGHT NASAL CAVITY—THE NASAL CONCHÆ HAVE BEEN REMOVED.
For the bones of the lateral wall, see Fig. 164, p. 193.

maxillary and frontal sinuses into the middle meatus. The naso-lacrimal duct opens into the inferior meatus. On removal of the middle concha, the lateral wall is seen to be marked by a curved groove, called the **hiatus semilunaris**,

which is limited above by an elevation—the **ethmoidal bulla**—due to the bulging of the middle ethmoidal sinuses, and below by the sharp edge of the **uncinate process** of the ethmoid bone; the anterior end of the hiatus semilunaris opens into the **ethmoidal infundibulum**, which leads to the frontal sinus; the openings of the middle ethmoidal sinuses are usually placed above the bulla; the anterior ethmoidal sinuses and the maxillary sinus open into the hiatus.

Roof.—The roof of the nasal cavity is very narrow, except at its posterior part, and it is divisible into three portions—fronto-nasal, ethmoidal, and sphenoidal—in accordance with the bones which enter into its formation.

Floor.—The floor of the nasal cavity is formed by the palatine process of the maxilla and the horizontal plate of the palatine bone. In it, close to the lower margin of the septum and immediately over the incisive canal, a funnel-shaped depression called the *naso-palatine recess* is sometimes seen; it is directed downwards and forwards, and indicates the position of a communication which existed between the nasal and oral cavities in early intra-uterine life.

Mucous Membrane of Nose.—The mucous membrane lines the entire nasal cavity except the vestibule; it is firmly bound to the subjacent periosteum and perichondrium. It is continuous, through the posterior apertures of the nose, with the mucous lining of the nasal part of the pharynx; through the apertures leading into the paranasal sinuses, with the lining of those cavities; and through the naso-lacrimal duct and the lacrimal sac and canaliculi, with the conjunctiva.

In the respiratory region the mucous membrane is thick and highly vascular and contains many acinous glands, especially in the posterior half of the cavity; in the olfactory region it is thin and yellow and contains the peripheral endings of the olfactory nerves.

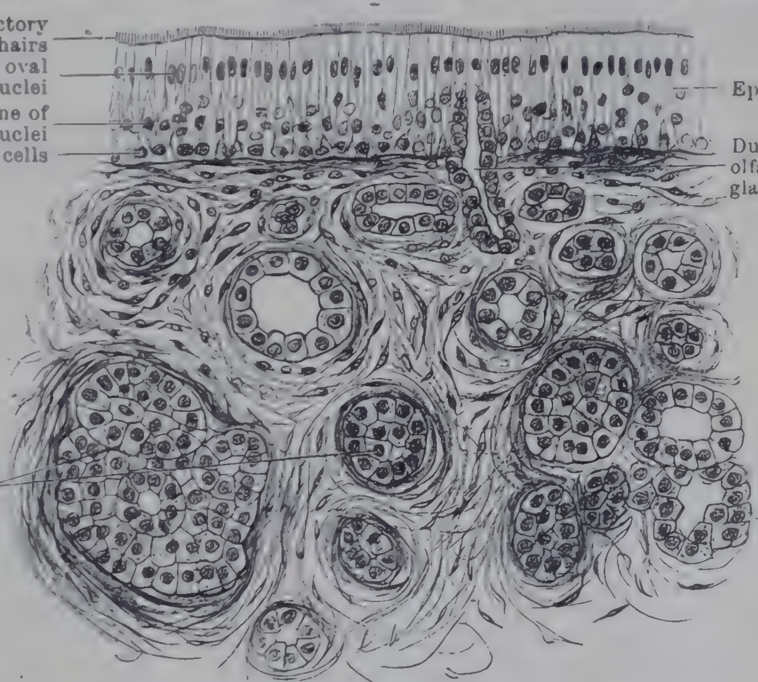

Fig. 1042.—Section through Olfactory Mucous Membrane.

Structure.—In the respiratory region the mucous membrane is covered with ciliated columnar epithelium; between the bases of the columnar cells smaller pyramidal cells occur, and goblet or mucous cells also are found. In children a considerable amount of adenoid tissue is present. In the olfactory region the mucous membrane is covered with non-ciliated columnar epithelium in which the cells may be divided into *supporting*, *olfactory* and *basal* cells.

The superficial parts of the **supporting cells** are columnar and contain fine granules of yellow pigment; the deep parts are continued for some distance as attenuated processes which may be branched. Their nuclei are elliptical or oval, and are situated at the deep ends of the columnar parts of the cells—forming the *zone of oval nuclei.*

The **olfactory cells** are bipolar nerve-cells, and their central processes are delicate and beaded filaments which are continued through the cribriform plate of the ethmoid to the brain. They are homologous with the nerve-cells of the spinal ganglia, but differ from them in that they retain their primitive position in the surface epithelium. The cell-bodies are spindle-shaped and are arranged in several rows between the deeper, attenuated parts of the supporting cells. Their nuclei are large and spherical, and form a layer of some thickness termed the *zone of round nuclei.* The peripheral process of each olfactory cell is rod-like, and extends between the columnar portions of the supporting cells as far as their free surfaces, where it pierces the external limiting membrane and divides into a number of fine hair-like processes named **olfactory hairs.**

The **basal cells** are branched, and they lie between the deep ends of the supporting and olfactory cells.

Olfactory Nerves.—The fibres of the olfactory nerves are non-myelinated but have a neurolemma; they arise as the central processes of the olfactory cells. They are collected into fasciculi which, in the rabbit (Le Gros Clark & Warwick, 1946), pass upwards to the cribriform plate in separate parallel bundles without forming any plexus in the nasal mucous membrane. Having passed into the cranial cavity they arborize around the dendrites of the mitral cells of the olfactory bulb, thus assisting in the formation of the **olfactory glomeruli** (Fig. 840, p. 957).

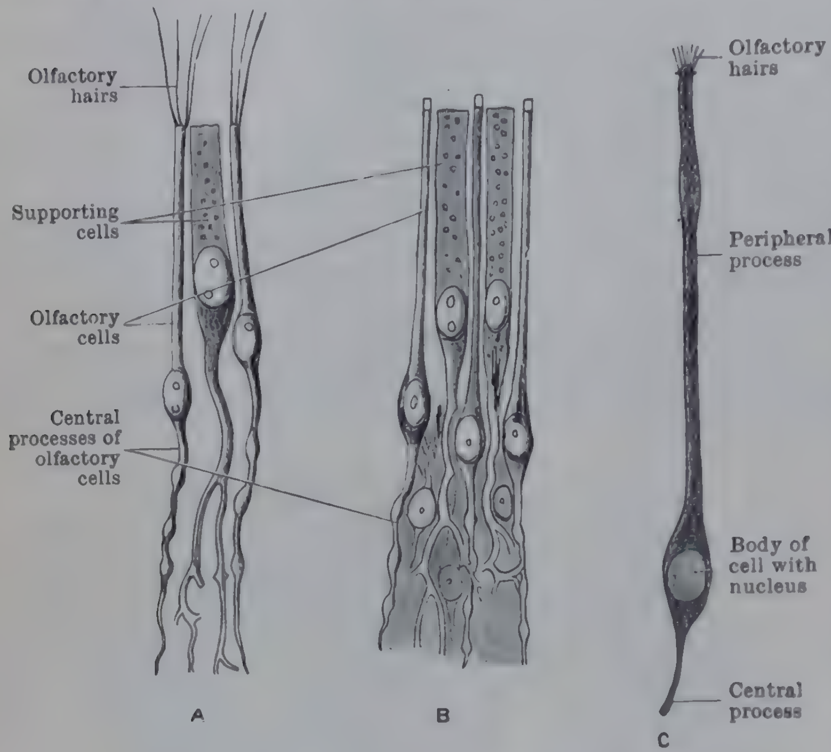

Fig. 1043.—Olfactory and Supporting Cells.

A. Frog, B. Human } M. Schultze. C. Human olfactory cell (v. Brunn).

The trigeminal nerve supplies branches of ordinary sensation to the nasal mucous membrane as follows: The septum is chiefly supplied by the long and short spheno-palatine nerves, and in its anterior portion by the anterior ethmoidal nerve. The lateral wall is supplied by the short spheno-palatine nerves; by the lower nasal branches of the greater palatine nerve; and in front by the anterior ethmoidal nerve. The floor and the anterior part of the inferior meatus are supplied by a nasal branch of the anterior superior dental nerve.

Blood-Vessels.—The chief **artery** of the nose is the spheno-palatine branch of the maxillary artery. It reaches the nasal cavity through the spheno-palatine foramen, and it divides into (*a*) an artery to the septum and (*b*) branches which ramify over the meatuses and conchæ and also supply the maxillary, frontal, and ethmoidal sinuses. In the conchæ the main arteries lie within the bone, and their branches then pass out to form a fine sub-epithelial plexus. This plexus, in turn, opens into wide venous 'blood-spaces' which are important constituents of the mucous membrane. In addition, there are direct arterio-venous anastomoses between the mucosal arteries and the 'blood-spaces' (Harper, 1947). The upper portion of the cavity receives a supply from the ethmoidal arteries, and the posterior part some small branches from the greater palatine artery. The nostrils are supplied by a branch of the facial artery and by the septal branch of the superior labial artery. The maxillary sinus is supplied by the infra-orbital and posterior superior dental arteries, and the sphenoidal sinus gets its chief supply from the spheno-palatine artery. The **veins** form a dense, cavernous plexus which is well seen in the respiratory region, and particularly over the inferior nasal concha and the lower and posterior parts of the septum. In the case of the conchæ the veins drain first into a periosteal venous plexus and thence into a system of veins contained in bony canals in the conchæ. The venous blood is carried in three chief directions, viz., *forwards* into the anterior facial vein, *backwards* into the pterygoid plexus through the spheno-palatine vein, and *upwards* into the ethmoidal veins. The ethmoidal veins communicate with the ophthalmic veins and the veins of the dura mater; one ethmoidal vein passes up through the cribriform plate, and opens either into the venous plexus of the olfactory bulb or directly into one of the veins on the orbital surface of the brain.

Lymph-Vessels.—These form an irregular network in the superficial part of the mucous membrane; they are separated from prolongations of the subarachnoid space along the olfactory nerves by very thin walls which act as semi-permeable membranes. The chief lymph-vessels are directed backwards towards the posterior apertures of the nose, and, on each side, are collected into two trunks, one passing to a retropharyngeal lymph-gland, the other to one or two upper deep cervical lymph-glands.

Paranasal Sinuses

The paranasal sinuses are the frontal, ethmoidal, sphenoidal, and maxillary; they open into the nasal cavities, and are lined with mucous membrane which is continuous with that of the nasal cavities.

The **frontal sinuses**—a right and a left—are placed behind the superciliary arches; they are rarely symmetrical because the septum which separates them frequently deviates from the median plane. Their average measurements are: height, 3·16 cm.; breadth, 2·58 cm.; depth from before backwards, 1·8 cm. Each opens, through the infundibulum, into the anterior part of the middle meatus of the nose.

The **ethmoidal sinuses**, about ten in number on each side, are thin-walled air-cavities, each about the size of a pea (Whitnall, 1932), that occupy the labyrinth of the ethmoid bone; their walls are completed by the frontal, maxillary, lacrimal, sphenoid, and palatine bones, with which the labyrinth articulates. They are separated from the orbits by thin bony laminæ; and they are arranged on each side in three groups—anterior, middle, and posterior. The anterior and middle groups open into the middle meatus of the nose, and the posterior group into the superior meatus.

The **sphenoidal sinuses** are a pair of cavities in the body of the sphenoid bone; they are rarely symmetrical, since the septum between them is often bent to one or other side. Their average measurements are: height, 2 cm.; width, 1·8 cm.; antero-posterior depth, 2·1 cm. Each opens into the spheno-ethmoidal recess of the nose.

The **maxillary sinuses** are pyramidal cavities in the bodies of the maxillæ. Their average measurements are: height, opposite the first molar tooth, 3·5 cm.; width, 2·5 cm.; antero-posterior depth, 3·2 cm. In the upper part of the medial wall of each sinus there is an opening through which it communicates with the lower part of the hiatus semilunaris in the middle meatus of the nose. An accessory opening is frequently seen above the posterior part of the inferior concha.[1]

The relations of the sinuses are given in the Section on Osteology (p. 197); their appearance in radiographs is dealt with in the Section on Surface and Surgical Anatomy and may be studied in Plates VII and VIII, p. 154, XLVII, p. 558, LXXIII, p. 944, LXXV, p. 960, and LXXVII, p. 1200.

Development of Nose

The first indication of the developing organ of smell is the **olfactory placode**—a proliferation of ectodermal cells on the ventro-lateral surface of the head—which can be recognized in an embryo of 4 mm. (Fig. 1028 A). The tissue on the medial and the lateral side of each placode becomes raised up into ridges which soon form rounded prominences called respectively the *globular* and the *lateral nasal processes*. The two globular processes, separated by a median groove, are parts of a *median nasal process*, and the whole area on which the nasal processes and the olfactory placodes appear constitutes the *fronto-nasal process* (Fig. 76A, p. 63).

As the nasal processes are developed the olfactory placodes sink into the substance of the head so as to form two grooves. The maxillary process grows from the first or mandibular pharyngeal arch and is at first separated from the lateral nasal process by a groove—the *naso-lacrimal sulcus*—which leads to the region of the developing eye, and when the maxillary process, by its growth in a ventral direction, joins the fronto-nasal process, this groove comes to be buried, and it later gives rise to the naso-lacrimal duct (Fig. 1044).

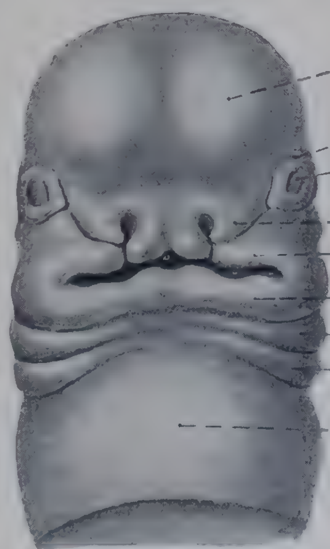

Fig. 1044.—Head of Human Embryo showing the relation of the Nasal and Maxillary Processes to the Olfactory Pit and the Naso-Lacrimal Sulcus.

As the maxillary process grows ventrally to form the upper lip, it fuses with the lateral nasal process and then with the globular process, and so forms a floor for the original olfactory groove, which thus becomes converted into a blind pit that opens on to the surface through an almost circular aperture—the primitive nostril. At the far end of the pit the floor breaks through, about the seventh week, and the pit then opens behind the maxillary process into the primitive mouth; this opening constitutes the *primitive posterior aperture* of the nose.

The olfactory pit enlarges, particularly in an upward direction, and forms the **nasal cavity**; the original ectodermal cells of the olfactory placode come to be situated in the upper part of the

[1] The measurements of the sinuses are those given by Logan Turner (1901); see also Onodi (1895).

cavity, and they become differentiated into the **olfactory epithelium**. The right and left nasal cavities are at first continuous with each other below the fronto-nasal process, and they open into the mouth cavity. In the meantime, the maxillary processes project towards the median plane as a pair of shelves—the *palatine processes* (Fig. 1039)—which about the tenth week join in the median plane and form a roof for the mouth so that the posterior apertures of the nose can no longer open into the cavity of the mouth but must open behind the fused palatine processes into the future naso-pharynx. At the same time the two nasal cavities become separated from each other by the fusion of the posterior edge of the fronto-nasal process with the upper surface of the fused palatine processes (Fig. 1045). From about the second to the sixth month the anterior aperture of the nose—the nostril—is closed with a plug of epithelial cells.

While the nasal cavities are being isolated changes are taking place on their medial and lateral walls which result in the formation of the *vomero-nasal organ* on the medial wall and the conchæ and paranasal sinuses on the lateral wall. The vomero-nasal organ (Fig. 1039) appears about the fifth or sixth week as an indentation of the nasal septum; it grows in an upward and backward direction, and, by about the sixth month, it attains a depth of 4 mm.; later, it atrophies.

The nasal conchæ develop as a series of ridges on the lateral wall, known as the *maxillo-turbinal*, which forms the **inferior concha**, and the *ethmo-turbinals*, of which the first forms the **middle concha** and the second and third the **superior concha**; an additional ethmo-turbinal may persist as the highest concha. A more anterior elevation on the lateral wall—the *naso-turbinal*—is represented in the adult by the **agger nasi**.

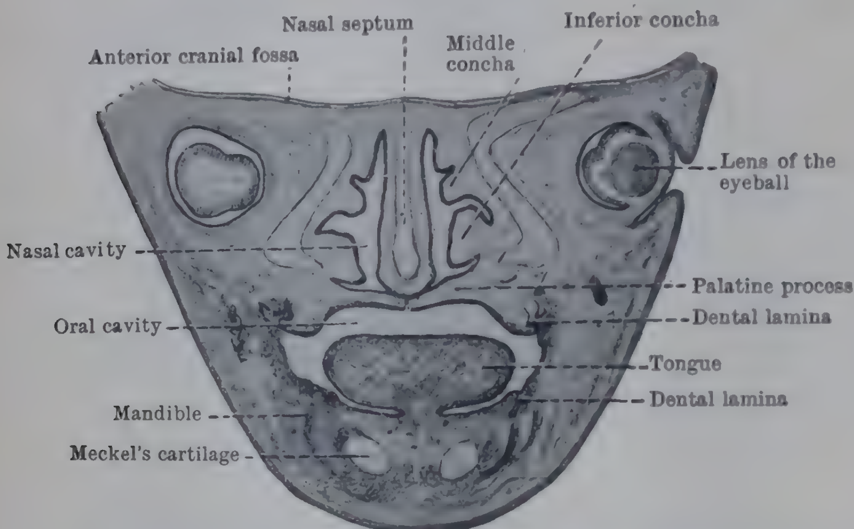

Fig. 1045.—Coronal Section through Face of Human Embryo about 9 weeks old.

With the continued growth of the maxillary processes, the fronto-nasal process, with its contained nostrils, becomes raised up from the surface of the face so as to form the rudiment of an external nose (Fig. 1028 D); and the nostrils come to be directed forwards, as they still are at birth.

The supporting skeleton of the nose constitutes what is called the *nasal capsule*. This arises by a process of chondrification in both the medial and lateral walls of the nasal cavities. The process begins near the surface and follows the growth of the cavities in an upward direction, so that finally fusion takes place with the base of the skull itself. An upward curling of the lateral cartilage gives rises to the inferior concha, and subsequent chondrification in the lateral wall forms the basis of the other conchæ. The chondrification in the lower part of the lateral wall forms what are known as the *paranasal cartilages* (p. 213). Chondrification occurs in the median part of the fronto-nasal process also, and this cartilage persists as the **septal cartilage**. Subsequent ossification, partly in cartilage and partly in membrane, forms the later bony framework of the nose.

When the outgrowths from the lateral wall to form the conchæ take place, the areas left between them constitute the primitive meatuses, and outgrowths from these form the various paranasal sinuses. The first of these to appear is the maxillary sinus, as an outgrowth from the middle meatus about the end of the third month; this is followed by the ethmoidal, frontal, and sphenoidal sinuses, but all of the sinuses undergo the major portion of their development only after birth—the frontal sinus not reaching that bone till the second year, and the sphenoid not excavating its cavity till the fifth year, the maxillary sinus, which is still only a mere groove at birth, not acquiring its full development till after puberty.

ORGAN OF TASTE

The peripheral **organ of taste** consists of groups of modified epithelial cells, termed **taste-buds**, found on the tongue, the palato-glossal arch, the oral surface of the soft palate, the posterior surface of the epiglottis, and the posterior wall of the upper part of the pharynx. They occupy nests in the epithelium of these regions.

They are most numerous on the tongue:—They are present in large numbers around the circumference of the vallate papillæ (Fig. 1046), and some are found also on the opposing walls of the vallum (Fig. 493, p. 576). They are very numerous over the folia linguæ, and are found also over the posterior part and

sides of the tongue, and on the fungiform papillæ. The full number of taste-buds developed on the papillæ is present at birth, and at a later date on the vallum. Atrophy of the taste-buds begins in adult life and increases rapidly with age. The mean number of taste-buds related to a vallate papilla is, at 20 years of age, 245 on the papilla and 74 on the vallum. In advanced age the numbers decrease to 88 and 13 respectively (Arey, Tremaine & Monzingo, 1935).

Structure (Fig. 1048).—The taste-buds are oval or flask-shaped; the deep end of each is expanded, and the free end shows a minute opening termed the **gustatory pore**. The taste-buds are composed of two kinds of epithelial cells—supporting cells and gustatory cells (Fig. 1047). The **supporting cells** are elongated, nucleated spindles, and are mostly arranged like the staves of a cask to form the outer envelope of the taste-bud; but some are found in the interior amongst the gustatory cells. The **gustatory cells** occupy the centre of the taste-bud, and each has a nucleated cell-body which is prolonged into a peripheral and a central process. The peripheral process is rod-like, and terminates at the gustatory pore in a slender filament called the **gustatory hair**. The central process passes towards the deep extremity of the taste-bud, where it ends in a single or branched varicose filament.

Nerves of Taste.—The chorda tympani (through the lingual nerve) supplies the taste-buds on the anterior two-thirds of the tongue; and the glosso-pharyngeal

supplies those on the posterior third and on the palato-glossal arch. The buds on the soft palate are supplied by the greater superficial petrosal nerve by way of the spheno-palatine ganglion and the palatine nerves; and the internal laryngeal

nerve supplies those on the epiglottis. The nerve-fibrils lose their medullary sheaths and ramify in the taste-buds, partly between the gustatory cells and partly among the supporting cells.

BLOOD-VASCULAR

AND

LYMPHATIC SYSTEMS

by J. C. Brash, *M.C.*, M.A., M.D., D.Sc., F.R.C.S.Ed., F.R.S.E.,
Professor of Anatomy, University of Edinburgh

All the tissues of the body require that food and other materials necessary for their growth, maintenance, and work shall be carried to them in a fluid form, and that their metabolic products shall be removed and conveyed either to the tissues by which they can be used, as in the case of internal secretions, or to the lungs and kidneys for elimination from the body.

The tubular, vascular system with the **blood** and **lymph** meets these necessities. It consists of the **heart, arteries, capillaries, veins,** and **lymph-vessels.**

The anatomical demonstration of the Circulation of the Blood by William Harvey (1628) was thus the starting point of modern Physiology. From consideration of the function of the valves of the veins (p. 1223)—described by Fabricius (1603)—by experiment, calculations and logical argument from the structure of the heart and the arrangement of its valves, Harvey reached the conclusion that " the movement of the blood is constantly in a circle, and is brought about by the beat of the heart ".

The heart is a rhythmically contractile muscular pump, and it is divided into receiving and ejecting chambers. During the intervals between its contractions blood flows from the **veins** into its receiving chambers, which are termed **atria**. As soon as the atria are full they contract and force their contents into ejecting chambers called **ventricles**; then the ventricles contract and project the blood into the **arteries.**

The two stem-arteries into which the blood is projected (the aorta and the pulmonary trunk) are necessarily large, but they break up into branches which again branch, and so, by repeated branchings, the arteries rapidly become smaller as they approach the tissue-areas they supply. Ultimately the smallest branches, which are called **arterioles**, end in plexuses of vessels of extremely small calibre which are known as **capillaries.**

Capillary networks, whose meshes vary in size and form in different regions, are found in all tissues except cartilage. They are drained by the **veins**, which gradually unite with one another to form larger trunks, and, through the terminal and largest trunks, the blood is returned to the atria of the heart.

As the blood enters the capillaries some of its fluid portion, which is termed **blood-plasma**, passes through their thin walls and permeates the tissues, from which a part re-enters the capillaries towards their venous ends, and so is returned to the heart. The remaining part is collected from the tissues by another set of capillary vessels from which it passes into **lymph-vessels**, which finally discharge into the great veins at the root of the neck; thus, all the fluid which irrigates the tissues is eventually returned to the heart.

Much watery fluid, however, is removed from the body as urine by the action of the kidneys. The fluid passes from the renal blood-capillaries into the renal tubules, and so by way of the ureters and urinary bladder to the exterior. A large quantity of fluid is also given off from the skin and in the breath from the lungs as watery vapour. The fluid thus passed out of the body is replenished by fluid taken in by the mouth

and passed through the walls of the abdominal part of the alimentary canal into the blood-capillaries and lymph-capillaries which lie in the tissues of those walls.

Besides ordinary food, **oxygen** is an indispensable necessity for the proper performance of tissue work; and one of the effete products which must be discharged is **carbon dioxide.**

The lowest vertebrates obtain their oxygen from water by means of capillary-plexuses in their gills through which the blood passes on its way from the heart to the tissues. In fishes, therefore, the heart is essentially a single tube, divided mainly into a single receiving chamber and a single ejecting chamber. With the evolution of land animals, however, other means for obtaining oxygen had to be adopted; and new respiratory organs called lungs were developed, in communication with the external air through the mouth and nose.

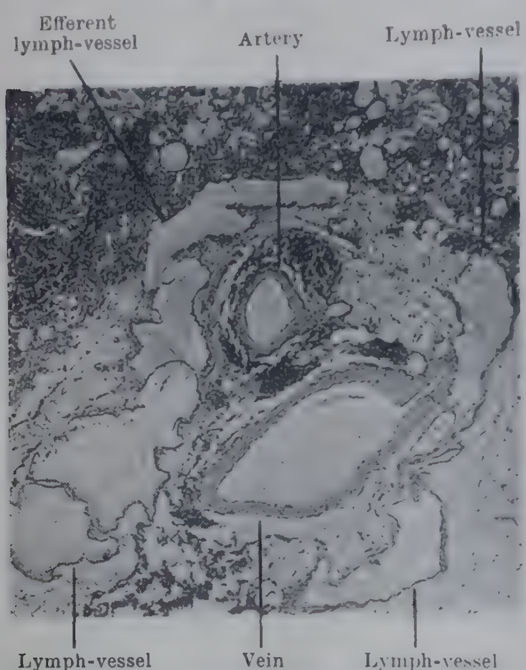

Fig. 1049.—Photomicrograph of Section of Artery, Vein, and Lymph-Vessels in the Hilum of a Lymph-Gland.

The question whether the lungs of higher vertebrates were evolved from the swim-bladder of the bony fishes is a complex morphological study; but in any case the development of lungs necessitated an alteration of the circulation whereby it would be possible for the venous blood, returned to the heart by the veins, to be sent first through the lungs, where it could lose its carbonic acid and obtain oxygen, and then through the body generally.

This could be brought about only by profound changes in the arrangement of the chambers of the heart; and the process of evolution whereby the object was attained was gradual during the period of transition from fish to mammal. It was fully achieved by the complete division of the single longitudinal tube of the primitive heart into right and left halves by the formation of septa. The right ventricle became connected with arteries passing to the lungs, and the left atrium with the veins returning blood from the lungs, whilst the left ventricle was connected with the arteries supplying the body generally and the right atrium with the veins returning blood from the body. In that way two circulations were established—the pulmonary and the systemic. The arteries, capillaries, and veins of the lungs constitute the **pulmonary circulation**, and those of the body generally the **systemic circulation.**

It should be added that there is a special arrangement, of great physiological significance, whereby the blood from the abdominal part of the alimentary canal, the spleen and the pancreas is conveyed by the *portal vein* to the liver, where it passes through a second capillary plexus before reaching the heart via the hepatic veins and the inferior vena cava. This is sometimes referred to as the **portal circulation** (p. 1328).

There is, in addition, the system of lymph-vessels which return some of the fluid from the tissues to the systemic veins. Lymph-glands are associated with the lymph-vessels, and together they constitute the **lymphatic system.**

TISSUES OF VASCULAR SYSTEM

The tissues of which the various parts of the vascular system are composed are: endothelium, areolar tissues, white fibrous tissue, elastic tissue, plain muscle, and cardiac muscle. Of these, endothelium alone is found in all parts of the system. It lines the cavities of the heart, the arteries, the arterioles, the veins, and the lymph-vessels, and it is almost the only constituent of the walls of the majority of the capillaries.

The **heart** consists mainly of cardiac muscle with a certain amount of areolar tissue, white fibrous tissue and elastic tissue; and its cavities are lined with a single layer of endothelial cells.

The cardiac muscle is peculiar, inasmuch as its cells are striated like voluntary muscle but are devoid of a cell-membrane (p. 1235). They branch and anastomose with one another, and their nuclei are central (Fig. 351, p. 403).

The **arteries** are composed of plain muscle, areolar tissue, white fibrous tissue, elastic tissue, and endothelium. All the arteries are lined with a single layer of endothelial cells, but the other tissues are present in different amounts in different vessels. The tissues are arranged in three coats.

In arteries of the largest size elastic tissue predominates, so that by their

FIG. 1050.—PHOTOMICROGRAPH OF LONGITUDINAL SECTION OF SMALL ARTERY.

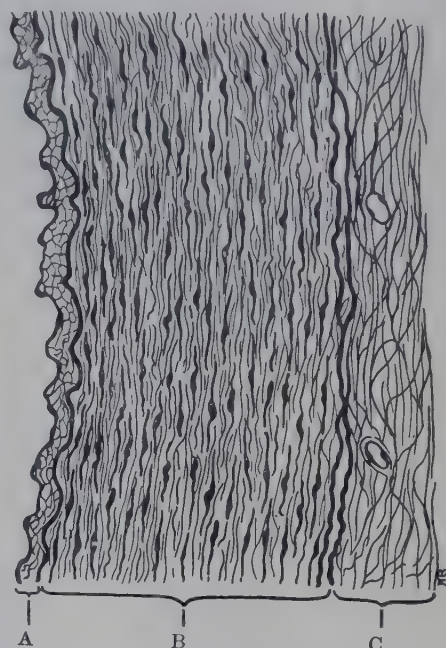

FIG. 1051.—TRANSVERSE SECTION OF WALL OF LARGE ARTERY.

A, Inner coat. B, Middle coat. C, Outer coat.

distension, as blood is suddenly forced into them by the contractions of the heart, the smaller vessels may be preserved from sudden great strain, whilst the elastic recoil of the distended walls keeps up a steady onflow of blood in the arteries in the intervals between the contractions of the heart.

All parts of the body are not equally active at the same time, and it is obvious that an active part will require more blood during its activity than it does when it is quiescent. Therefore it is necessary that the flow of blood to any particular tissue or organ shall be capable of regulation. The regulation is obtained by means of plain muscle, which predominates in the arteries of medium and small size.

The muscle consists of spindle-shaped cells which, for the main part, are arranged in spiral bundles in the middle parts of the walls of the arteries, where they form, with a little intermingled areolar tissue, the middle coat (*tunica media*) of the artery.

The muscle-fibres are not under control of the will, but they are under control of the nervous system. Therefore, when there is a call from any area for more blood the muscle-fibres relax, the calibres of the arteries enlarge, and more blood is permitted to flow through them; and, when less blood is required, the muscle-fibres contract and the lumina of the arteries are diminished.

The constituent parts of the **inner coat** (*tunica intima*) in arteries of medium size are the *endothelial lining*, a thin *subendothelial layer* of fine areolar tissue and a layer of elastic fibrils, running more or less longitudinally, or an elastic

fenestrated membrane called the *elastic lamina*. In the smaller arteries the subendothelial tissue disappears. The smallest arteries are devoid of the elastic lamina also.

In the larger arteries, on the other hand, the subendothelial tissue increases in amount and contains more elastic fibrils which merge into the elastic lamina, so that the boundary between the two is lost; whilst in the largest arteries the combined subendothelial tissue and elastic lamina are blended with the middle coat, which itself consists mainly of layers of elastic fibrils.

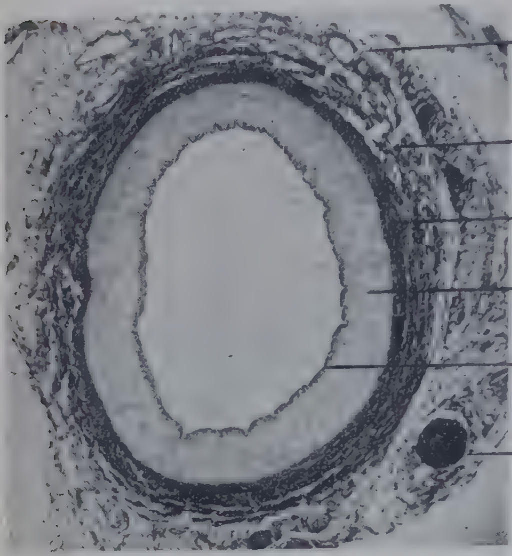

FIG. 1052.—PHOTOMICROGRAPH OF TRANSVERSE SECTION OF SMALL ARTERY.

In typical arteries — that is, arteries of medium size—the **middle coat** (*tunica media*) consists mainly of plain muscle-fibres bound together in more or less spiral strata by fine areolar tissue.

As the arteries become smaller and the middle coat is reduced, the muscular strata become fewer and fewer until only a single layer of scattered fibrils remains (Fig. 1053). In the largest arteries the muscle-fibres are largely replaced by elastic fibrils.

The **outer coat** (*tunica adventitia*) of an artery consists almost entirely of fine fibrous tissue in which lie many fibrous tissue cells. In all but the smallest arteries numerous elastic fibres also are present. The elastic element is specially strong near the middle coat in small and medium-sized vessels, and is sometimes described as an external elastic membrane. The outer coat of some arteries contains also plain muscle-fibres arranged longitudinally.

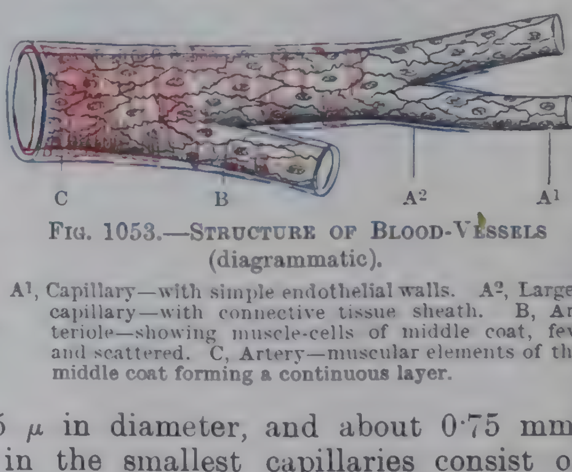

FIG. 1053.—STRUCTURE OF BLOOD-VESSELS (diagrammatic).

A1, Capillary—with simple endothelial walls. A2, Larger capillary—with connective tissue sheath. B, Arteriole—showing muscle-cells of middle coat, few and scattered. C, Artery—muscular elements of the middle coat forming a continuous layer.

The outer coat is the strongest and least friable coat of the artery. It disappears from the smallest arteries as the muscle-fibres disappear, but is very strong around small, medium, and large arteries.

In addition to their three coats, arteries are enclosed in a **sheath** of the surrounding fibro-areolar tissue.

Capillaries measure from 8 μ to 12·5 μ in diameter, and about 0·75 mm. in length. Their walls are simple, and in the smallest capillaries consist of elongated elastic and contractile endothelial cells with sinuous edges, pointed extremities, and oval nuclei. The cells are cemented to one another along their margins by intercellular cement which readily stains with nitrate of silver. In places the cement-substance appears to accumulate, forming minute spots indicative of the less perfect apposition of the edges of the cells. Here and there on the outer surfaces of the capillaries there are isolated cells called **Rouget cells.** They have been thought to be contractile, but their function is uncertain. For detailed discussion of anatomical and functional aspects of capillaries, consult Krogh (1929).

The larger capillaries are invested by an areolar tissue sheath consisting largely of branched cells which are united to one another and to the endothelial cells of the capillary-wall.

Capillaries are arranged in networks, and there are great variations in the size and form of the meshes of these networks in different tissues.

In some organs (*e.g.*, liver, suprarenal glands) the capillary-like spaces between the cells of the organ are not true capillaries. They have been developed by the growth of columns of cells of the organ into blood-spaces which are then

broken up into narrow channels. These channels are not completely lined with endothelium and the cells of the organ are therefore in direct contact with the blood; they have been called **sinusoids** (Minot, 1900).

In erectile tissue also there are no true capillaries, since the small arteries open directly into cavernous spaces, lined with endothelium, from which the blood is drained by the small veins.

The walls of **veins** are similar in structure to those of arteries; they are, however, thinner—so much so that, although veins are cylindrical tubes when

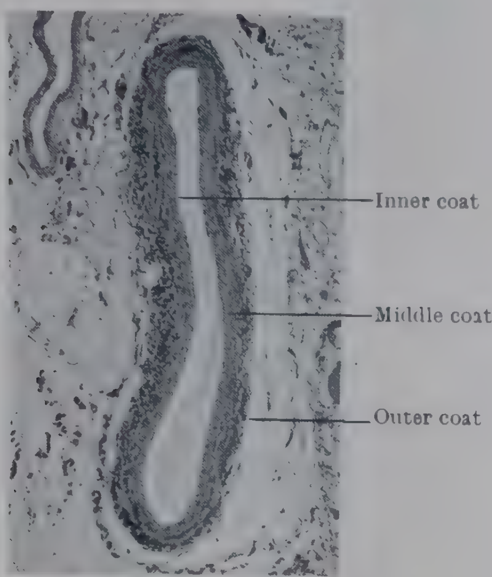

FIG. 1054.—PHOTOMICROGRAPH OF TRANSVERSE SECTION OF SMALL VEIN.

FIG. 1055.—TRANSVERSE SECTION OF WALL OF GASTRIC VEIN.

A, Inner coat. B, Middle coat.
C, Outer coat (with longitudinal muscle).

full of blood, they collapse when empty and their lumina almost disappear. The structural details of the three coats vary considerably in different veins. Like the arteries, the veins are enclosed in fibro-areolar sheaths.

In the majority of the veins the **inner coat** includes an internal endothelial layer, a middle layer of subendothelial areolar tissue, and an outer layer of elastic tissue. The inner coat of a vein is less brittle than the inner coat of an artery, and is more easily peeled off from the middle coat. The subendothelial tissue is a fine fibrillated areolar tissue, less abundant than in the arteries, and in many cases it is absent. The elastic layer consists of lamellæ of elastic fibres which are arranged longitudinally; it rarely has the appearance of a fenestrated membrane.

One of the chief peculiarities of the inner coat of veins is the presence of folds of its substance which constitute **valves** (Fig. 1056). The cusps of the valves are of semilunar shape, and they are usually arranged in pairs. Their convex borders are continuous with the vessel-wall, and their free borders are turned towards the heart; whilst, therefore, they do not interfere with the free flow of blood from the periphery, they prevent any backward flow towards it, and they help to sustain the column of blood in all vessels in which there is an upward flow. Each cusp is formed by a fold of the endothelial layer, strengthened by a little areolar tissue. As a general rule, the wall of the vein is dilated on the cardiac side of each valve into a shallow pouch or sinus; consequently, when the veins are distended they assume a nodulated appearance. Competent valves do not occur in the large veins of the trunk or in the portal system of veins in the adult (p. 1364). They are more numerous in the deep veins than in the superficial veins of the limbs, and in the veins of children than in the veins of adults. (See also Franklin, 1927, 1929.)

The presence of valves in the superficial veins of the forearm is readily demonstrated by Harvey's simple, classical experiment (Pl. LXXIX, p. 1216). The venous return being obstructed by pressure on the upper arm, a finger is placed on one of the distended veins, which is then emptied of its blood as far as the nearest valve by stroking it upwards. The column of blood will be sustained by the valve while the part of the vein below it

between the right and left pulmonary veins forms the anterior boundary of a section of the pericardial cavity called the oblique sinus.

The base is limited below by the inferior part of the atrio-ventricular groove, in which the principal vein of the heart—the coronary sinus—lies ; its upper border is in relation with the pulmonary arteries. At the upper part of its left border a small fold of pericardium, called the *fold of the left vena cava*, descends from the left pulmonary artery to the upper left pulmonary vein (see p. 1242). Further, it is from the base that the visceral layer of the pericardium, which elsewhere completely

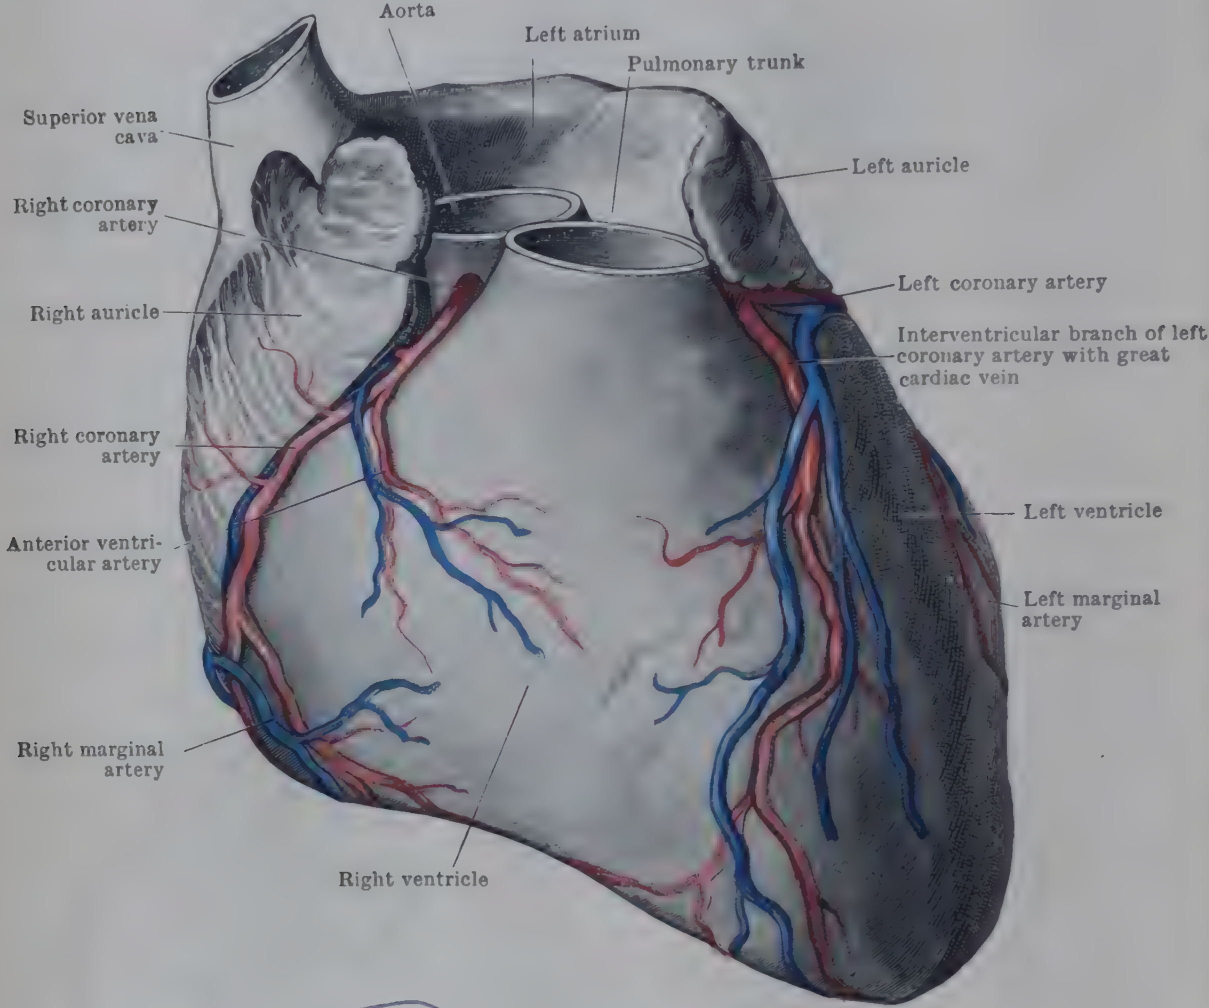

Fig. 1058.—Sterno-Costal Surface of Heart.

invests the heart, is reflected on to the fibrous layer, the lines of reflexion corresponding with the orifices of the great vessels.

In the fœtus and young child the atrial portion of the heart forms not only the base but also the posterior part of the inferior or diaphragmatic surface.

The **apex of the heart**, bluntly rounded, is formed entirely by the left ventricle. It is directed downwards, forwards, and to the left, and is situated, under cover of the left lung and pleura, behind the fifth left intercostal space, or behind the sixth rib, 3 or 3½ inches from the anterior median line. The *apex-beat* of the heart may be seen and felt in that situation, where also the stethoscope is placed to hear the sound of the mitral valve (p. 1489).

The **sterno-costal surface** is directed upwards, forwards, and to the left. It is opposite the body of the sternum and the medial ends of the cartilages of the third, fourth, fifth and sixth ribs of the right side, and a greater extent of the corresponding cartilages of the left side. This surface is incompletely separated into upper and lower sections by the upper part of the atrio-ventricular groove, which runs obliquely from the right side of the pulmonary trunk to the lower end of the right border (Fig. 1058). The upper section of the surface, which is concave forwards, is formed by the atria ; it is separated from the sternum by the ascending aorta and

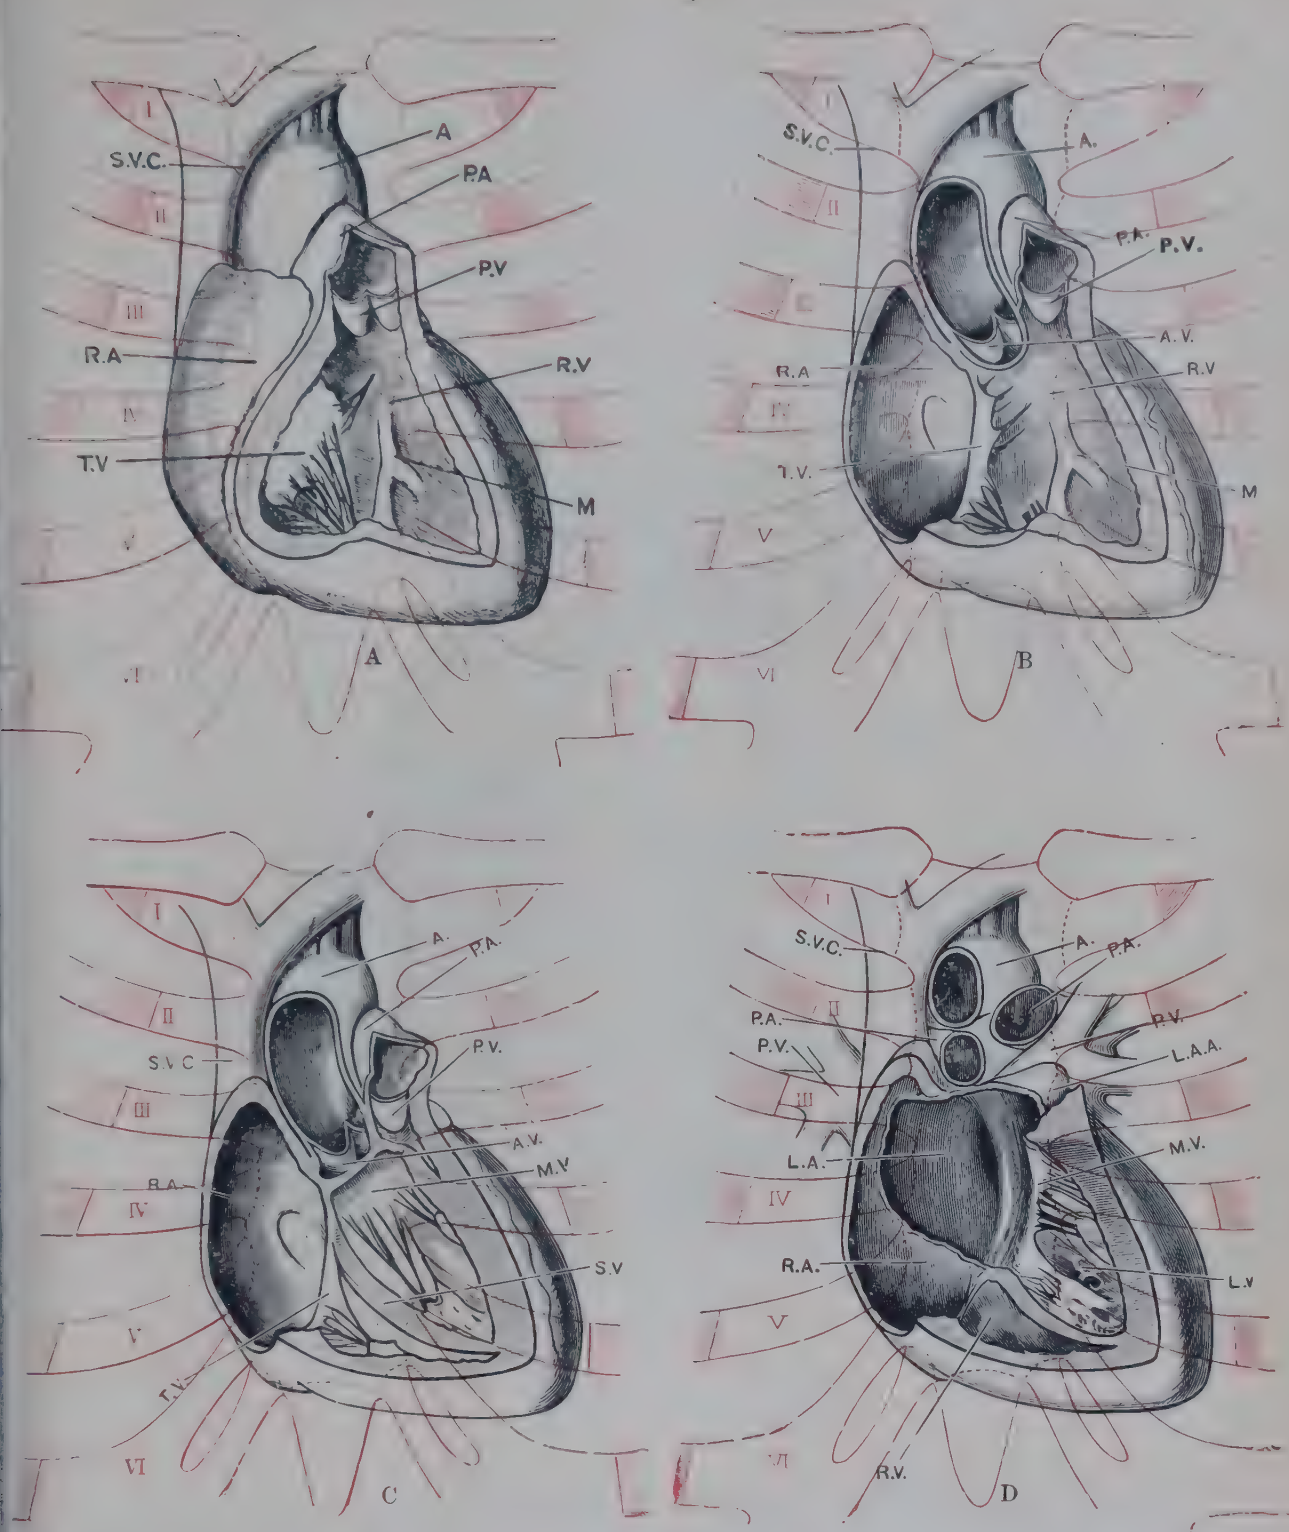

FIG. 1059.—RELATIONS OF CAVITIES AND VALVES OF HEART TO ANTERIOR WALL OF THORAX. (From photographs of a formalin-hardened subject, with the heart dissected *in situ.*)

In A the anterior wall of the right ventricle has been removed and the pulmonary trunk opened.

In B the anterior walls of the ascending aorta and of the right atrium have been removed ; also the anterior cusp of the tricuspid valve.

In C the greater part of the ventricular septum has been removed, and the anterior cusp of the mitral valve exposed.

In D the ascending aorta, anterior cusp of mitral valve, pulmonary trunk, and atrial septum have been removed ; the cavities of the left atrium and left ventricle are exposed.

the pulmonary trunk; from its lateral parts the auricles of the atria project forwards and, curving medially, embrace those great vessels. The lower section of the sterno-costal surface is convex; it is formed by the ventricular part of the heart, and is divided, by an **anterior interventricular groove**, into a smaller left and a larger right part. The orifices of the pulmonary trunk and the aorta, the former anterior to the latter, are at the junction of the atrial and ventricular parts of the sterno-costal surface.

The **upper border** of the sterno-costal surface is formed by the two atria—chiefly the left atrium. It is in relation with the bifurcation of the pulmonary trunk and its two branches; the superior vena cava enters the heart at its right end.

The **right border** is formed by the right atrium. It is in relation with the right pleura and lung (the phrenic nerve with its accompanying vessels intervening) and it is sometimes marked by a shallow groove—the *sulcus terminalis*—which passes from the front of the superior vena cava to the front of the inferior vena cava, and marks the position of a ridge in the interior of the atrium (p. 1229).

The **lower border** of the sterno-costal surface is sharp, thin, and usually concave, corresponding with the curvature of the anterior part of the diaphragm; it is formed mainly by the right ventricle, but near the apex by the left ventricle. It lies, almost horizontally, in the angle between the diaphragm and the anterior wall of the thorax, passing from the lower end of the right border behind the xiphisternal joint to the apex.

The **left border** separates the sterno-costal surface from the left surface of the heart.

The **left surface** is formed mainly by the left ventricle, and only to a small extent by the left atrium and its auricle; it is convex from above downwards and from before backwards. It is crossed at its widest part by the left part of the atrio-ventricular groove, and narrows towards the apex of the heart. It is separated by the pericardium and the pleura (the phrenic nerve and its accompanying vessels intervening) from the left lung, which is excavated to receive it. It descends obliquely, with a convexity towards the left, from the left end of the upper margin to the apex.

The **diaphragmatic surface** is formed by the ventricular part of the heart. It rests upon the diaphragm, chiefly on the central tendon, but, towards the left side, on a small portion of the muscular substance also; and it is divided into two areas —a smaller to the right and a larger to the left—by an oblique antero-posterior groove called the **inferior interventricular groove**. It is separated from the base by the inferior part of the atrio-ventricular groove.

For the surface-anatomy of the heart, see Figs. 1059, 1062 and p. 1488.

CHAMBERS OF HEART

Atria.—The **atrial portion** of the heart is cuboidal in form, with an anterior concave surface. Its cavity is divided into two chambers—the right and left atria—by a septum which runs from the anterior wall backwards and to the right so obliquely that the right atrium lies anterior and to the right, and the left atrium posterior and to the left.

The long axis of each atrium is vertical, and each possesses a well-marked ear-shaped prolongation, known as the **auricle**, which projects forwards from its anterior and upper angle.

The **right atrium** receives, posteriorly, the superior vena cava above and the inferior vena cava below. Between them, and a little above its middle, it is crossed behind by the lower right pulmonary vein on its way from the hilum of the lung to the left atrium. It is continuous below and in front with the right ventricle, at the atrio-ventricular orifice. Above and in front, it is in relation with the ascending aorta, and from that part of the atrium the right auricle is prolonged forwards and to the left. Its right side forms the right border of the heart, and is separated by the pericardium from the right phrenic nerve and its accompanying vessels, and the right pleura and lung. Behind and on

ie left, the right atrium is limited by the septum which separates it from the ‹ft atrium.

Interior of Right Atrium.—The walls are lined with a glistening membrane alled **endocardium**, and are smooth except anteriorly and in the auricle, where uscular bundles, called the **musculi pectinati**, form a series of small vertical olumns. The musculi pectinati spring from a network of ridges in the auricle and un downwards and backwards to end behind in a crest, called the **crista terminalis**. 'he crista terminalis, which corresponds in position with the sulcus terminalis p. 1228) on the external surface, indicates the junction of the primitive sinus 'enosus with the atrium proper (see p. 1371).

The opening of the superior vena cava, devoid of a valve, is situated at the

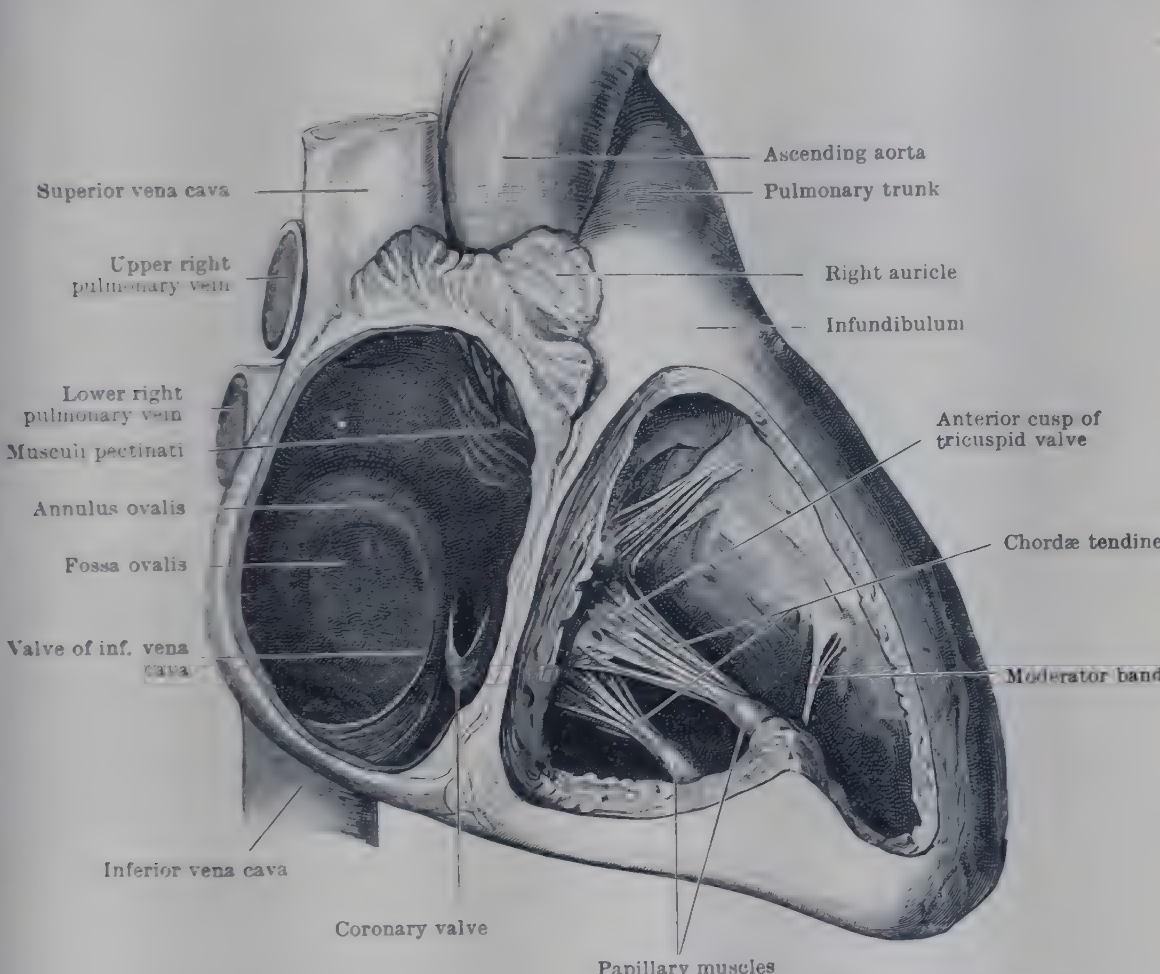

FIG. 1060.—CAVITIES OF RIGHT ATRIUM AND RIGHT VENTRICLE OF HEART.

upper and posterior part of the cavity. At the lower and posterior part is the orifice of the inferior vena cava, bounded, anteriorly, by the vestigial **valve of the inferior vena cava**, and immediately in front and to the left of that valve, between it and the atrio-ventricular orifice, is the opening of the coronary sinus, guarded by the unicuspid **coronary valve**. The **right atrio-ventricular orifice**, guarded on the ventricular side by a tricuspid valve, is known also as the **tricuspid orifice**. It is situated in the inferior part of the anterior boundary, and admits the tips of three fingers. A number of small fossæ are scattered over the walls, and into some of them small veins from the substance of the heart—**venæ cordis minimæ**—open directly by minute orifices. In the septal wall is an oval depression, called the **fossa ovalis**. It is bounded above and in front by a raised margin—the **annulus ovalis**—which is continuous, below, with the valve of the inferior vena cava; the fossa is the remains of the **foramen ovale**, through which the right atrium communicated with the left atrium before birth. Even in the adult a portion of the aperture persists at the upper part of the fossa in about one in five cases. Between the orifices of the superior and inferior venæ cavæ, and behind the upper part of the fossa ovalis, the posterior wall of the atrium may sometimes be seen to bulge forwards a little; the

bulge is called the **intervenous tubercle**, and it has been supposed to help in directing the blood from the superior vena cava to the tricuspid orifice during fœtal life (see p. 1385).

The **valve of the inferior vena cava** is a thin and sometimes fenestrated fold of endocardium and subendocardial tissue which extends from the anterior and lower margin of the orifice of the inferior vena cava to the anterior part of the annulus ovalis. It varies very much in size, and is usually of falciform shape; its apex is attached to the annulus ovalis and its base to the margin of the inferior caval orifice. It is an important structure in the fœtus, directing the greater part of the blood from the inferior vena cava through the foramen ovale into the left atrium (p. 1384).

The **valve of the coronary sinus** is a fold of endocardium placed at the right margin of the orifice of the coronary sinus. It is usually single and is almost invariably incompetent; but it serves to direct the blood from the coronary sinus forwards to the atrio-ventricular orifice.

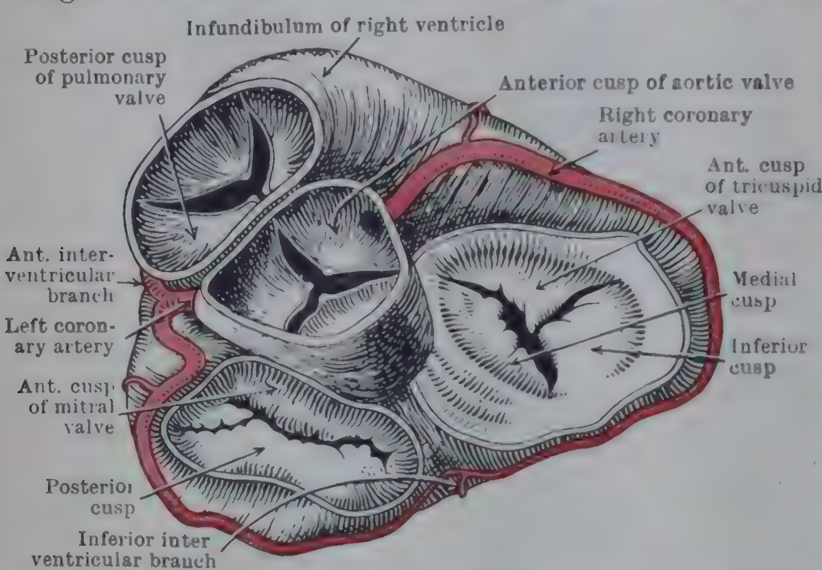

Fig. 1061.—Base of the Ventricles of the Heart, showing Atrio-Ventricular and Arterial Orifices with their Valves, and the Coronary Arteries.

The **left atrium** is in relation behind with the descending thoracic aorta and the œsophagus, but is separated from them by the pericardium and its oblique sinus (Fig. 1063). Its lower part is continuous in front with the left ventricle. Its sterno-costal surface is concave, and lies in close relation to the ascending aorta, the pulmonary trunk, and the left coronary artery. Its right side, formed by the interatrial septum, is directed forwards and to the right. Its left side forms a very small portion of the left surface of the heart, and from it, at its junction with the antero-superior surface, the long and narrow left auricle is prolonged forwards round the left side of the ascending aorta and the pulmonary trunk. Four pulmonary veins enter the upper part of the posterior surface, two on each side.

Interior of Left Atrium.—The walls are lined with endocardium, and are smooth except in the auricle, where musculi pectinati are present, and on the septum, in a position corresponding with the upper part of the fossa ovalis on the right side, where there are several musculo-fibrous bundles radiating forwards and upwards. These septal bundles are separated at their bases by small semilunar depressions, in the largest of which a remnant of the foramen ovale may be found. The apertures of venæ cordis minimæ are scattered irregularly over the wall, and in the inferior part of the anterior boundary is the **left atrio-ventricular** or **mitral orifice** (Figs. 1063, 1065). The orifice is oval in form; its long axis runs obliquely from above downwards and to the right. It is capable of admitting the tips of two fingers, and it is guarded on the ventricular side by a valve formed of two large cusps and known as the **left atrio-ventricular** or **mitral valve**.

Ventricles.—The **ventricular portion** of the heart is conical and slightly flattened. The base, directed backwards and upwards, is partly continuous with the atrial portion and partly free. It is perforated by four orifices—the two atrio-ventricular, the aortic, and the pulmonary. The atrio-ventricular orifices are placed inferiorly, one on each side; above and between them is the aortic orifice, whilst the orifice of the pulmonary trunk is still higher up and farther forward, and slightly to the left of the aortic orifice (Fig. 1061).

In the triangle between the atrio-ventricular and the aortic orifices a

mass of dense fibrous tissue is embedded—the *fibrous trigone*—which is the representative of the os cordis of the ox. It is continuous with the upper part of the interventricular septum, and with fibrous rings which surround the apertures at the bases of the ventricles.

The ventricular portion of the heart is divided into right and left chambers by the **ventricular septum**, which is placed obliquely, with one surface directed forwards and to the right, and the other backwards and to the left; its anterior end lies to the right of the apex of the heart. The margins of the septum are indicated on the two surfaces of the ventricular part of the heart by anterior and inferior interventricular grooves.

The **right ventricle** is triangular in form. Its base is directed upwards and to the right, and, in the greater part of its extent, it is continuous with the right atrium, with which it communicates by the atrio-ventricular orifice; but its left and upper angle is free from the atrium, and gives origin to the pulmonary trunk. Its inferior wall rests upon the diaphragm. The left or septal wall bulges into its interior, and on that account the transverse section of the cavity has a semilunar outline (Fig. 1064).

Interior of Right Ventricle.—The cavity itself is a bent tube consisting of two parts: an inferior portion or **body**, which communicates with the atrium through the atrio-ventricular orifice; and an antero-superior part—the **infundibulum**—which ends in the pulmonary trunk (Fig. 1060). In the angle between the two limbs there is a thick ledge of muscle called the **infundibulo-ventricular crest**.

S.V.C. Superior vena cava.
T. Tricuspid orifice.

The **right atrio-ventricular or tricuspid orifice** is guarded by the **right atrio-ventricular or tricuspid valve**. The three cusps are an *inferior*, a *medial* or septal, and an *anterior* which intervenes between the atrio-ventricular orifice and the infundibulum. Each cusp consists of a fold of endocardium, strengthened by a little enclosed fibrous tissue. The bases of the cusps are attached to a fibrous ring at the atrio-ventricular orifice, where they are usually continuous with one another, but they may be separated by small secondary cusps which fill the angles between the main segments. The apices of the cusps project into the ventricle. The margins, which are thinner than the central portions, are notched and irregular. The atrial surfaces are smooth. The ventricular surfaces are roughened, and, like the margins and apices, they give insertion to the **chordæ tendineæ**. The chordæ tendineæ are fine tendinous cords which pass to the cusps from conical muscular projections on the wall of the ventricle called the **papillary muscles** (Fig. 1060).

The **pulmonary orifice** is in front and to the left of the tricuspid orifice. It is guarded by a **pulmonary valve** composed of three semilunar segments, two of

which are placed in front and one behind. The convex or outer border of each segment is attached to the wall of the pulmonary artery at its root. The inner border is free, and it presents at its middle a small **nodule**. On each side of the nodule there is a small, thin marginal portion, of semilunar form, called the **lunule**. Each segment of the valve is composed of a layer of endocardium on its ventricular surface, an endothelial layer on its arterial surface, continuous with the inner coat of the artery, and an intervening stratum of fibrous tissue. Both the attached and the free margins of the cusps are strengthened by fibrous bands, and strands of condensed fibrous tissue radiate from the outer border of

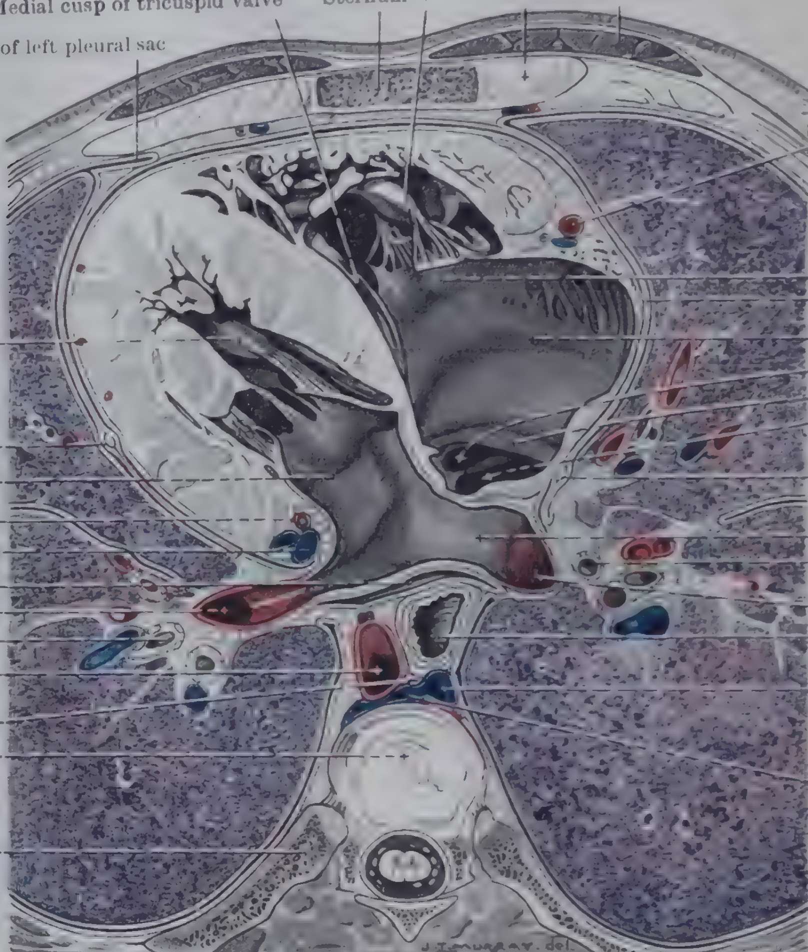

FIG. 1063.—TRANSVERSE SECTION OF THORAX OF YOUNG MAN SHOWING THE CAVITIES AND SOME RELATIONS OF THE HEART. The section is in the Plane D—D, Fig. 1109, p. 1330.

each cusp to the nodule, but they do not enter the lunules. When the valve closes, the nodules are closely apposed, the lunules of the adjacent segments of the valve are pressed together, and both nodules and lunules project vertically upwards into the interior of the artery.

The walls of the ventricle are lined with endocardium. They are smooth in the infundibulum, but are rugose and sponge-like in the body owing to the inward projection of numerous muscular bundles called the **trabeculæ carneæ**. The trabeculæ are of three kinds: the simpler are merely columns raised in relief on the wall of the ventricle. The second class are rounded bundles, free in the middle, but attached at each end to the wall of the ventricle. One special bundle of the second group, the so-called **moderator band**, is attached by one end to the septum, and by the other to the sterno-costal wall at the base of the anterior papillary muscle; it has been supposed to prevent over-distension of the cavity; but its chief importance is that it conducts the right septal division of the atrio-ventricular bundle from the septum to the anterior wall of the ventricle (see p. 1236). The **papillary muscles**—which may be reckoned as a third variety—project into the cavity of the ventricle. Their bases are continuous with the wall of the ventricle, and their

apices give origin to numerous chordæ tendineæ which are attached to the apices, the borders, and ventricular surfaces of the cusps of the tricuspid valve.

The papillary muscles of the right ventricle are—(1) a large *anterior* muscle, from which the chordæ pass to the anterior and inferior cusps of the valve; (2) a smaller and more irregular *inferior* muscle, sometimes represented by two or more segments, from which chordæ pass to the inferior and medial cusps; and (3) a group of small *septal* muscular cones, varying in size and number, which project from the septum and are united by chordæ to the anterior and medial cusps.

The walls of the right ventricle, other than the septal, are much thinner than those of the left, but the trabeculæ carneæ are coarser and less numerous in the right ventricle than in the left.

The **left ventricle** is a conical chamber, and its cavity is oval in transverse section. The base is directed upwards and backwards, and in the greater part of its extent it is continuous with the corresponding atrium, with which it communicates through the mitral orifice; but above and to the right of its communication with the atrium it is continued into the ascending aorta. Its apex is the **apex of the heart**. The inferior wall is related to the diaphragm; it is flat, and it forms two-thirds of the diaphragmatic surface of the heart. The sterno-costal wall is convex, and it forms nearly one-third of the ventricular part of the sterno-costal surface of the heart The right or septal wall is concave towards the interior. The walls of the left ventricle are three times as thick as those of the right ventricle (Fig. 1064). They are thickest around the widest part of the cavity, and that is about one-fourth of its length from the base. The muscular part is thinner at the apex than elsewhere; but the thinnest part of the wall is the upper posterior part of the septum, which is membranous.

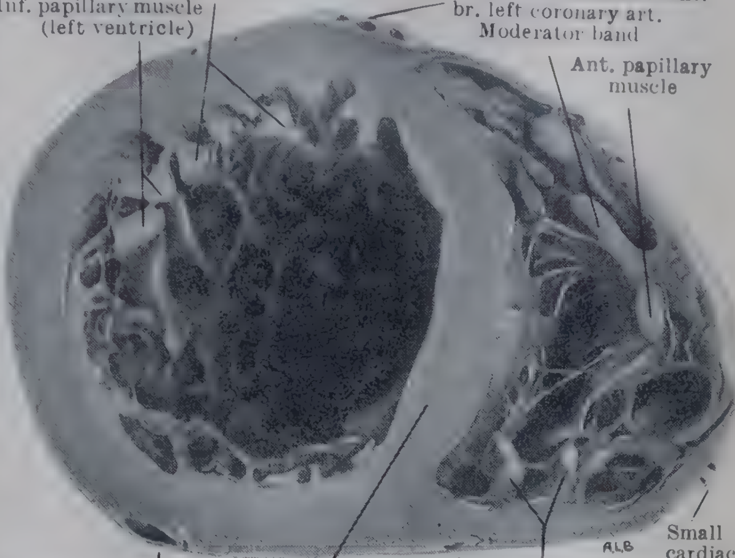

Fig. 1064.—Transverse Section of Ventricles of Heart.

Interior of Left Ventricle.—The cavity is separable into two parts. The lower part is the **body**, which communicates with the left atrium through the atrio-ventricular orifice. The upper and anterior part is called the **aortic vestibule**, for it leads into the aorta; its walls consist of tough fibrous tissue, and are therefore non-contractile (Fig. 1065).

The **left atrio-ventricular** or **mitral orifice** is oval; its long axis runs obliquely from above downwards and to the right; it is guarded by a bicuspid valve known as the **left atrio-ventricular** or **mitral valve**. The two cusps are triangular and of unequal size. The smaller *posterior cusp* is placed behind and to the left of the orifice; and the larger *anterior cusp* is placed in front and to the right, between the mitral and aortic orifices. The bases of the cusps are either continuous with each other at their attachments to the fibrous ring around the mitral orifice, or they are separated by small secondary cusps of irregular form and size. The apices of the cusps project into the cavity of the ventricle. The atrial surfaces are smooth; the ventricular surfaces are roughened by the attachments of the chordæ tendineæ, which are connected also with the apices and with the margins, which are notched and irregular. The structure is the same as that of the cusps of the tricuspid valve (p. 1231); but the ventricular surface of the anterior (*aortic*) cusp is relatively smooth, and therefore the blood-flow into the aorta is not impeded.

The **aortic orifice** is circular; it is immediately above and to the right of the mitral orifice, from which it is separated by the anterior cusp of the mitral

valve, and it is guarded by the **aortic valve**, formed of three semilunar segments, one of which is placed in front and the other two behind. The structure and attachments of the cusps of the aortic valve are similar to those of the cusps of the pulmonary valve (see p. 1231).

The walls of the left ventricle are lined with endocardium. The septum and the upper part of the sterno-costal wall are relatively smooth. The rest is sponge-like owing to numerous fine **trabeculæ carneæ**. There are two **papillary muscles**—a *superior* and an *inferior*. They are much larger than the papillary muscles of the right ventricle; and each is connected by chordæ tendineæ with both cusps of the mitral valve. Two or three fine strands, corresponding in

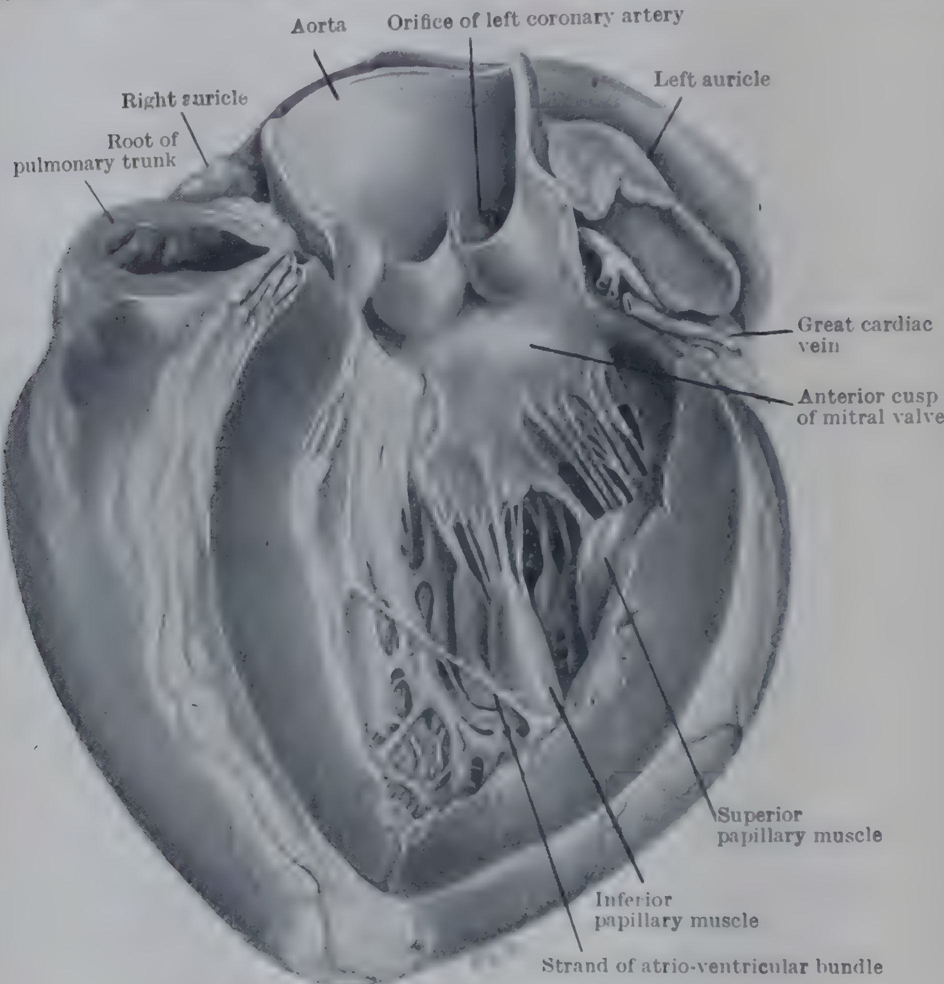

Fig. 1065.—Cavity of Left Ventricle of Heart.
The greater part of the pulmonary trunk has been removed, and the aorta opened to show the aortic valves.

position to the moderator band in the right ventricle, but formed entirely by branches of the atrio-ventricular bundle (p. 1237), are usually to be found passing across the cavity from the septum to the superior papillary muscle (Fig. 1065).

The **ventricular septum** is a strong musculo-membranous partition. It is placed obliquely, so that one surface looks forwards and to the right and bulges into the right ventricle, whilst the other looks backwards and to the left and is concave towards the left ventricle. It extends from the right of the apex to the interval that separates the pulmonary and tricuspid orifices from the aortic and mitral. Its sterno-costal and inferior borders correspond respectively with the anterior and inferior interventricular grooves. Almost the whole of the septum is muscular, and is developed from the wall of the ventricular part of the primitive heart. The upper posterior part is developed from the septum of the truncus arteriosus. It is called the **membranous part**, for it is entirely fibrous; and it is the thinnest portion of the ventricular walls. It separates the aortic vestibule not only from the upper part of the right ventricle, but also from the lower part of the right atrium. Occasionally it is defective or absent; the two ventricles then communicate with each other directly.

Structure of Heart

The walls of the heart consist mainly of peculiar striated muscle, called the myocardium, which is enclosed between the epicardium, or visceral layer of the pericardium, externally, and the endocardium internally.

The **epicardium** consists of white fibrous and of elastic tissue, the latter forming a distinct reticulum in the deeper part. The surface which looks towards the pericardial cavity is covered with flat polygonal mesothelial plates.

The **endocardium** lines the cardiac cavities and is continuous with the inner coats of the vessels. It is much thinner than the epicardium. It consists, like the inner coat of the blood-vessels, of an inner lining of flat endothelial cells, a layer of fine subendothelial areolar tissue, and an external elastic layer which usually assumes the form of a fenestrated membrane.

The fibres of the **myocardium** differ from those of ordinary voluntary striated muscle in several ways: they are less distinctly striated; they appear to be made up of short, oblong cells joined end-to-end by transverse discs, the exact nature of which is not quite certain; the nuclei of the cells lie centrally; many of the cells fork towards one end or give off a side-branch, and, as these branches are united by transverse discs to similar processes of adjacent fibres, the whole forms an irregular network (Fig. 351, p. 403). Moreover, still more peculiar fibres—the **fibres of Purkinje**—are found immediately subjacent to the subendocardial tissue. The fibres of Purkinje are large cells which unite with one another at their extremities; their central portions consist of granular protoplasm, in which sometimes one but more frequently two nuclei are embedded, and the peripheral portion of each cell is transversely striated. Those cells present, in a permanent form, a condition which is transitory in all other striated muscle-cells.

The network of cardiac muscle-cells forms sheets and strands which have a more or less characteristic and definite arrangement in different parts of the heart; they are separated and at the same time bound together by intervening lamellæ of fine areolar tissue. By careful dissection, and after special methods of preparation, it is possible to recognize many layers and bundles, some of which are, however, probably artificially produced.

In the **atria** the muscular fasciculi fall naturally into two groups: (*a*) superficial fibres common to both atria; (*b*) deep fibres peculiar to each atrium.

The superficial fibres are most numerous on the sterno-costal aspect and in the neighbourhood of the atrio-ventricular sulcus. They run transversely across the atria and a few of them dip into the atrial septum.

The deep fibres are:—(1) Looped fibres; the ends of the looped fibres are attached to the fibrous rings around the atrio-ventricular orifices and the fibres pass antero-posteriorly over the atria. (2) Annular fibres which surround (*a*) the extremities of the large vessels which open into the atria, (*b*) the auricles, and (*c*) the fossa ovalis.

In the **ventricles** the muscular fasciculi form more or less definite V-shaped loops which begin and end at the fibrous rings which surround the large orifices at the bases of the ventricles. These loops embrace the cavities of either one or both ventricles, one limb of each loop lying on the outer surface of the heart and the other in the interior, and some of the loops possess very acute bends whilst others are very open.

The superficial fibres on the sterno-costal surface pass towards the left, those on the inferior surface towards the right. At the apex all are coiled into a whorl or *vortex* through which they pass into the interior of the ventricular walls and run towards the base, some in the septum and others in the papillary muscles. The various bundles which have been described can, according to Mall, be resolved into two main systems. One system arises from the infundibulum and the root of the aorta, that is, from the remains of the primitive aortic trunk: it is called the "bulbo-spiral" system. The other springs from the region of the primitive venous sinus and is termed the "sino-spiral". Both systems are separable into superficial and deep portions, and the general plan of more or less spirally curved V-shaped loops is retained in each; but the details of the arrangement are too complex for consideration within the limits of an ordinary text-book (see MacCallum, 1900; Mall, 1911). For an analysis of the muscular structure of the heart from a functional point of view, in relation also to its blood-supply and to the conducting system, see Robb & Robb (1942).

The heart also possesses a fibrous skeleton which strengthens its orifices, is continuous with the roots of the aorta and the pulmonary trunk, and gives attachment to the valves and the muscular layers. *Fibrous rings* surround the atrio-ventricular, pulmonary and aortic orifices, and the *fibrous trigone*, situated in the interval between the atrio-ventricular and aortic orifices, has already been mentioned (p. 1231). The back of the infundibulum is also connected to the aorta by a fibrous band which is continuous with the membranous part of the ventricular septum.

The valves of the heart consist of a thin layer of fibrous tissue, continuous with the fibrous rings that surround the orifices and covered by a reduplication of the lining membrane. Atrial muscle-fibres are found in the base of the atrio-ventricular valves, but the associated capillary vessels extend into the valves for a distance of not more than 3 mm. in health (Dow & Harper, 1932). Otherwise, these valves, like the pulmonary and aortic, are avascular.

Conducting System of Heart (Neuro-myocardium).—It would appear from the description of the muscular structure of the heart that the atrial and ventricular muscle-fibres are entirely separated from each other by the fibrous rings which surround

the atrio-ventricular orifices; that, however, is not the case, for the two groups are connected by a bundle of muscle-fibres of pale colour and rudimentary structure which lies immediately subjacent to the endocardium and constitutes the atrio-ventricular bundle. This, however, is only part of the conducting system of the heart.

The function of initiating the sequence of events in the cycle of heart-action, of controlling its regularity, and of transmitting the impulses from atria to ventricles, resides in certain special parts of the myocardium. Heart-muscle has the power of rhythmic contraction. One collection of the special myocardial tissue, situated in the wall of the right atrium, sets the pace of the rhythm; another, extending from the septal wall of the right atrium across the otherwise fibrous atrio-ventricular junction, and spreading out to form a subendocardial network in the walls of the ventricles, propagates the rhythm of the atrial contraction to the ventricles. If the connecting link is severed, experimentally or by disease, the remarkable result follows that the ventricles contract independently of the atria, and with a much slower rhythm. This condition is known as "heart-block".

FIG. 1066.—NERVE-FIBRILS AND NERVE-TERMINALS IN THE ATRIO-VENTRICULAR BUNDLE OF THE RHESUS MONKEY. (After Nonidez, 1943.)

The parts concerned in this controlling and conducting mechanism are composed of myocardial tissue, distinguished from the ordinary cardiac muscle not only because it is less highly differentiated from the original cells, but also because the muscle-fibres are intimately associated with numerous nerve-cells and nerve-fibrils (Fig. 1066), which probably have a share in the initiation and transmission of the rhythmic contraction of the heart (Morison, 1912; Meiklejohn, 1913; Stotler & McMahon, 1947; Akkeringa, 1949). The functional connexion between the parts of the heart has thus a neuro-muscular basis; and the system as a whole may therefore be distinguished as the "neuro-myocardium". Its parts are named the *sinu-atrial node*, the *atrio-ventricular node*, and the *atrio-ventricular bundle* with its right and left septal divisions, which end in the *terminal subendocardial network*. For references to the earlier literature, see Holmes (1921).

The **sinu-atrial node** (Keith and Flack) is a small collection of vascular neuromyocardium situated in the wall of the right atrium at the upper end of the crista terminalis.

The **atrio-ventricular node** (Tawara) is a nodule of the same kind of vascular tissue, situated in the septal wall of the right atrium immediately above the opening of the coronary sinus.

The atrio-ventricular bundle (Kent, His) is a pale bundle, about the thickness of a match, of the special muscle-fibres, with which nerve-fibres are associated. It springs from the node, runs forward on the septum, passes through the fibrous atrio-ventricular junction, and appears beneath the endocardium of the right ventricle under cover of the medial (septal) cusp of the tricuspid valve. There it swells out a little, and then passes forwards along the posterior and lower border of the membranous upper part of the ventricular septum to the upper end of the muscular part of that septum, where it divides into right and left branches (Figs. 1067, 1068).

The *right septal division* continues the course of the main bundle on the muscular part of the septum towards the moderator band, along which it passes from the septum to the anterior wall of the ventricle, which it reaches at the base of the anterior papillary muscle (see Truex & Copenhaver, 1947). Fine branches arise from it as it reaches the moderator band, and these continue along the septum to the base of the inferior papillary muscle. One or two of them occasionally appear as free threads passing across the cavity of the ventricle.

The *left septal division* pierces the ventricular septum between its membranous and muscular parts and appears on the left side of the septum, along which it runs, as a flattened band, to the base of the inferior papillary muscle of the left ventricle. As it passes over the septum, two or three fine strands usually spring from it and pass across the cavity of the ventricle to the base of the superior papillary muscle (Fig. 1065). These strands are very distinct in the hearts of the sheep and calf, in which both septal branches and the network in which they end can be recognized very easily by the naked eye as whitish structures beneath the endocardium.

The bundle and its divisions are readily dissected in the heart of an ungulate, but in the human heart they are less easily displayed (Walls, 1945).

The **terminal subendocardial network** (Purkinje) is spread out beneath the endocardium of the greater part of both ventricles. It receives the branches of the bundle at the bases of the papillary muscles, which are consequently the first parts of the ventricles to contract. The network forms a characteristic collar around each papillary muscle, the apex of the muscle being free of the network. The meshes of the network become finer, and

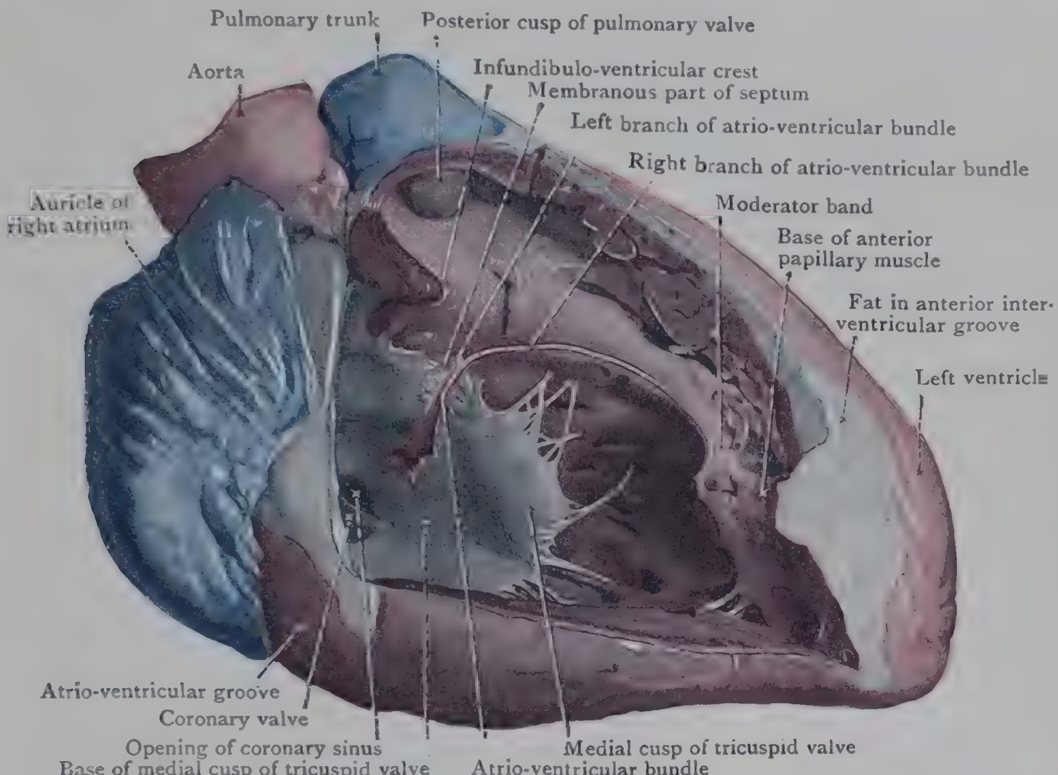

Fig. 1067.—Dissection of Right Ventricle of Heart showing Course and Division of Atrio-Ventricular Bundle.

then disappear, towards the atrio-ventricular and arterial orifices of the ventricles. A striking picture of the distribution of the subendocardial network and of the course of the bundle and its branches may be obtained by the injection of Indian ink or other suitable coloured liquid into the sheath which surrounds the whole system. Good results are most easily obtained in the heart of an ungulate (Fig. 1068).

For a review of the anatomy of the conducting system of the vertebrate heart and the history of its investigation with full bibliography to date, see Davies & Francis (1946). For general observations on the system, consult Blair & Davies (1935), and for its development Shaner (1930) and Walls (1947).

Action of Heart.—The differences between the various parts of the heart, *e.g.*, the relative thickness of the walls of the chambers, are associated with the functions of the various chambers, and with the action of the heart in the maintenance of the circulation of the blood. The heart is a muscular pump, provided with receiving and ejecting chambers. It has three phases of action: (1) a period of atrial *systole* or contraction; (2) a period of ventricular contraction, which immediately succeeds the atrial contraction; (3) a period of *diastole* or rest.

During the period of rest the chambers, previously contracted, expand as the muscular fibres of the heart relax. The expansion is aided by the respiratory movements of the thorax, and, as it progresses, blood flows into the right atrium from the venæ cavæ and the coronary sinus, and into the left atrium through the four pulmonary veins. As the blood enters the atria, it begins at once to flow into the ventricles through the open atrio-

ventricular orifices, and the onward movement is completed by the contraction of the atria. The atrial systole begins with the contraction of the circular fibres which surround the mouths of the veins entering the atria, and thus the blood is prevented from passing back into the veins. As the contraction spreads, the atria are emptied and the ventricles become distended. Then the ventricular systole begins, the atrio-ventricular valves close, the arterial valves open, and, as the contraction proceeds, the blood is driven out of the ventricles through the arterial orifices—from the right ventricle into the pulmonary trunk, and from the left ventricle into the aorta.

When the ventricular contraction is completed, the period of systole is at an end and the period of diastole begins; and, so long as the heart remains alive, the cycle is repeated.

The work of the atria is merely to complete the discharge of the blood through the

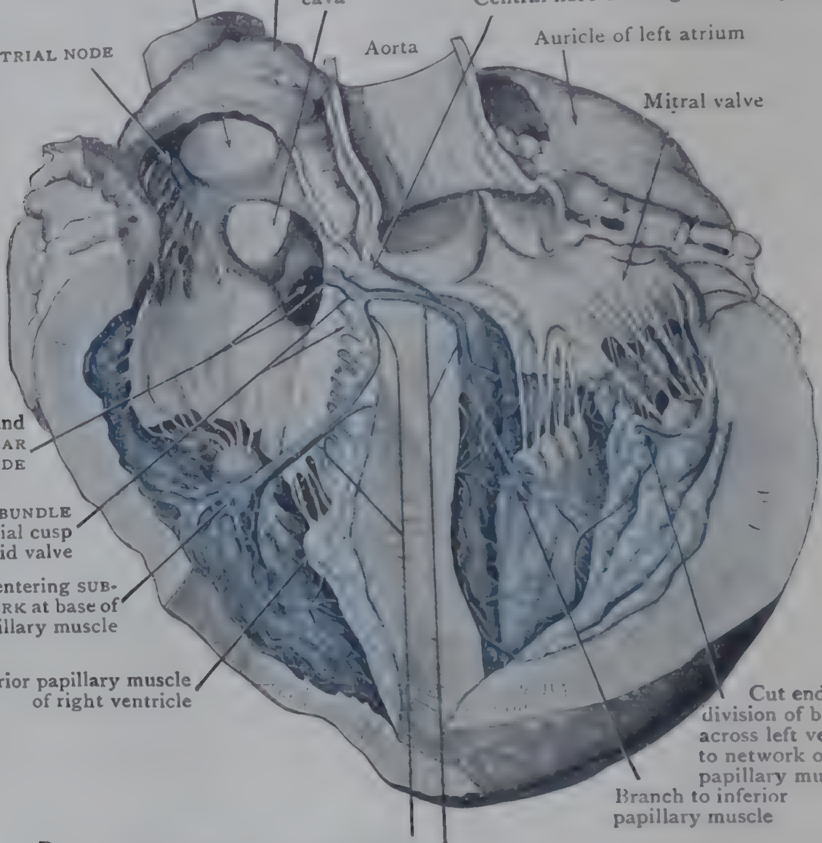

Fig. 1068.—Conducting System of Sheep's Heart; from Dissected and Injected Specimens.

widely open atrio-ventricular orifices into the ventricles and to expand the ventricles. For that purpose no great force is required; the walls of the atria are therefore thin. The work of the ventricles is much more severe; their walls are therefore thicker. The right ventricle, however, has only to exert sufficient force to drive the blood through the lungs to the left atrium—that is, through a comparatively short distance and against a relatively small resistance. Its walls are therefore thin compared with the walls of the left ventricle, which have to be sufficiently strong to force the blood through the whole body. The pressure created in the aorta (150 mm. Hg.) is about three times as great as that in the pulmonary arteries; corresponding to the relation between these pressures is the fact that the left ventricular wall is about three times as thick as the right (Fig. 1064).

Size of Heart.—The heart is about 5 inches (125 mm.) long, $3\frac{1}{2}$ inches (85 mm.) broad; its greatest depth from its sterno-costal to its diaphragmatic surface is $2\frac{1}{2}$ inches (60 mm.), and it is roughly estimated as being about the same size as the closed fist. The size, however, is variable even in health, the volume increasing at first rapidly, and then gradually, with increasing age, from 22 cc. at birth to 155 cc. at the fifteenth year, and to 250 cc. by the twentieth year. From that period to the fiftieth year, when the maximum volume (280 cc.) is attained, the increase is much more gradual, and after fifty a slight decrease sets in. The

volume is the same in both sexes up to the period of puberty, but thereafter it preponderates in the male.

Weight.—The average weight of the heart in the male adult is 11 ounces (310 grms.), and in the female adult 9 ounces (255 grms.); but the weight varies greatly, always, however, in definite relation to the weight of the body, the relative proportions changing at different periods of life. Thus, at birth the heart weighs 13½ drachms (24 grms.), and its relation to the body weight is as 1 to 130, whilst in the adult the relative proportion is as 1 to 205. The heart is said to increase rapidly in weight up to the seventh year, then more slowly up to the age of puberty, when a second acceleration sets in; but after the attainment of adult life the increase, which continues till the seventieth year, is very gradual.

These changes affect the whole heart, but the several parts also vary in their relation to one another at different periods of life. During fœtal life the right atrium is heavier than the left; in the first month after birth the two become equal; at the second year the right again begins to preponderate, and it is heavier than the left during the remainder of life. In the latter part of fœtal life the two ventricles are equal; after birth the left grows more rapidly than the right, until, at the end of the second year, a position of stability is gained, when the right is to the left as 1 to 2, and this proportion is maintained until death.

Capacity.—During life the capacity of the ventricles is probably the same, and each is capable of containing from three to four ounces of blood, whilst the atria are a little less capacious. After death the cavity of the right ventricle appears larger than that of the left.

Blood-Supply of Heart.—The walls of the heart are supplied by the **coronary arteries** (p. 1250), the branches of which pass through the interstitial tissue to all parts of the muscular substance and to the subendocardial and subepicardial tissues; the endocardium and the free parts of the valves are devoid of vessels. The capillaries, which are numerous, form a close-meshed network around the muscular fibres. Sometimes the valves contain a few muscular fibres, and in those cases they also receive some minute vessels (p. 1235). Special branches of the coronary arteries supply the conducting system of the heart (Haas, 1911; Gross, 1921). The right coronary supplies the atrio-ventricular node, the main bundle and the posterior branches of its left septal division; the left coronary supplies the anterior branches of the left division and assists the right coronary in the supply of the right septal division by sending a branch from the ventricular septum along the moderator band of the right ventricle.

The majority of the veins of the heart end in the coronary sinus, which opens into the lower part of the right atrium; some few small veins, however, open directly into the right atrium, and others are said to end in the left atrium, and in the cavities of the ventricles.

Lymph-Vessels of Heart.—A subendocardial plexus communicates through the substance of the heart with a superficial network beneath the epicardium. Efferent vessels from the subepicardial network follow the coronary arteries and end in right and left trunks which pass respectively to innominate and tracheo-bronchial glands (p. 1426).

Nerves of Heart.—The heart receives its nerves from the superficial and deep cardiac plexuses. The former lies below the aortic arch and the latter between the arch and the bifurcation of the trachea. Through the plexuses it is connected with the vagus, the accessory (through the vagus) and the sympathetic nerves (see p. 1138). After leaving the cardiac plexuses many of the nerve-fibres enter the walls of the atria and form a subepicardial plexus in which many ganglion-cells are embedded, especially near the terminations of the inferior vena cava and the pulmonary veins. From the subepicardial atrial plexus, nerve-filaments, with which nerve-cells are associated, pass into the substance of the atrial walls.

Other fibres from the cardiac plexuses accompany the coronary arteries to the ventricles, and upon those also nerve-cells are found in the region immediately below the atrio-ventricular sulcus.

The nerve-fibres which issue from the plexuses of the heart are non-medullated. They form fine plexuses around the muscle-fibres, and they end either in fine fibrils on the surfaces of the muscle-fibres, or in nodulated ends which lie in contact with the muscle-cells. Many nerve-fibres accompany the branches of the atrio-ventricular bundle (p. 1236). See also the account of the cardiac plexuses (p. 1138).

Abnormalities of Heart.—The **heart** may be transposed from the left to the right side of the body, a condition which is usually associated with general transposition of the viscera, and with the presence of a right aortic arch instead of a left.

The external form of the heart does not as a rule vary much, but occasionally the apex is slightly bifid, a character it normally possesses at an early stage of its development, and which is retained in the adult in many cetaceans and sirenians. The internal conformation of the heart deviates from the normal much more frequently; more particularly is this the case with regard to the septa which separate the right from the left chambers. The interatrial septum may be entirely absent, as in fishes; it may be fenestrated and incomplete, as in some amphibians; or the foramen ovale may remain patent, as in amphibians and reptiles.

The ventricular septum may be absent, as in fishes and amphibians, or incomplete, as in reptiles; when incomplete, it is usually the membranous part which is deficient, but perforations are occasionally found in the muscular portion.

The communication between the infundibulum of the right ventricle and the body of the ventricle may be constricted or the infundibulum may be entirely cut off from the remainder of the cavity. In such cases of "pulmonary stenosis" there is always an interventricular foramen, and the pulmonary arteries receive their blood from the aorta via a patent ductus arteriosus. Many congenital malformations of the heart are incompatible with life. (See also p. 1371, and consult Keith, 1909; Walmsley, 1929; Abbott, 1936.)

Radiographic Examination of Heart and Blood-Vessels.—The heart, having a solid wall and a cavity filled with blood, absorbs X-rays to such an extent that it causes a dense white shadow in radiographs. With modern apparatus the time of exposure can be reduced to $\frac{1}{25}$ of a second or less; this high speed prevents blurring by movement, and the cardiac outline appears quite sharp.

The general shape of the shadow of the **heart** with the great vessels is seen in Pl. LXV, p. 704. Apart from local modifications according to the phase of heart-action, it is important to note that the shape is greatly altered by the position of the diaphragm (Pls. LXVI, p. 705, LXVII, p. 720). These alterations are easily understood if it is remembered that the pericardium is firmly attached to the diaphragm, and that the arch of the aorta is prevented from descending to any great extent by the passage of its branches out of the thorax and of the left bronchus under it. Thus, with the descent of the diaphragm in full inspiration the mediastinum as a whole is elongated and the shadow of the heart in particular appears long and narrow (Pl. LXVI); at the same time it is more clearly defined, partly because the lungs have become more translucent (p. 721). As the diaphragm ascends the mediastinum shortens, until in full expiration the combined shadow of the heart and great vessels is quite broad (Pl. LXVII).

Screen examination permits direct observation of the alteration of the outline of the heart during systole and diastole, and the alterations produced by respiration may be studied as they take place.

These changes in the normal appearance of the heart are paralleled by permanent differences in persons of different build or who suffer from abnormal conditions in the thorax or the abdomen. Thus, in thin patients with marked emphysema (see p. 721) the air-content of the lungs is so much increased that the diaphragm is pushed much farther down than normal, and the heart may become so narrow that it is scarcely broader than the vertebral column. On the other hand, in stout patients with much intra-abdominal fat the diaphragm is elevated, and the cardiac shadow is broader than the average in all phases of respiration.

In the ordinary anterior radiograph of the chest, the shadows cast by the great vessels merge into that of the heart, but the aorta at least can always be distinguished in two places. The wide curve of the **ascending aorta** is visible to the right of the shadow of the vertebral column, while to the left of it the terminal part of the **arch** forms a rounded prominence known to radiologists as the aortic "knob" or "knuckle". When the heart-shadow is elongated in deep inspiration the shadow of the **pulmonary trunk** also may be seen (Pl. LXVI). The *left* subclavian vessels may sometimes be seen as they cross the apex of the lung. In children, the **superior vena cava** is prominent as it passes upwards to the right of the shadow of the vertebral column; but in adults it is visible only in cases of venous congestion. Low position of the diaphragm may render the **inferior vena cava** visible in the "cardio-hepatic angle" at the junction of the cardiac shadow with the right dome of the diaphragm (Pl. LXVI).

Peripheral blood-vessels are not usually seen in radiographs unless their walls are calcified. They may be shown, however, by the injection of thorium dioxide (thorotrast) by which means radiographs of even the cerebral arteries (Pl. LXXX, Fig. 1, p. 1217) may be produced. Unfortunately, the use of thorotrast is not free from risk as it is radio-active; this method, therefore, has to be restricted to the investigation of certain pathological conditions in which the desired information cannot be obtained in any other way.

PERICARDIUM

The **pericardium** is a fibro-serous sac which surrounds the heart. It lies in the middle mediastinum. It is attached below to the diaphragm, and above and behind to the roots of the great vessels. In front and behind it is in relation with structures in the anterior and posterior mediastina; laterally it is in close apposition with the pleural sacs.

The **fibrous pericardium** is a strong fibrous sac of conical form; its base is attached to the central tendon and to the adjacent part of the muscular substance of the diaphragm, and it is pierced by the inferior vena cava. At its apex and posteriorly it is gradually lost upon the great vessels which enter and emerge from the heart, and it gives sheaths to them—namely, the aorta, the two branches of the pulmonary trunk, the superior vena cava, the four pulmonary veins, and the ligamentum arteriosum. Its anterior surface forms the posterior boundary of the anterior mediastinum, and it is attached, above and below, by the sterno-pericardial

ligaments to the sternum. In the greater part of its extent it is separated from the anterior wall of the thorax by the anterior parts of the lungs and pleural sacs, but it is in direct relation with the left half of the lower portion of the body of the sternum and often with the medial ends of the cartilages of the fourth, fifth, and sixth ribs of the left side and the left sterno-costalis muscle. Its posterior surface forms the anterior boundary of the upper part of the posterior mediastinum; it is in relation with the œsophagus and the descending aorta, both of which it separates from the back of the left atrium (Fig. 1063). Each lateral surface is in close contact

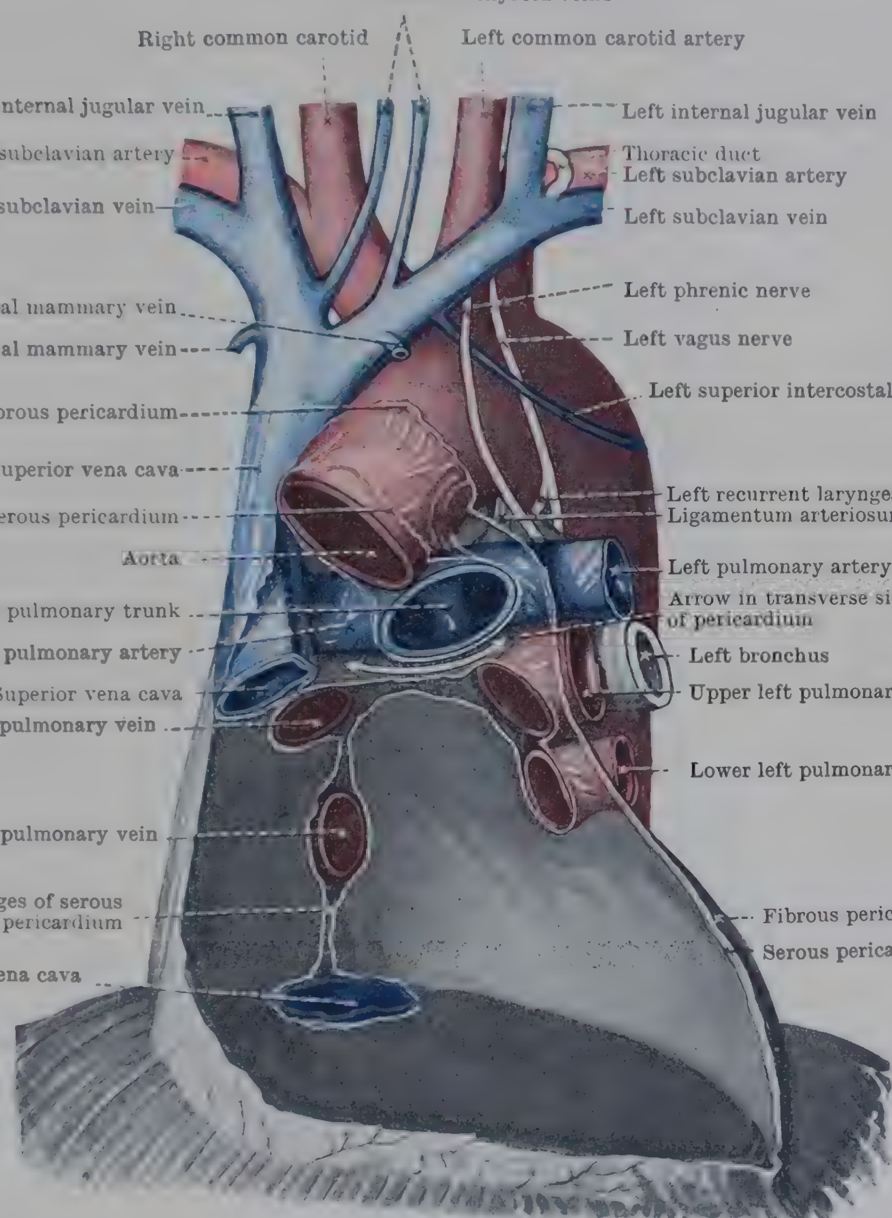

Fig. 1069.—Posterior Wall of Pericardium after Removal of the Heart.
Showing the relation of the serous pericardium to the great vessels.

with the mediastinal portion of the parietal pleura, the phrenic nerve and its accompanying vessels intervening. The inner surface of the fibrous sac is lined with, and is closely attached to, the parietal part of the serous pericardium.

The **serous pericardium** is a closed sac containing a little lubricating fluid. It is surrounded by the fibrous pericardium and invaginated by the heart. It is, therefore, separable into two portions—the parietal, which lines the inner surface of the fibrous sac, and the visceral, which ensheaths, or partially ensheaths, the heart and the great vessels; but the two portions are, of course, continuous with each other where the serous layer is reflected on to the great vessels as they pierce the fibrous layer. The majority of the great vessels receive only partial coverings from the visceral layer: thus, the superior vena cava is covered in front and on each side; the pulmonary veins in front, above, and below; and the inferior vena

cava in front and on each side. The aorta and the pulmonary trunk are enclosed together in a complete sheath of the visceral layer. Therefore, when the pericardial sac is opened from the front, it is possible to pass a finger behind them and in front of the atria, from the right to the left side, through a passage called the **transverse sinus** of the pericardium (Fig. 1069). The spaces or pouches which intervene between the vessels which receive partial coverings from the serous pericardium are also called sinuses; and the largest of them, which is called the **oblique sinus**, is bounded below and on the right by the inferior vena cava, and above and on the left by the lower left pulmonary vein. It passes upwards and to the right behind the left atrium, and lies in front of the œsophagus and the descending thoracic aorta.

A small fold of the serous pericardium, called the **fold of the left vena cava**, passes from the left pulmonary artery to the upper left pulmonary vein, behind the left end of the transverse sinus. It merits special attention because it encloses a fibrous strand—the *ligament of the left vena cava.* That is a remnant of the left superior vena cava, or duct of Cuvier, which atrophied at an early period of fœtal life. From the lower end of the ligament a small vein—*the oblique vein of the left atrium*—passes below the orifice of the lower left pulmonary vein, and descends to the coronary sinus; it represents the continuation of the duct of Cuvier to the heart (see pp. 1329, 1381).

Structure.—The fibrous pericardium is a dense unyielding fibrous membrane. The serous pericardium is covered on its inner aspect by a layer of flat mesothelial cells. The mesothelium rests upon a basis of mixed white and elastic fibres in which run numerous blood-vessels lymph-vessels, and nerves.

PULMONARY CIRCULATION

PULMONARY ARTERIES

The **pulmonary trunk** springs from the infundibulum of the right ventricle, and runs backwards and upwards, towards the concavity of the aortic arch, curving from the front round the left side of the ascending aorta to reach a plane behind it. It is slightly wider at its origin than the aorta, and is slightly dilated, immediately above the cusps of the pulmonary valve, into three shallow pouches or **sinuses**. It ends, by dividing into right and left pulmonary arteries, at the level of the sternal end of the second left costal cartilage. Its length is a little more than two inches.

Relations.—The pulmonary trunk is enclosed within the fibrous pericardium, and is enveloped, along with the ascending aorta, in a common sheath of the visceral layer of the serous pericardium (Fig. 1069). It lies behind the anterior end of the second left intercostal space, from which it is separated by the anterior margins of the left lung and pleural sac.

Its posterior relations are first the ascending aorta, and then the left atrium (Figs. 1058, 1061). To the right it is in relation with the auricle of the right atrium and the ascending aorta, and to the left with the auricle of the left atrium. Immediately above its bifurcation, between it and the aortic arch, is the superficial cardiac plexus of nerves.

Both the coronary arteries are in relation to its root—the right coronary artery on its right, the left at first behind and then on its left.

The **right pulmonary artery** is longer and wider than the left. It passes to the right lung, in its root, enters the hilum and descends, with the main bronchus, to the lower end of the lung (Fig. 1071).

Relations.—Before it enters the lung the right pulmonary artery passes behind the ascending aorta, the superior vena cava, and the upper right pulmonary vein. At first it lies below the arch of the aorta and the right bronchus, in front of the œsophagus, and above the left atrium and the lower right pulmonary vein; then it crosses in front of the right bronchus, immediately below its eparterial branch, and reaches the hilum of the

lung (Fig. 606, p. 719). In the lung the artery descends posterior and lateral to the main bronchus.

Branches.—Before entering the hilum it gives off a large branch which accompanies the eparterial bronchus to the upper lobe of the right lung. In the substance of the lung it gives off numerous branches which accompany the lobar and segmental branches of the right bronchus. (See Respiratory System, p. 720.)

The **left pulmonary artery**, shorter, narrower, and a little higher in position than the right, passes laterally and backwards from the bifurcation of the pulmonary trunk, and runs, in the root, to the hilum of the left lung; it then descends, in company with the main bronchus, to the lower end of the lung.

Relations.—Before it enters the lung it is crossed, *anteriorly*, by the upper left pulmonary vein; *posterior* to it are the left bronchus and the descending aorta; *above*, are

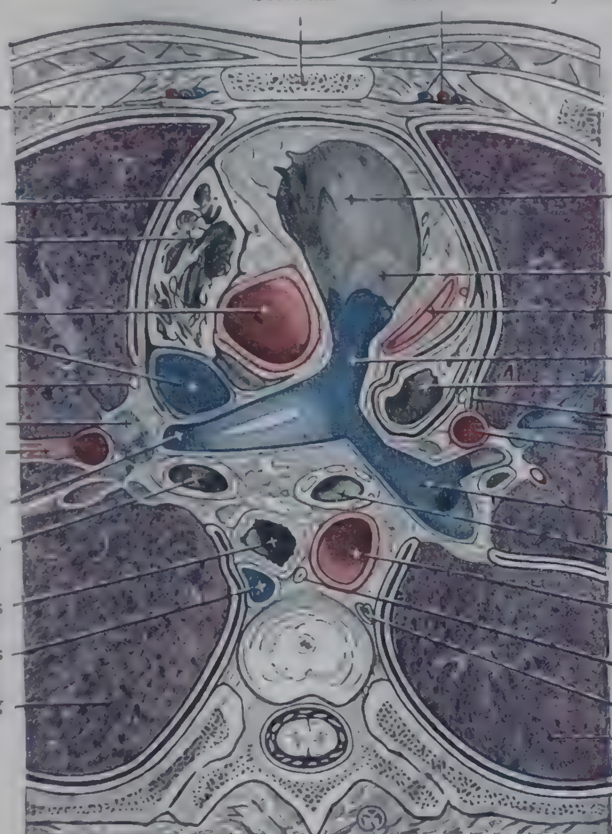

FIG. 1070.—TRANSVERSE SECTION OF THORAX OF YOUNG MAN THROUGH PULMONARY TRUNK AND ARTERIES. The section is in the plane C-C, Fig. 1109, p. 1330, and is seen from below.

the aortic arch (to which it is connected by the ligamentum arteriosum, pp. 1373, 1386) and the left recurrent laryngeal nerve; *below*, it is in relation with the lower left pulmonary vein (Figs. 606, 1071). After entering the lung it descends, like the right pulmonary artery, posterior and lateral to the stem bronchus.

Branches.—Just before it passes through the hilum it gives off a branch to the upper lobe of the left lung, and in the substance of the lung its branches correspond with the lobar and segmental branches of the left bronchus. (See also p. 720.)

Variations.—Abnormal formation of the **pulmonary trunk** is very uncommon and is associated with abnormality of the aorta (p. 1250). Congenital malformation of the right ventricle may cause stenosis (narrowing) of the trunk which may obliterate its lumen (p. 1239).

PULMONARY VEINS

The terminal **pulmonary veins** (Figs. 1057, 1063, and 1069), two on each side, open into the left atrium of the heart. Their tributaries arise in capillary plexuses in the walls of the pulmonary alveoli. By the union of the smaller veins larger vessels are formed which run in front of the bronchial tubes, and unite to form in each lobe a single efferent vessel which passes into the root of the lung. Thus there are

five main pulmonary veins, but, immediately after entering the root of the lung, the vessels from the upper and middle lobes of the right lung usually join together, and so only four terminal pulmonary veins open into the left atrium. Neither the main stems nor their tributaries possess valves.

Relations.—In the root of each lung the upper pulmonary vein lies below and in front

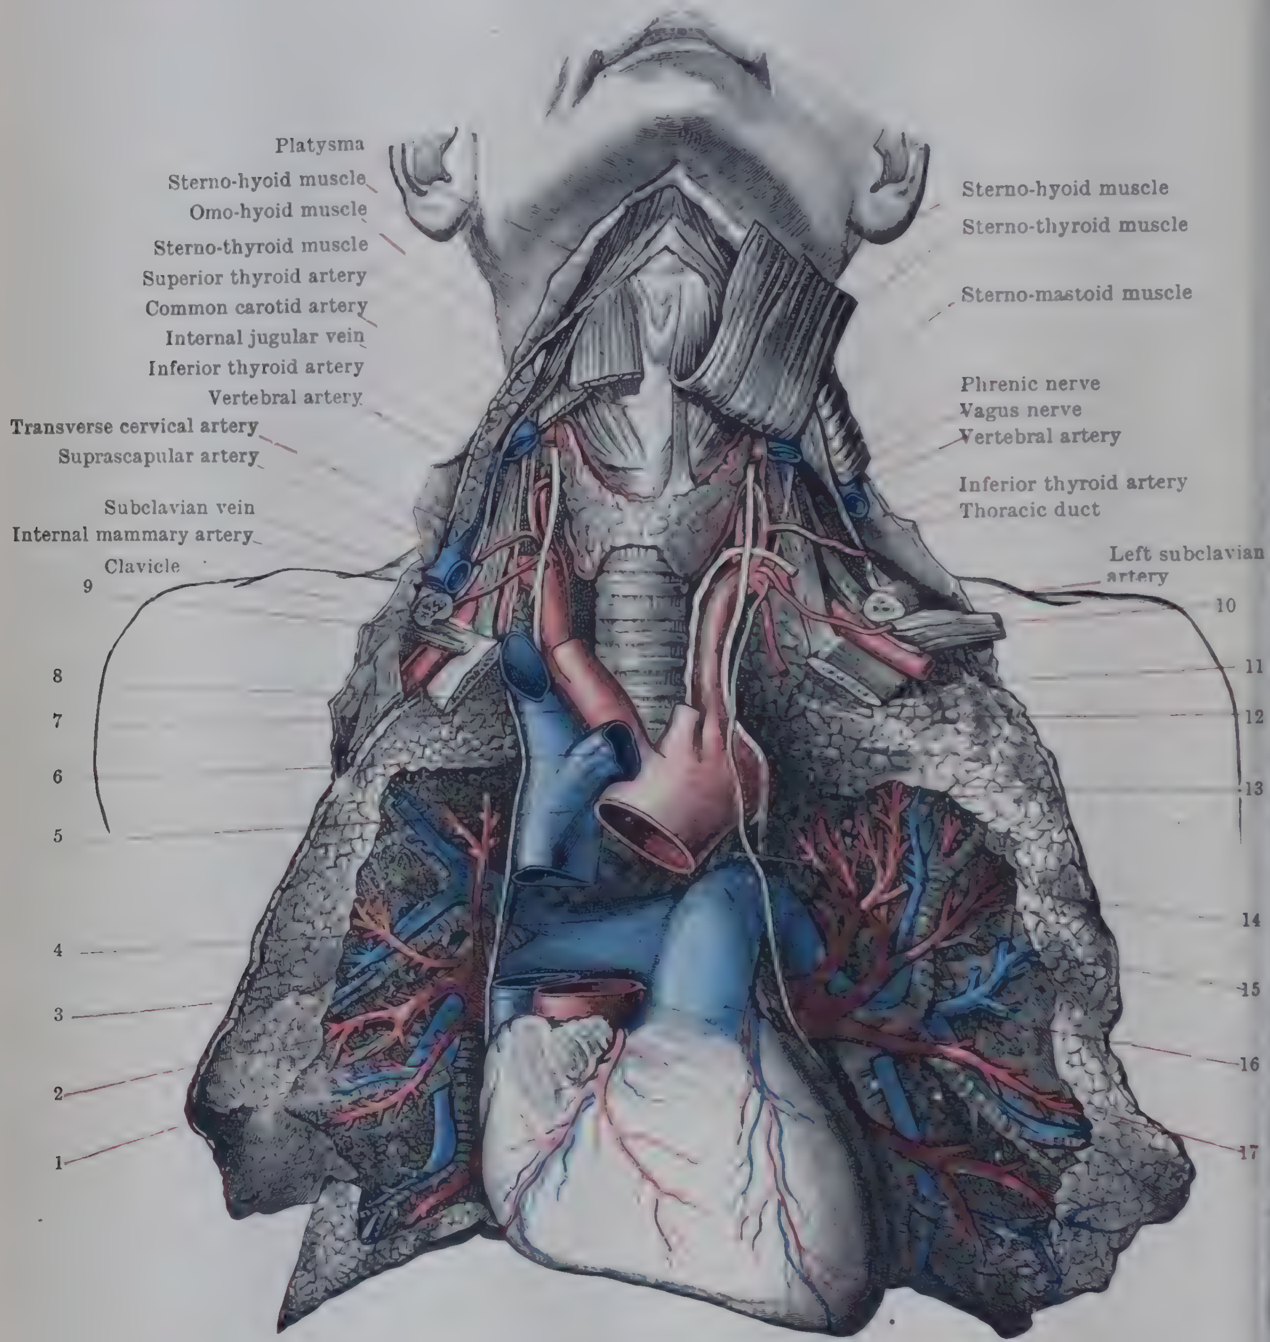

FIG. 1071.—PULMONARY ARTERIES AND VEINS AND THEIR RELATIONS.

17. Pulmonary trunk.

of the pulmonary artery (Fig. 606, p. 719). The lower pulmonary vein is in the lowest part of the root, and also in a plane posterior to the upper vein.

On the right side the upper pulmonary vein passes behind the superior vena cava, and the lower passes behind the right atrium. They both end in the upper and posterior part of the left atrium close to the atrial septum. *On the left side* both upper and lower pulmonary veins cross in front of the descending aorta, and they end in the upper and posterior part of the left atrium near its left border.

All four pulmonary veins perforate the fibrous layer of the pericardium, and receive partial coverings of the serous layer before they enter the atrium.

Variations.—The openings of the pulmonary veins into the left atrium of the heart may be reduced or increased in number. The commonest variations are the fusion of the left veins into a single trunk, and separate openings for the veins from all three lobes of the right lung.

SYSTEMIC CIRCULATION

ARTERIES

The systemic arteries all spring from the aorta, and the whole system, with reference to its branching and re-branching, is sometimes spoken of as the "arterial tree". The tissues of the body are supplied with blood through the ultimate branches, or *arterioles*, and the capillaries which arise from them; some tissues, however, are devoid of arteries, *e.g.*, the transparent cornea of the eye, articular cartilages, the epidermis of the skin with the nails and the hairs.

The larger arteries are naturally protected from injury by their situation both in the trunk and the limbs. In particular, the main arteries of the limbs emerge from the trunk into the medial side of the limb and run distally on the flexor side so that protection is more effective as the limbs are bent. Most main arteries pursue a more or less straight or evenly curved course, but some, for functional reasons, are very tortuous; for example, the facial artery because of the movements of the mandible, and the uterine artery probably in anticipation of necessary enlargement as the uterus grows during pregnancy. The tortuosity of arteries tends to increase or develop with age as changes occur in their coats.

The mode of division of arteries varies according to their situation and the areas they supply. The usual arrangement is illustrated by the arteries of the limbs, which give off a series of branches in succession yet retain their individuality as main vessels; some arteries end by dividing into two more or less equal branches—the most notable example is the aorta itself; a few arteries represent the combined origin of several branches which spring together from a short trunk, *e.g.*, the thyro-cervical trunk and the cœliac artery. The sectional area of the "arterial tree" increases steadily towards the periphery. When an artery divides into two, each branch is narrower than the parent trunk but the two together have a greater capacity; and the combined sectional area of all the arterioles is much greater than that of the aorta.

Functional Distribution.—The functional distribution of some arteries (pulmonary, renal) is obvious, but Hilton (1863) raised the interesting question whether the distribution of other arteries, not confined to single organs, may have a general functional significance. For example, he named the maxillary artery the "masticatory artery" because of its distribution to the bones, muscles and nerve concerned. The subclavian, apart from its continuation to the upper limb, he considered to be essentially a "respiratory artery", analysing the distribution of its branches including the vertebral artery, which supplies the respiratory nerve-centres. The palate is another example, its multiple blood-supply being related to the part it plays in respiration, mastication and deglutition.

Shellshear (1920) quotes Hilton on this interesting and rather neglected subject, and discusses the functional distribution of the cerebral arteries.

Anastomoses.—There are few arteries in the body that are entirely independent of their neighbours, for the great majority communicate with other arteries through branches that unite to form *anastomoses*. In some regions anastomosis occurs directly between arteries of considerable size, so that there is an even distribution of blood to the parts supplied, *e.g.*, the union of the two vertebral arteries to form the basilar artery which takes part in the remarkable "circulus arteriosus" at the base of the brain (Fig. 1084, p. 1272), and the formation of the "arterial arcades" in the supply of the intestines (Fig. 1094, p. 1300). But the most widespread anastomoses take place between the smaller arteries, and there are usually so many communications between arterioles that extensive networks are formed from which the capillaries arise. In the limbs there are notable anastomoses between medium-sized arteries around the joints (Pls. LXXXI, p. 1296; LXXXIV, p. 1313); these anastomoses are of surgical importance as they are the means by which the blood-supply to the distal part of the limb is maintained by the opening up of a *collateral circulation* after ligature of a main artery. Quiring (1949) provides a convenient, illustrated survey of the chief anastomoses, both arterial and venous, in the body.

Arterio-Venous Anastomoses.—Direct connexions, without the intervention of capillaries, occur between small arteries and veins in many situations in the body. The best known are the anastomoses that form the basis of the 'glomera' found in the skin of the palmar surface of the digits (Fig. 1072). Contraction and relaxation of the arteriole determine the flow of the blood either through the capillaries or direct into the venule, the glomus thus acting as a "by-pass" for the capillaries. Grant & Bland (1930) have obtained evidence that this mechanism is of some importance in the regulation of temperature.

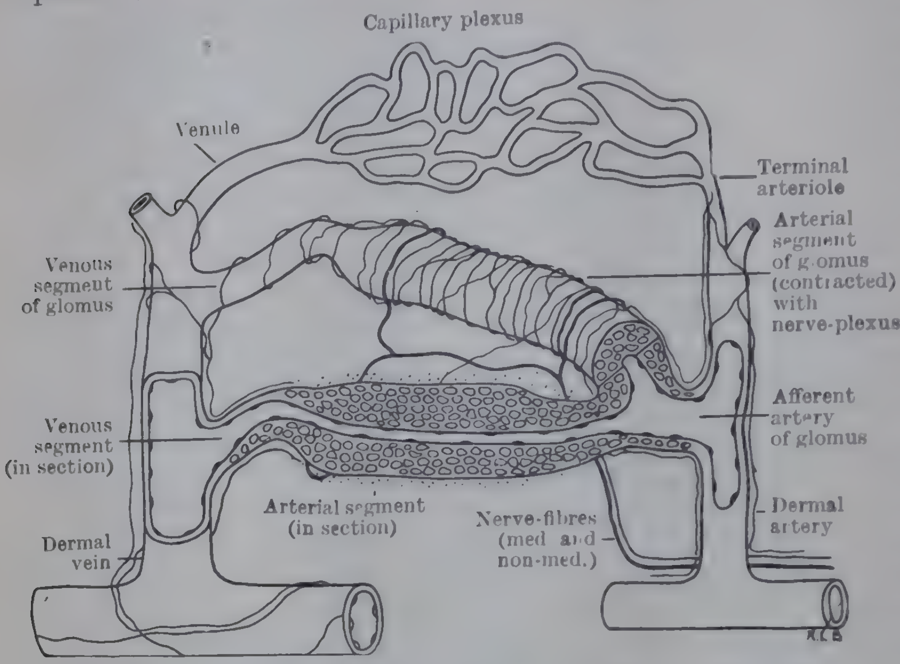

FIG. 1072.—ARTERIO-VENOUS ANASTOMOSIS IN THE SKIN OF THE HAND. (After Masson, 1937.)

The glomus coccygeum (p. 809) contains numerous arterio-venous anastomoses; they are present in the kidney (p. 736), in the spleen (p. 831), in the nasal mucous membrane (p. 1212), in the villi of the small intestine (p. 626), and in the wall of the stomach (Walder, 1950); Hayek (1940) has described them in the lung and Nonidez (1942) in the ganglia of the sympathetic trunk. For a general review of the whole subject consult Clark (1938) and Boyd (1939).

End-Arteries.—Small arteries which do not anastomose with others and therefore (apart from capillary communications) constitute the sole source of blood to the areas they supply are called *end-arteries* ; they are of pathological importance since occlusion of such an artery causes death of the tissues it supplies. End-arteries are found in the distribution of the main vessels to some organs, *e.g.*, kidney (p. 735) and spleen (p. 831) ; and in the case of the blood-supply of the substance of the spinal cord and brain, although communications do exist, there is reason to believe that the smaller vessels act as "functional end-arteries" owing to the difficulty of establishing an effective collateral circulation. One of the most important of the end-arteries is the central artery of the retina (p. 1172), since its occlusion causes blindness.

AORTA

The **aorta** is the main trunk of the general arterial system. It begins at the base of the left ventricle and runs upwards (**ascending aorta**), with an inclination to the right and forwards, to the level of the second right costal cartilage ; continuing upwards it curves first to the left and then backwards and downwards, until it reaches the left side of the lower border of the fourth thoracic vertebra (**arch of aorta**) ; from that level it runs downwards (**descending aorta**) through the thorax into the abdomen, where it ends, on the left of the median plane, on the front of the fourth lumbar vertebra, by bifurcating into the two common iliac arteries. The descending portion of the aorta is, for convenience, divided into the *descending thoracic aorta*, and the *abdominal aorta*.

Ascending Aorta.—The ascending aorta lies in the middle mediastinum. It springs from the base of the left ventricle, behind the left margin of the sternum, opposite the lower border of the third left costal cartilage. From its origin it passes upwards, forwards, and to the right, and it ends by becoming the arch of the aorta behind the right margin of the sternum at the level of the second costal cartilage. Its *length* is from 2 to 2¼ inches (about 55 mm.) and its diameter is a little over 1 inch (about 28 mm.). In the adult it is a little narrower at its origin than the pulmonary artery, but as age advances it enlarges and exceeds that vessel in size. The diameter, however, is not uniform throughout the whole

length of the ascending aorta. Its root is dilated owing to three bulgings in its wall—the **sinuses of the aorta**. The sinuses are immediately opposite the cusps of the aortic valve. One is therefore anterior in position, and two posterior. At a higher level a diffuse bulging of the right wall is sometimes known as the *great sinus of the aorta*.

Relations.—The ascending aorta is completely enclosed within the fibrous pericardium which blends above with the sheath of the vessel, and it is enveloped, together with the pulmonary trunk, in a tube of the serous pericardium. At its origin it has the infundibulum of the right ventricle and the pulmonary trunk in front, the transverse sinus of the pericardium and the left atrium behind, and the right atrium on its right side. In the upper part of its course the ascending aorta is overlapped by the anterior margins of the right lung and right pleural sac, whilst posterior to it are the

FIG. 1073.—TRANSVERSE SECTION THROUGH SUPERIOR MEDIASTINUM AT LEVEL OF FOURTH THORACIC VERTEBRA.

right pulmonary artery, the right bronchus, and the left margin of the superior vena cava. The superior vena cava lies on the right side and partly behind the upper part of the ascending aorta, whilst the pulmonary trunk is at first in front and then, at a higher level, on its left side.

Branches.—Two branches arise from the ascending aorta, viz., the right and the left coronary arteries (p. 1250). The right coronary artery springs from the anterior sinus of the aorta, and the left artery from the left posterior sinus (Fig. 1061).

Arch of Aorta.—The arch of the aorta lies in the superior mediastinum opposite the lower part of the manubrium sterni. It begins behind the right margin of the sternum, at its union with the second costal cartilage, and ends at the left side of the lower border of the fourth thoracic vertebra. The arch makes two curves, one with the convexity upwards (Fig. 1069), and the other with the convexity to the left and slightly forwards. From its origin it runs for a short distance upwards and to the left anterior to the trachea; then it passes backwards, round the left side of the trachea to the left side of the body of the fourth thoracic vertebra (Fig. 1073). Finally it turns downwards to become continuous with the descending aorta.

The arch has at first the same diameter as the ascending aorta, a little more than one inch (28 mm.), but after giving off three large branches, the diameter is reduced to a little less than one inch (23 mm.).

Relations.—*In front* it is related to the remains of the thymus, and is overlapped, almost equally, by the right and left pleuræ and lungs. *On its left* it is very closely related to the left pleura and lung. Under cover of the pleura its left side is crossed vertically by four nerves in the following order from before backwards: the left phrenic, the inferior cervical cardiac branch of the left vagus, the cardiac branch of the left superior cervical ganglion of the sympathetic, and the trunk of the left vagus. The left superior intercostal vein passes obliquely upwards and to the right, across it, superficial to the left vagus nerve and deep to the left phrenic nerve.

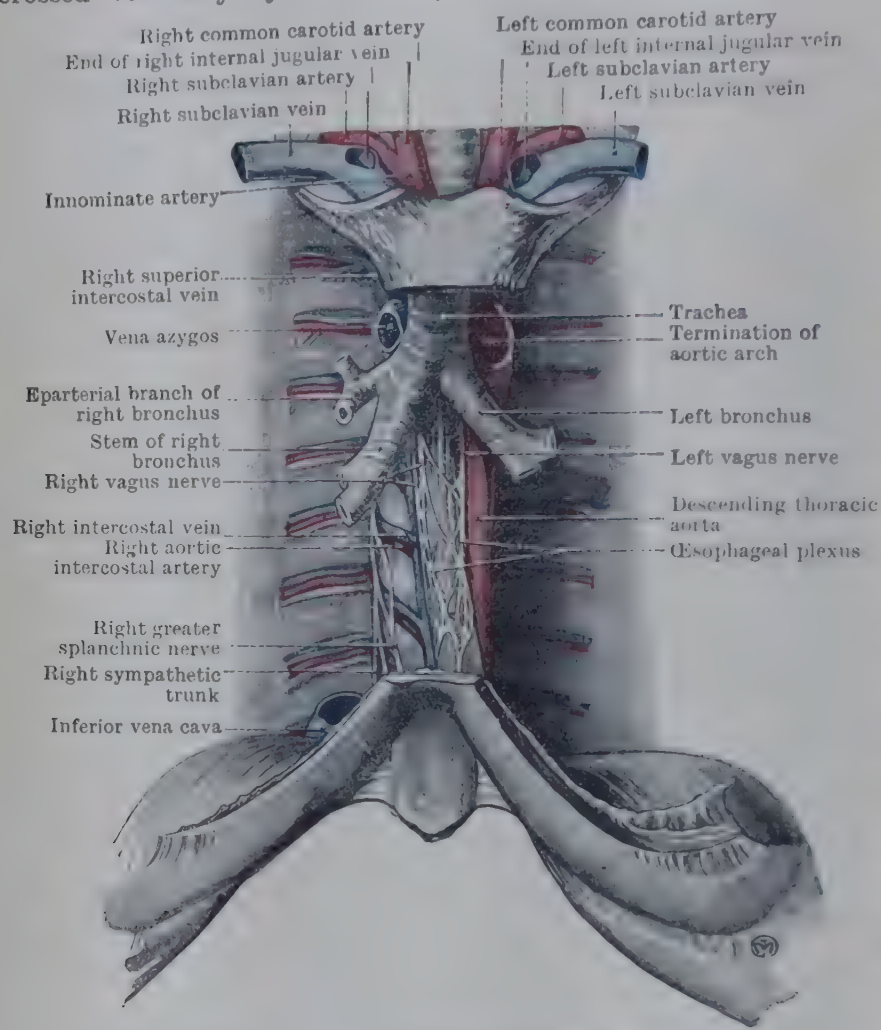

FIG. 1074.—DISSECTION OF POSTERIOR MEDIASTINUM AND POSTERIOR PART OF SUPERIOR MEDIASTINUM, FROM THE FRONT.

Behind, and *on the right* of the arch, are the deep cardiac plexus, the trachea, the left recurrent laryngeal nerve, the left border of the œsophagus and the thoracic duct. *Above* are its three large branches—the innominate, the left common carotid and the left subclavian arteries; and crossing anterior to them is the left innominate vein. *Below* are the bifurcation of the pulmonary trunk and the root of the left lung; the ligamentum arteriosum (p. 1386), which also is below, attaches it to the left pulmonary artery, whilst in front and to the right of the ligament lies the superficial cardiac plexus, and to its left and behind it the left recurrent laryngeal nerve.

Branches.—The three great vessels which supply the head and neck, part of the thoracic wall, and the upper limbs—the innominate, the left common carotid, and the left subclavian arteries—arise from the aortic arch (p. 1251).

Descending Aorta.—The **descending thoracic aorta** lies in the posterior mediastinum; it extends from the end of the arch, at the lower border of the left side of the fourth thoracic vertebra, to the aortic opening in the diaphragm where, opposite the twelfth thoracic vertebra, it becomes continuous with the abdominal aorta. Its length is from seven to eight inches (17·5 to 20 cm.), and its diameter diminishes slightly as it gives off branches.

Relations.—Its *posterior* relations are: the vertebral column and the anterior longitudinal ligament; the superior and inferior hemiazygos veins, which cross behind it; the posterior intercostal arteries, which spring from its posterior surface; and the left pleura and lung, which are behind its left margin—especially in its upper part.

In front it is in relation, from above downwards, with the root of the left lung, the pericardium, which separates it from the back of the left atrium, the œsophagus with the œsophageal plexus of nerves, and the diaphragm, which separates it from the caudate lobe of the liver. On the *left side* are the left lung and pleura. On

he *right side* the thoracic duct and the vena azygos are in relation to it along its whole length. The vertebral bodies and the œsophagus also lie to the right of the upper part of the descending thoracic aorta, whilst the right lung and pleura are in relation below.

Branches.—Nine pairs of posterior intercostal arteries, one pair of subcostal arteries, two left bronchial arteries, four or five œsophageal, some small pericardial, and

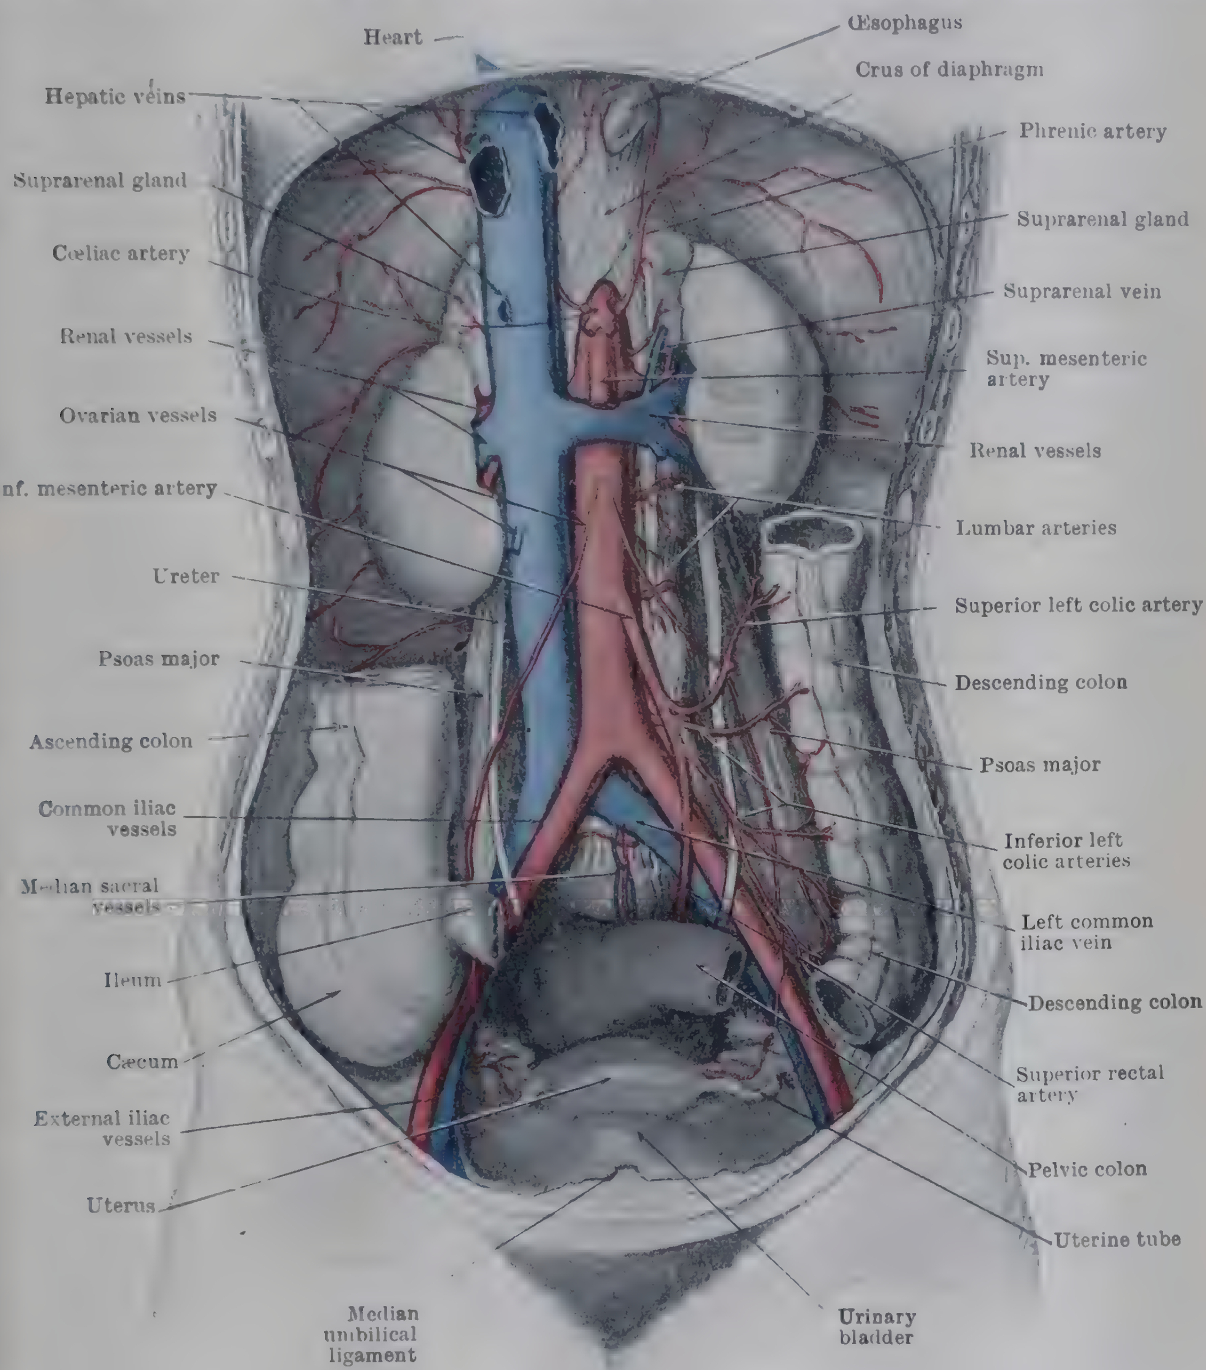

FIG. 1075.—ABDOMINAL AORTA AND ITS BRANCHES.

a few mediastinal and phrenic branches, usually arise from the descending thoracic aorta (p. 1293).

The **abdominal aorta** extends from the middle of the lower border of the last thoracic vertebra to the body of the fourth lumbar vertebra, where, to the left of the median plane, it bifurcates into the right and left common iliac arteries. The point of division is usually a little below and to the left of the umbilicus, opposite a line drawn transversely across the abdomen on a level with the highest points of the iliac crests.

At first it is about 21 mm. in diameter, but after the origin of two large branches—the cœliac and the superior mesenteric arteries—it diminishes considerably, and then retains a fairly uniform diameter to its termination.

Relations.—*Behind*, it is related to the upper four lumbar vertebræ and the intervertebral discs between them, the anterior longitudinal ligament, and the third and fourth left lumbar veins; four pairs of lumbar arteries and a single median sacral artery also spring from the posterior surface of the vessel. *In front* is the aortic plexus of nerves, and also in close relation with it from above downwards are the cœliac artery and cœliac plexus, the pancreas and splenic vein, the superior mesenteric artery, the left renal vein, the third part of the duodenum, the inferior mesenteric artery, the root of the mesentery, and the peritoneum and coils of small intestine. More superficially the stomach, the transverse colon, and the greater and lesser omenta are in front. On the *right side*, in the upper part of its extent, are the thoracic duct and cisterna chyli, the vena azygos, and the right crus of the diaphragm—the latter separating it from the right cœliac ganglion and from the upper part of the inferior vena cava. Its lower part is in direct relation, on the right side, with the inferior vena cava. On the *left side*, the left crus of the diaphragm with the left cœliac ganglion, and the terminal portion of the duodenum, are in close relation with its upper part, whilst in the lower portion of its extent the peritoneum and some coils of the small intestine are in contact with it. Aortic lymph-glands lie in front and on both sides of it.

Branches.—The branches form two groups—visceral and parietal—and each group consists of paired and unpaired vessels, as follows: *Visceral*—Cœliac, superior mesenteric, inferior mesenteric; pairs of suprarenal, renal, and testicular or ovarian; *Parietal*—Median sacral (which is the original continuation of the aorta); one pair of phrenic, four pairs of lumbar, and a terminal pair of common iliac arteries (p. 1295).

Abnormalities of Pulmonary Trunk and Aorta.—The **pulmonary trunk** and the **aorta** may arise by a common stem as in fishes and some amphibians, and the common stem may spring from either the right or the left ventricle, or from both. In those cases the truncus arteriosus has remained undivided, and the normal position of the ventricular septum in relation to the lower orifice of the bulbus cordis (p. 1369) has been altered. Again, owing to malposition of the aortic septum, the pulmonary trunk may spring from the left ventricle and the aorta from the right ventricle.

Occasionally the arch of the aorta is on the right side instead of the left, a condition which is normal in birds. More rarely there are two permanent aortic arches, right and left, as in reptiles; the œsophagus and trachea are then enclosed in a vascular collar, the two arches unite dorsally, and the descending aorta has a double origin. Quite independent of that condition, however, the two primitive dorsal aortæ sometimes fail, either altogether or partially, to unite together, and the descending aorta is accordingly represented, to a corresponding extent, by two tubes. A more common, though still rare, form of double aorta is that due to the persistence, in whole or in part, of the septum formed by the fused walls of the primitive dorsal aortæ from which the descending aorta is developed.

The length of the descending aorta is determined largely by the extent to which fusion of the two primitive aortæ takes place. Accordingly, when that deviates from the normal, the end of the descending aorta is at a correspondingly higher or lower level than usual, and the lengths of the common iliac arteries are almost invariably proportionately modified. The bifurcation of the aorta may be as low as the fifth lumbar vertebra; less frequently it is higher than usual; it is rare, however, to find it as high as the third lumbar vertebra, and still more rare to find it at the level of the second.

The aorta, instead of bifurcating into two common iliac arteries, may end in a common iliac artery on one side and an internal iliac artery on the opposite side, the external iliac artery on the irregular side arising, at a higher level, as a branch of the aortic stem. That arrangement approaches the condition met with in carnivores and many other mammals, in which the aorta bifurcates into two internal iliac arteries, the external iliacs arising from the aorta at a higher level as collateral branches; it is probably due either to a fusion of the secondary roots of the umbilical arteries of opposite sides or to a caudal continuation of the fusion of the primitive dorsal aortæ (see pp. 1373, 1391, and 1393, where references to special works are given).

BRANCHES OF ASCENDING AORTA

Coronary Arteries

The coronary arteries are two in number, a right and a left; they are distributed almost entirely to the heart, but give also some small branches to the roots of the great vessels, and to the pericardium (Figs. 1057, 1058, 1061). The branches of the coronary arteries anastomose freely in the substance of the heart, but form no important anastomoses with any other arteries. Communications do exist, however, between the coronary system and arteries of neighbouring parts by means of the small branches which pass out of the pericardium on the vessels that

iter and leave the heart (p. 1293). For detailed information consult Gross (1921) nd Spalteholz (1924); and, from the physiological point of view, Gregg (1946).

The **right coronary artery** springs from the anterior aortic sinus. It runs orwards, between the root of the pulmonary trunk and the auricle of the right trium, to the atrio-ventricular groove, in which it passes downwards and to the ight to the junction of the right and lower borders of the heart. There it turns ackwards into the inferior part of the groove, together with the small cardiac ein, and runs as far as the posterior end of the inferior interventricular groove, where it gives off its interventricular branch and then ends by anastomosing with the left coronary artery. It is accompanied by branches from the cardiac plexus and lymph-vessels, and in the second part of its course by the small cardiac vein.

Branches.—The **interventricular** branch runs forwards in the inferior interventricular roove; it supplies both ventricles and the ventricular septum, and anastomoses, at the apex of he heart, with the interventricular branch of the left coronary artery.

Twigs are distributed to the roots of the aorta and pulmonary trunk. Branches pass pwards on the anterior surface of the right atrium, and downwards on the anterior surface f the right ventricle; a larger **marginal** branch runs along the lower border of the heart and ives branches to both surfaces of the right ventricle.

The **left coronary artery** arises from the left posterior aortic sinus. Its trunk, horter and often slightly wider than that of the right artery, runs to the left and then forwards, between the root of the pulmonary trunk and the auricle of the left atrium, to the upper end of the anterior interventricular groove, where it gives off an interventricular branch. It then runs round the left surface of the heart, in the left part of the atrio-ventricular groove, where it comes into relation with the coronary sinus and ends by anastomosing with the right coronary artery.

Branches.—The **interventricular branch** passes down the anterior interventricular groove to the lower border of the heart, where it anastomoses with the interventricular branch from the right coronary; it supplies both ventricles and the ventricular septum, and is accompanied by cardiac nerves and lymph-vessels and by the great cardiac vein.

Branches of small size pass to the wall of the left atrium, the left surface of the heart, and the posterior part of the inferior surface of the left ventricle; and small twigs are also given to the roots of the aorta and pulmonary trunk.

Variations.—The two **coronary arteries** may arise by a single stem. When arising separately both may spring from the same aortic sinus; or, again, an interventricular branch may arise as a distinct vessel from the same aortic sinus as the coronary to which it belongs. The variability is not very remarkable, seeing that the arteries in question are equivalent to enlarged "vasa vasorum" raised to a position of special importance by the development of the heart.

BRANCHES OF ARCH OF AORTA

The branches which arise from the arch of the aorta supply the head and neck, the upper limbs, and part of the body-wall.

They are three in number—the **innominate**, the **left common carotid**, and the **left subclavian arteries**. The innominate is a short but wide trunk, from the termination of which the right common carotid and the right subclavian arteries spring (Figs. 1069 and 1071); thus there is, at first, a difference between the stem-vessels of opposite sides, but their branches are distributed to similar areas.

Variations.—The **branches of the arch** may be increased or decreased in number.

The highest number recorded is six—right subclavian, right vertebral, right common carotid, left common carotid, left vertebral, and left subclavian. Apparently that condition is the result of the absorption into the arch of the innominate artery and of the roots of the subclavian arteries, to points beyond the origins of the vertebrals. By variations of that process of absorption other combinations may be produced; thus, instead of the roots of the subclavian arteries being absorbed, the right common carotid and innominate arteries may alone be absorbed, in which case the five following branches spring separately from the arch of the aorta: right subclavian, right external carotid, right internal carotid, left common carotid, and left subclavian. The trunk most commonly absorbed is the initial part of the left subclavian; the number of branches then arising from the arch of the aorta is four, the additional vessel being the left vertebral, which arises between the left common carotid and the left subclavian. Occasionally the usual three branches from the arch are increased to four by the formation of a

new vessel, the "thyroidea ima". That may be placed between the innominate and left caroti trunks, in which case it represents a persistent ventral visceral branch from the ventral root of th fourth left aortic arch; in other cases the thyroidea ima springs from the innominate artery an represents a ventral visceral branch of the ventral root of the fourth *right* arch. Very rarel the right vertebral artery arises separately, and forms a fourth branch of the arch of the aorta the rest of the branches being normal. That condition cannot be accounted for by any modifica tion of the ordinary developmental processes. It may possibly be due to the persistence of a irregular or unimportant anastomosis between the ventral root of an aortic arch and the sevent somatic intersegmental artery.

Decrease in the number of branches from the arch of the aorta is most frequently due t fusion of the ventral roots of the fourth aortic arches, the result being that a stem is forme common to the right subclavian and the right and left common carotid arteries; whilst the lef subclavian, arising separately, is the only other branch which springs from the arch of the aort

If the fusion of the ventral roots proceeds farther and includes those of the third arches, th result, as regards the branches given off from the arch of the aorta, is the same, *i.e.*, there is common stem for the right subclavian and both carotids, and a separate left subclavian trunk; bu the common stem then gives off the right subclavian artery, and afterwards continues for som distance before it divides into the two common carotids, of which the left crosses in front of th trachea. That arrangement is common in many quadrumana and in some other mammals.

When the number of branches from the arch of the aorta is reduced to two, it is onl rarely that they are a right subclavian artery and a single stem common to the tw carotids and the left subclavian artery. In such cases, however, the right common caroti crosses in front of the trachea, and the variation is one of practical importance, but it doe not appear to exist as a normal condition in any mammal. Probably it is due to fusion of th ventral roots of the fourth aortic arches, with absorption of the left fourth arch and the left sub clavian into the stem so formed, whilst the right subclavian is relatively displaced. The tw common carotids may arise by a common stem, and the left subclavian arise separately fro the arch of the aorta, whilst the right subclavian springs from the descending aorta, an passes upwards and to the right behind the œsophagus. That arrangement probably results fro the disappearance of the fourth right arch, the fusion of the ventral roots of the fourth arches o opposite sides and the persistence of the dorsal roots of the right fourth and sixth arches. (Se Development of Vascular System, p. 1373.)

Sometimes two innominate arteries, right and left, replace the usual three branches of th arch of the aorta. That is the normal arrangement in bats, moles, and hedgehogs. It obviously the result of the disappearance of that portion of the arch which intervenes betwee the left carotid and left subclavian arteries, and the consequent fusion of these two vessels.

In a similar way may be explained the rarer condition in which the three ordinar branches of the arch arise by one single stem which divides into right and left innominat arteries. In most ruminants (Pl. LXXXVII, p. 1386), in the horse and in the tapir, that arrang ment is constant.

Other combinations and modifications may be met with in the branches of the arch of th aorta as the result of fusions and absorption. Other arteries also—internal mammary, inferi thyroid, bronchial—may occasionally arise from it. On this subject consult in particular th splendid, classical work of R. Quain (1844).

INNOMINATE ARTERY

The **innominate artery** (Fig. 1071) arises behind the middle of the manu brium sterni as the first branch from the convexity of the arch of the aorta, and i ends behind the upper part of the right sterno-clavicular joint, where it divid into the right subclavian and right common carotid arteries.

Course.—The trunk (from 35 to 50 mm. in length) runs upwards, backward and to the right, out of the superior mediastinum into the root of the neck.

Relations.—*Posterior.*—It is in contact behind, with the trachea below and wit the right pleura above. *Anterior.*—The left innominate vein crosses in front of th lower part of the artery, and the remains of the thymus are in front of that vein; abov that level, the sterno-thyroid muscle separates it from the sterno-hyoid and the righ sterno-clavicular joint. *Right Side.*—The right innominate vein and the upper part of th superior vena cava are on the right side of the artery. *Left Side.*—On its left side is th origin of the left common carotid artery, whilst at a higher level the trachea is in conta with it.

Branches.—As a rule the innominate artery does not give off any branches excep its two terminals, but occasionally it furnishes an additional branch—the thyroidea ima.

Variations.—The innominate artery may be absent. On the other hand there may two innominate arteries, a right and a left, each ending in corresponding common carotid an subclavian trunks, and the two vessels may themselves arise by a common stem. The branch of the innominate artery may be increased in number; or the innominate may vary from th

ormal only in length. As a consequence of such modifications in length, the origins of the ight common carotid and right subclavian arteries may be at a higher or lower level than sual, whilst, in the absence of the innominate artery, both these arteries may arise directly from he aorta.

The **thyroidea ima** is an inconstant and slender vessel. When present it nay arise from the arch of the aorta between the innominate and left common arotid arteries, but it springs usually from the lower part of the innominate. It passes upwards, on the front of the trachea, and is distributed to the thyroid gland and the trachea.

ARTERIES OF HEAD AND NECK

The vessels distributed to the Head and Neck are derived chiefly from the carotid trunks; there are, however, in addition, other vessels which arise from the main arterial stems of the Upper Limbs, and it will be advantageous to describe the most important of those, namely, the vertebral arteries, with the carotid system. The smaller additional branches will be considered along with the remaining branches of the subclavian arteries.

The **carotid system of arteries** consists, on each side, of a **common carotid** trunk, which divides into **internal** and **external carotid arteries**, from which numerous branches are given off (Figs. 1069, 1076, 1078, 1079).

The internal carotid arteries are distributed, almost entirely, to the contents of the cranial cavity that lie internal to the dura mater, and to the structures in the cavity of the orbit. The external carotid arteries, on the other hand, supply structures of the head and neck more externally situated.

It is to be noted, however, that the vascular supply of the brain is not wholly derived from the internal carotid vessels, but that the vertebral arteries also make an important contribution to it.

COMMON CAROTID ARTERIES

The two **common carotid arteries** are of unequal length. The *right common carotid artery* begins at the bifurcation of the innominate artery behind the right sterno-clavicular joint; the *left common carotid* arises, in the superior mediastinum, from the arch of the aorta; but each terminates at the level of the upper border of the thyroid cartilage. The left artery has thus a short intrathoracic course, and, so far, its relations call for separate consideration; whilst in the rest of its course it passes upwards in the neck, like the right common carotid, and has almost similar relations.

Left Common Carotid Artery.—The **left common carotid artery** springs from the upper aspect of the aortic arch immediately behind and to the left of the origin of the innominate artery, and its *thoracic portion* extends to the left sterno-clavicular joint, where the cervical portion begins. It is from 1 to $1\frac{1}{2}$ inches (25–37 mm.) in length, and it runs upwards and slightly laterally through the upper part of the superior mediastinum.

Relations.—*Posterior.*—The vessel is in contact behind, and from below upwards, with the trachea, the left recurrent laryngeal nerve, the œsophagus, and the thoracic duct; and the thoracic part of the left subclavian artery is a postero-lateral relation. *Anterior.*—The left innominate vein runs obliquely across the artery, and cardiac branches from the left vagus and sympathetic descend vertically in front of it. Those structures, together with the remains of the thymus and the anterior margins of the left lung and pleura, separate the artery from the manubrium sterni and from the origins of the sterno-hyoid and sterno-thyroid muscles. *Medial.*—The innominate artery below, and the trachea above, are on the right side. *Lateral.*—The left pleura, and, on a posterior plane, the left phrenic and vagus nerves and the left subclavian artery are on its left side.

The *cervical portion* of the **left common carotid artery** is about $3\frac{1}{2}$ inches (85 mm.) long; it extends from the left sterno-clavicular joint to the level of the upper border of the thyroid cartilage and the lower border of the third

cervical vertebra, where it ends by dividing into external and internal carotid arteries.

Course.—It runs upwards, laterally, and backwards, through the anterior triangle of the neck. Below it is separated from its fellow of the opposite side by the trachea and the œsophagus, and above by the relatively wide larynx and pharynx.

Relations.—It is enclosed, together with the internal jugular vein and the vagus nerve, in a sheath of cervical fascia—the **carotid sheath.**

Posterior.—The longus cervicis, below, and the longus capitis, above, are separated from the artery by the prevertebral fascia with the sympathetic trunk intervening. The

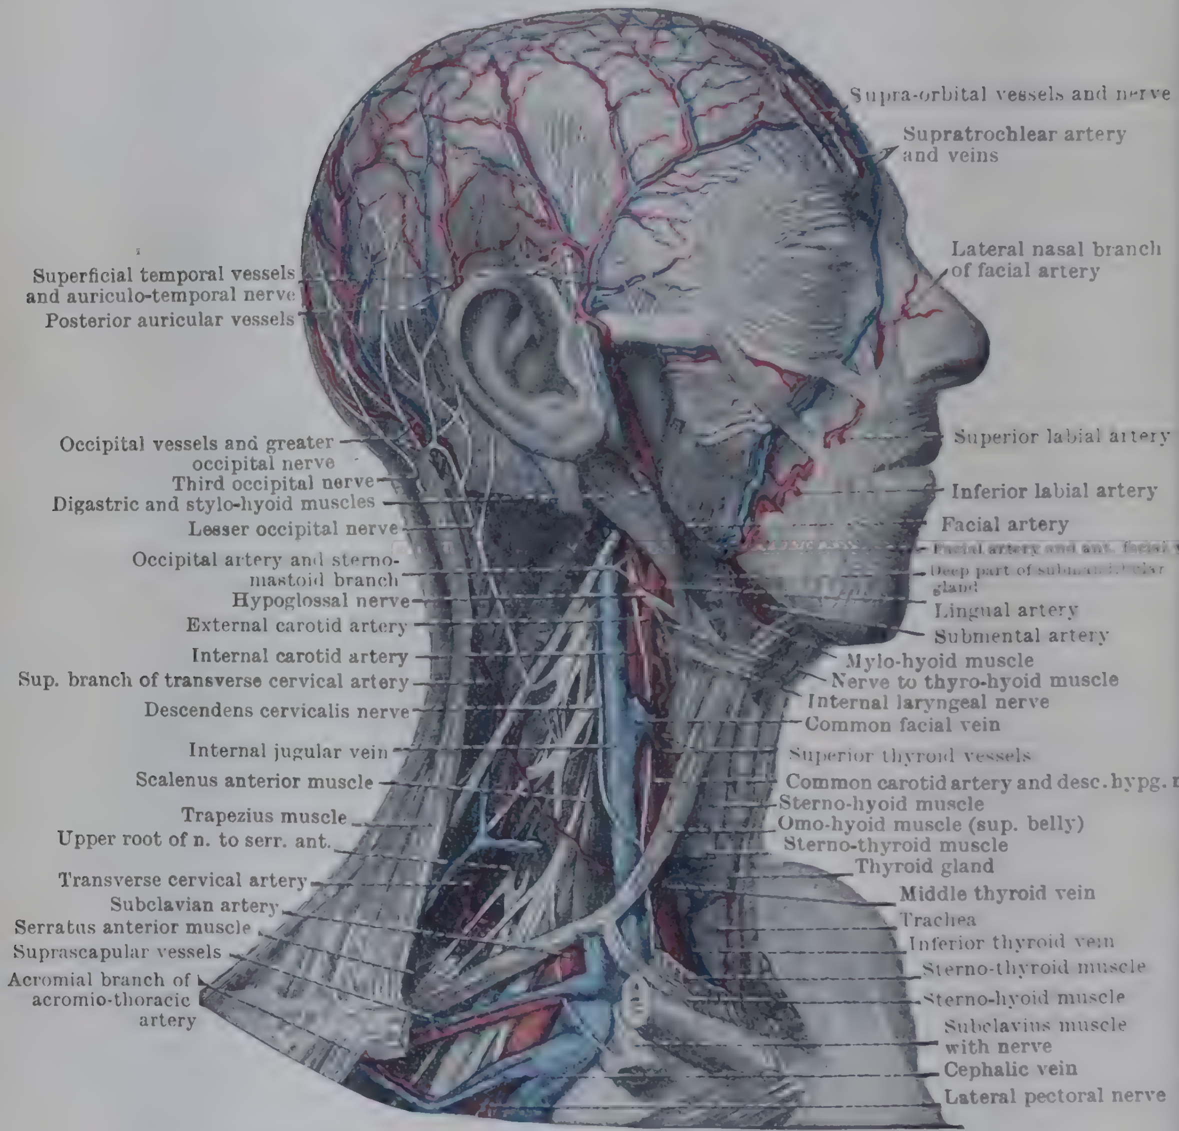

Fig. 1076.—Dissection of Head and Neck showing the Carotid Arteries.

vertebral artery and the thoracic duct are posterior to it at the level of the seventh cervical vertebra; the inferior thyroid artery crosses behind it, between it and either the vertebral artery or the transverse process of the sixth cervical vertebra; and the vagus nerve lies postero-lateral to it.

Superficial.—The descending branch of the hypoglossal nerve lies superficial to the artery, usually outside the sheath, but sometimes enclosed in it (Fig. 1076). Opposite the sixth cervical vertebra the omo-hyoid muscle and the sterno-mastoid branch of the superior thyroid artery cross superficial to the common carotid artery, which is overlapped, above the omo-hyoid muscle, by the anterior border of the sterno-mastoid and by deep cervical lymph-glands. It is frequently crossed, in that part of its extent, by the superior thyroid vein. Below the omo-hyoid the artery is covered by the sterno-thyroid, the sterno-hyoid, and the sterno-mastoid muscles, and it may be overlapped by the lobe of the thyroid gland; it is also crossed, deep to the muscles, by the middle thyroid

ein, whilst occasionally a communication between the common facial and anterior ugular veins descends in front of the artery along the anterior border of the sterno-nastoid. Just above the sternum the anterior jugular vein is in front of the artery, but eparated from it by the sterno-hyoid muscles.

Medial.—The trachea and œsophagus, with the recurrent laryngeal nerve in the angle between them, are medial to the lower part of the artery; the larynx and pharynx are medial to its upper part. The carotid body lies on the medial side of the termination of the artery.

Lateral.—The internal jugular vein occupies the lateral part of the carotid sheath. The vein lies not only to the lateral side of the artery, but also slightly in front of it, especially in the lower part of the neck.

Branches.—As a rule no branches are given off from either of the common carotid arteries, except the terminal branches and some minute twigs to the carotid sheath and carotid body. But occasionally one or more of the branches usually given off by the external carotid may arise from the common carotid; the most frequent is the superior thyroid artery.

Right Common Carotid Artery.—The **right common carotid artery**, as already stated, differs as regards origin from the left common carotid. In length and general position it corresponds with the cervical portion of the left common carotid, and its relations also are very similar. Such differences as exist may be briefly summarized as follows:—The internal jugular vein lies lateral to the artery on each side; on the left side in the lower part of the neck it is also anterior to the artery whilst on the right side the vein is separated from the lateral surface of the artery at its lower end, by a well-marked interval in which the vagus nerve appears The thoracic duct does not come into relation with the right common carotid. There is also a difference in the relations of the recurrent laryngeal nerves to the arteries on the two sides. The left nerve is posterior to the mediastinal part of the left artery, and lies medial to its cervical part, whilst the right nerve passes posterior to the lower part of the corresponding artery in the neck to reach its medial side. The œsophagus has a less intimate relation with the right common carotid artery than with the left.

Carotid Sinus.—The terminal portion of the common carotid artery and the root of its internal carotid branch are dilated to form the *carotid sinus.* This sinus is part of the mechanism that regulates blood-pressure; its walls are more elastic than adjacent parts of the arteries, and it is specially innervated by the glosso-pharyngeal nerve, which supplies the carotid body also (see Fig. 689, p. 808).

Variations.—The right common carotid artery may arise separately from the arch of the aorta; then it may be the first, or, much more rarely, the second branch. In the former case the fourth right aortic arch has been obliterated, and the right subclavian artery springs from the descending aorta; in the latter case either the innominate stem has been absorbed into the arch of the aorta, or the ventral root of the fourth right aortic arch has fused with part of an elongated fourth left arch.

Whether the artery arises as the first or second branch, the origin may be to the left of the median plane, and the trunk may pass in front of the trachea, or behind the œsophagus, before it ascends into the neck.

The left common carotid artery varies, as regards its origin, much more frequently than the right vessel; not uncommonly, and apparently because of the fusion of the ventral roots of the fourth aortic arches, it arises from a stem common to it and to the right common carotid and right subclavian arteries.

Both common carotids may vary as regards their termination. They may divide at a higher or lower level than usual, the former more commonly than the latter; whilst in a few exceptional cases the common carotid does not divide, but is continued directly into the internal carotid; then the branches usually given off by the external carotid spring from it. That arrangement is probably due to obliteration of the ventral roots of the first and second aortic arches, the arches persisting and being divided into the branches which generally arise from their ventral extremities.

EXTERNAL CAROTID ARTERY

The **external carotid artery** (Figs. 1076, 1078) is the smaller of the two terminal branches of the common carotid; its length is about 2½ inches (62 mm.). It extends from the upper border of the thyroid cartilage to the back of the neck of the mandible, where it ends by dividing into the superficial temporal and maxillary arteries.

Course.—It begins in the carotid triangle, passes upwards, medial to the posterior belly of the digastric and the stylo-hyoid muscles and the lower part of the parotid gland; then it grooves the medial border of the gland, and passes through its substance to the upper part of its antero-medial surface behind the neck of the mandible, where it ends.

At first it lies anterior and medial to the internal carotid artery, but it inclines backwards as it ascends, and thus becomes superficial to the internal carotid. Its course is indicated by a line drawn from the tip of the greater horn of the hyoid bone to the lobule of the ear.

Relations.—*Deep.*—At first the inferior constrictor muscle is in relation with its medial side, but at a higher level the structures which intervene between it and the internal carotid—the stylo-pharyngeus muscle, the styloid process (or the stylo-glossus muscle), the glosso-pharyngeal nerve, the pharyngeal branch of the vagus and a portion of the parotid gland—separate it from the wall of the pharynx; whilst medial both to it and to the internal carotid artery are the external and internal laryngeal branches of the superior laryngeal nerve.

Superficial.—In the carotid triangle it is overlapped by the anterior border of the sterno-mastoid. Immediately below the level of its occipital branch it is crossed by the hypoglossal nerve; and it is crossed by the lingual and common facial veins also, and sometimes by the superior thyroid vein. At the level of the angle of the mandible it passes under cover of the posterior belly of the digastric and the stylo-hyoid muscles, which separate it from the parotid gland. As it emerges from under cover of the stylo-hyoid, it grooves the parotid gland, and, as it passes through the gland, the posterior facial vein descends superficial to the artery, and both the artery and the vein are crossed, usually superficially, by the branches of the facial nerve.

Branches.—Eight branches arise from the external carotid artery; of those, three—the superior thyroid, the lingual, and the facial—spring from the front of the artery in the carotid triangle; two arise from the back of the artery, namely, the occipital and the posterior auricular, the former below the posterior belly of the digastric and the latter above it; one from its medial side, namely, the ascending pharyngeal, which arises in the carotid triangle. Its terminal branches are the superficial temporal and maxillary arteries.

Variations.—The external carotid artery may be absent, or it may, in rare cases, arise directly from the arch of the aorta. The number of its branches may be diminished either by fusion of their roots or by transference to the internal or common carotid arteries. On the other hand, the number of its branches may be increased; thus, the sterno-mastoid artery, or the infrahyoid branch usually given off by the superior thyroid artery, or the ascending palatine branch of the facial artery, may arise directly from the external carotid.

Branches of External Carotid Artery

(1) The **superior thyroid artery** (Figs. 1071 and 1076) springs from the front of the lower part of the external carotid artery, just below the tip of the greater horn of the hyoid bone, and it ends at the apex of the corresponding lobe of the thyroid gland by dividing into glandular branches.

Course.—From its origin, in the carotid triangle, the artery runs downwards and forwards to its termination.

Relations.—*Medially* it is in relation with the inferior constrictor muscle and the external laryngeal branch of the superior laryngeal nerve.

Superficially it is covered, at its origin, by the anterior border of the sterno-mastoid; afterwards, for a short distance, by fascia, platysma, and skin, and in the lower part of its extent by the omo-hyoid, the sterno-hyoid, and the sterno-thyroid muscles, and it is overlapped by an accompanying vein.

Branches.—*In the carotid triangle.*—A small **infrahyoid artery** runs along the lower border of the hyoid bone, under cover of the thyro-hyoid muscle, to anastomose with its fellow of the opposite side and with the suprahyoid branch of the lingual artery. It supplies the thyro-hyoid muscle and membrane.

The **superior laryngeal artery** runs forwards, deep to the thyro-hyoid muscle. It pierces the thyro-hyoid membrane and enters the lateral wall of the piriform fossa, in company with the internal laryngeal nerve, supplies the muscles, ligaments, and mucous

membrane of the larynx, and anastomoses with its fellow of the opposite side, with the crico-thyroid branch, and with the inferior thyroid artery.

The **sterno-mastoid branch** passes downwards and backwards, along the upper border of the superior belly of the omo-hyoid muscle and across the common carotid artery, to the deep surface of the sterno-mastoid muscle. It anastomoses, in the sterno-mastoid, with branches of the occipital and suprascapular arteries.

In the muscular triangle.—A **crico-thyroid branch** passes forwards, either superficial or deep to the sterno-thyroid. It crosses the crico-thyroid muscle to anastomose, in front of the crico-thyroid ligament, with its fellow of the opposite side, and, by branches which perforate the ligament, with laryngeal branches of the superior and inferior thyroid arteries. It supplies the adjacent muscles and membrane.

The terminal **glandular branches** are anterior, medial, and lateral. The *anterior glandular branch* descends along the anterior border of the lobe of the thyroid gland, and runs along the upper border of the isthmus to anastomose with its fellow of the opposite side. The *medial glandular branch* is the largest; it is distributed to the medial surface of the lobe. The *lateral glandular branch*, which ramifies in the lateral surface of the lobe, is the smallest. All three branches anastomose with one another and with branches from the inferior thyroid artery.

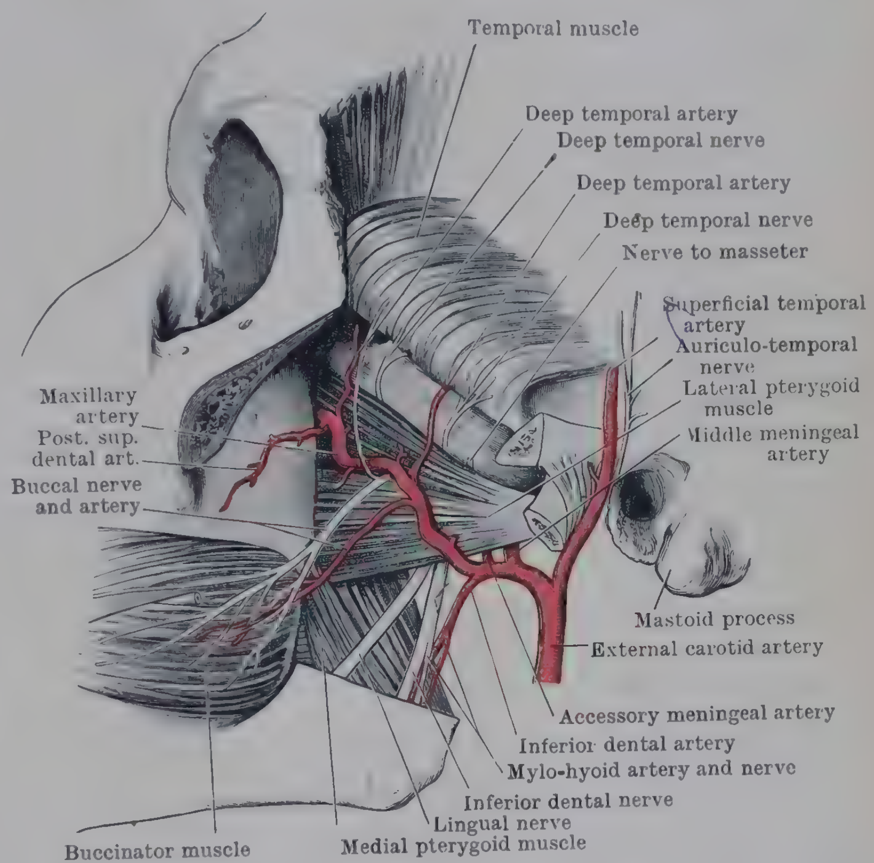

FIG. 1077.—DISSECTION SHOWING TERMINATION OF EXTERNAL CAROTID ARTERY AND FIRST AND SECOND PARTS OF MAXILLARY ARTERY.

(2) The **lingual artery** (Figs. 1076 and 1078) springs from the front of the external carotid, opposite the tip of the greater horn of the hyoid bone, and, becoming the *arteria profunda linguæ*, it ends beneath the tip of the tongue, where it anastomoses with its fellow of the opposite side.

Course.—Whilst in the carotid triangle, the *first part of the artery* forms a loop with the convexity upwards. The *second part* passes forwards, medial to the hyo-glossus muscle immediately above the greater horn of the hyoid bone, to the anterior border of the hyo-glossus, where it becomes the *third part*, which ascends along the anterior border of the hyo-glossus, and, having given off a sublingual branch, ends as the profunda artery of the tongue. The **profunda artery of the tongue** takes a tortuous course forwards on the under surface of the tongue to the tip.

Relations.—The *first part* of the lingual artery is crossed superficially by the hypoglossal nerve, and is covered by skin, fascia, and the platysma; it rests medially against the middle constrictor of the pharynx. The *second part* is deeper. It lies between the middle constrictor medially and the hyo-glossus laterally, and is separated by the latter from the hypoglossal nerve and its vena comitans, and the lower part of the submandibular gland. The *third part* ascends between the genio-glossus and the anterior border of the hyo-glossus, which is covered by the mylo-hyoid. The profunda artery runs forwards between the inferior longitudinal muscle and the genio-glossus, and is covered, on its lower surface, by the mucous membrane of the tongue. Thus, at its termination, near the frenulum of the tongue, the artery is comparatively superficial.

Branches.—The **suprahyoid artery** is a small branch which arises in the caroti triangle and runs along the upper border of the greater horn of the hyoid bon superficial to the hyo-glossus. It anastomoses with its fellow of the opposite side an with the infrahyoid artery.

The **dorsales linguæ branches**—usually two—arise from the second part of the arter and are of moderate size. They ascend, between the hyo-glossus and the genio-glossus to the dorsum of the tongue, where they branch and anastomose with their fellows c the opposite side around the foramen cæcum. They supply the posterior part of th tongue as far back as the epiglottis, and send branches backwards to the tonsil whic anastomose with the tonsillar artery and tonsillar twigs of the ascending palatine branc of the facial and with the ascending pharyngeal artery.

A **sublingual branch** arises at the anterior border of the hyo-glossus muscle an runs forwards and upwards, between the mylo-hyoid and the genio-glossus, to the sub lingual gland, which it supplies: it supplies also the mylo-hyoid, the genio-glossus, an the genio-hyoid muscles. It anastomoses with its fellow of the opposite side, with th profunda artery by a branch which it sends along the frenulum of the tongue, and, throug the mylo-hyoid muscle, with the submental branch of the facial artery.

(3) The **facial artery** (Fig. 1076) arises from the front of the external caroti immediately above the lingual. It ends at the medial angle of the eye, where i anastomoses with the dorsal nasal and palpebral branches of the ophthalmic artery.

Course.—The course of the facial artery is very tortuous. It begins in th carotid triangle and passes *upwards* to the angle of the mandible, on the later surface of the middle constrictor muscle. Still ascending, it lies between th posterior belly of the digastric and the stylo-hyoid muscles laterally and th superior constrictor medially. When it reaches the upper border of the stylo hyoid it enters a groove in the posterior part of the submandibular gland an runs *downwards* and *forwards*, between the lateral surface of the gland and th medial pterygoid muscle, to the lower border of the mandible. There it pierce the deep cervical fascia, turns round the inferior border of the mandible a the anterior border of the masseter, enters the face, and continues *upwards* an *forwards* in a tortuous manner to its termination.

Relations.—In the carotid triangle the artery is comparatively superficial, excep just at its origin, which is overlapped by the anterior fibres of the sterno-mastoid muscl As it ascends it is in relation, on the medial side, with the middle and superior constricto muscles, and the superior constrictor separates it from the tonsil. Its relations betwee the point where it passes medial to the posterior belly of the digastric and the poin where it turns round the lower border of the mandible have been given in the descriptio of its course.

After turning round the lower border of the body of the mandible, which it groove slightly, the artery becomes more superficial than in any other part of its course, bein covered only by platysma, fascia, and skin. At that point the anterior facial vein i immediately posterior to the artery, lying on the surface of the masseter. As it passe upwards in the face the artery is deep to the platysma, the risorius, the zygomaticu major, the levator labii superioris, and the fascia and skin, and superficial to the mandibl the buccinator and the levator anguli oris: it then enters the substance of the levator lab superioris alæque nasi.

The anterior facial vein is posterior to the artery in the face, is situated at som little distance from it, and runs a straighter course.

Branches.—Four named branches are given off in the neck and several in the face.

In the Neck.—The **ascending palatine artery** (Fig. 1083) is a small branch whic arises under cover of the posterior belly of the digastric. It ascends between the stylo glossus and the stylo-pharyngeus muscles towards the base of the skull, and turns dow wards over the upper border of the superior constrictor of the pharynx, accompanyin the levator palati muscle, and enters the soft palate (Fig. 1079).

It supplies the lateral wall of the upper part of the pharynx, the soft palate, th tonsil, and the pharyngo-tympanic tube. It anastomoses with the tonsillar branc of the facial, the dorsales linguæ, the greater palatine branch of the maxillary, and wit the ascending pharyngeal artery, which sometimes replaces it.

The **tonsillar artery** is a small branch which arises close to the ascending palatine It passes upwards between the medial pterygoid and the stylo-glossus, pierces the superio

ıstrictor, and ends in the tonsil. It supplies the middle and superior constrictor ıscles, and it anastomoses with the dorsales linguæ, with the ascending palatine and e ascending pharyngeal arteries.

The **glandular branches** are two or three small twigs which pass directly into the ıbmandibular gland.

The **submental artery** arises from the facial near the lower border of the mandible. is the largest branch given off in the neck; it runs forwards, on the lateral surface the mylo-hyoid muscle, and medial to the upper part of the submandibular gland, to ıe symphysis menti; there it turns upwards, round the margin of the mandible, and it ıds by anastomosing with branches of the mental and inferior labial arteries. In the eck the submental artery supplies the mylo-hyoid muscle, and the submandibular and ıblingual glands, the latter by a branch which perforates the mylo-hyoid muscle. It ıastomoses with the mylo-hyoid branch of the inferior dental and with the sublingual ranch of the lingual artery.

In the Face.—The **inferior labial arteries** arise from the front of the facial below ıe level of the angle of the mouth. There are usually two, the lower arising below ıe level of the alveolar border of the mandible. They run medially, under cover of the ıuscles of the lower lip, supply the skin, muscles, mucous membrane, and glands of the ıp, and anastomose with each other, with the mental artery, and with their fellows of ıe opposite side. The upper of the two arteries pierces the orbicularis oris and runs ıose to the mucous membrane near the margin of the lip.

The **superior labial artery** springs from the front of the facial about the level of ıe angle of the mouth. It runs medially, between the orbicularis oris and the mucous ıembrane of the upper lip, to the median plane, supplying the skin, muscles, mucous ıembrane and glands of the upper lip, and, by a *septal branch*, the lower and anterior part f the nasal septum. It anastomoses with its fellow of the opposite side, with the *lateral asal* branch of the facial, and with the septal branch of the spheno-palatine artery.

The *lateral nasal* is a constant branch that ramifies on the side of the nose (Fig. 1052).

Numerous other small branches arise from the facial artery in the face; through these t anastomoses also with the transverse facial artery, and with the buccal and infra-rbital branches of the maxillary artery.

(4) The **occipital artery** (Figs. 1076, 1078) arises from the back of the external arotid artery, below the posterior belly of the digastric muscle, and ends, near he medial end of the superior nuchal line of the occipital bone, by dividing into medial and lateral terminal branches.

Course.—It begins in the carotid triangle and runs upwards and backwards, parallel with and under cover of the posterior belly of the digastric, to the interval between the transverse process of the atlas and the base of the skull; there it turns backwards, in a groove on the lower surface of the mastoid portion of the temporal bone; as it leaves the groove it alters its direction and runs upwards and medially, on the superior oblique muscle, to the junction of the medial and intermediate thirds of the superior nuchal line of the occipital bone, where it pierces the deep fascia of the neck and enters the superficial fascia of the scalp.

Relations.—In the first part of its course the occipital artery crosses successively the internal carotid artery, the hypoglossal nerve (which hooks round it), the vagus nerve, the internal jugular vein, and the accessory nerve; it is covered by the lower fibres of the posterior belly of the digastric and the anterior part of the sterno-mastoid muscle. In the second and more horizontal part of its course it is still under cover of the sterno-mastoid and digastric, and lies, medially, against the rectus capitis lateralis, which separates it from the vertebral artery. In the third part of its course it rests upon the superior oblique and semispinalis capitis, under cover of the sterno-mastoid and the splenius capitis muscles, and either superficial or deep to the longissimus capitis. Near its termination it is crossed by the greater occipital nerve, and it passes either through the trapezius or between the trapezius and the sterno-mastoid.

Branches.—**Muscular branches** go to the surrounding muscles. There are usually two **sterno-mastoid branches**; one springs from the occipital near its origin, is looped downwards across the hypoglossal nerve, and is continued downwards and backwards, below and anterior to the accessory nerve, into the sterno-mastoid muscle, where it anastomoses with the sterno-mastoid branch of the superior thyroid artery. The other arises higher up and accompanies the accessory nerve into the muscle.

The **descending branch** is given off from the occipital upon the surface of the superior

oblique and supplies the muscles of the back of the neck. It passes medially, and divides at the lateral border of the semispinalis capitis into superficial and deep branches. The superficial branch runs between the semispinalis and the splenius capitis, and anastomoses with the superficial branch of the transverse cervical artery. The deep branch descends between the semispinalis capitis and the semispinalis cervicis, and anastomoses with branches of the deep cervical artery.

The **meningeal** are irregular branches which enter the skull through the condylar canals and the jugular foramen; they supply the dura mater in the posterior fossa of the skull and anastomose with branches of the middle meningeal and ascending pharyngeal arteries.

The **mastoid** is a small and inconstant branch which arises behind the mastoid process. It enters the posterior fossa of the skull through the mastoid foramen, supplies the mastoid air-cells on its way to the dura mater, and anastomoses with branches of the middle meningeal artery.

The **auricular** is an inconstant branch which is given off from the occipital, as a rule only when the posterior auricular artery is absent. It ramifies over the mastoid process, and supplies the medial surface of the auricle.

The terminal **occipital branches** are medial and lateral. They ramify in the superficial fascia of the posterior part of the scalp, where they anastomose with the posterior auricular and superficial temporal arteries. Both branches are accompanied by branches of the greater occipital nerve. The medial branch gives off a *meningeal* twig which passes into the skull through the parietal foramen to supply the walls of the superior sagittal sinus and to anastomose with the middle meningeal artery.

(5) The **posterior auricular artery** (Figs. 1076, 1078, 1083) springs from the back of the external carotid immediately above the posterior belly of the digastric muscle, and it ends between the mastoid process and the back of the auricle by dividing into occipital and auricular branches.

Course and Relations.—From its origin it runs upwards and backwards superficial to the styloid process under cover of the parotid gland, to the interval between the mastoid process and the auricle. It is accompanied in the terminal part of its course by the posterior auricular branch of the facial nerve.

Branches.—In addition to twigs of supply to the parotid gland and *muscular* branches to the sterno-mastoid, the digastric, and the styloid group of muscles, there are three named branches.

The **stylo-mastoid artery** is given off at the lower border of the external auditory meatus, runs upwards by the side of the facial nerve, and enters the stylo-mastoid foramen. It accompanies the facial nerve in its canal to the upper part of the medial wall of the tympanum, where it ends by anastomosing with the superficial petrosal branch of the middle meningeal artery; other branches anastomose with tympanic branches from the internal carotid and the ascending pharyngeal arteries, and with the internal auditory branch of the basilar. It supplies the tympanic cavity and antrum, the vestibule, and semicircular canals, *mastoid* branches to the mastoid air-cells and a *stapedial* to the stapedius muscle; and it gives off a *posterior tympanic branch*, which anastomoses with the anterior tympanic branch of the maxillary artery, forming, in young subjects, a vascular circle around the tympanic membrane.

The **auricular branch** ascends medial to the posterior auricular muscle. It gives branches to the auricle and to the scalp in the posterior part of the temporal region, which anastomose with the superficial temporal and occipital arteries. The auricular branches supply both surfaces of the auricle, piercing or turning round the margins of the cartilage to gain the lateral surface; and they anastomose with the auricular branches of the superficial temporal artery.

The **occipital branch** runs upwards and backwards along the insertion of the sterno-mastoid muscle. It supplies the sterno-mastoid muscle, the occipital belly of the occipito-frontalis, and the skin; and it anastomoses with the occipital artery.

(6) The **ascending pharyngeal artery** (Fig. 1083) arises from the medial surface of the lower part of the external carotid, and its terminal branches are distributed to the wall of the pharynx and in the soft palate.

Course.—It begins in the carotid triangle, usually as the first or second branch of the external carotid, and it ascends on the wall of the pharynx to the apex of the petrous portion of the temporal bone.

Relations.—*Medially* it is in relation with the constrictor muscles of the pharynx. *Posterior* to it is the longus capitis. *Laterally* it is in relation with the internal carotid artery, and it is crossed by the stylo-pharyngeus muscle, the glosso-pharyngeal nerve, and the pharyngeal branch of the vagus.

Branches.—The branches of this artery are very irregular and inconstant; in addition to those named, small branches are distributed to the prevertebral muscles and fascia, the deep cervical lymph-glands, and the large nerve-trunks. They anastomose with branches of the ascending cervical and vertebral arteries.

Small **pharyngeal branches** ramify on the walls of the pharynx and supply the middle and superior constrictor muscles, the tonsil, and the lower part of the pharyngo-tympanic

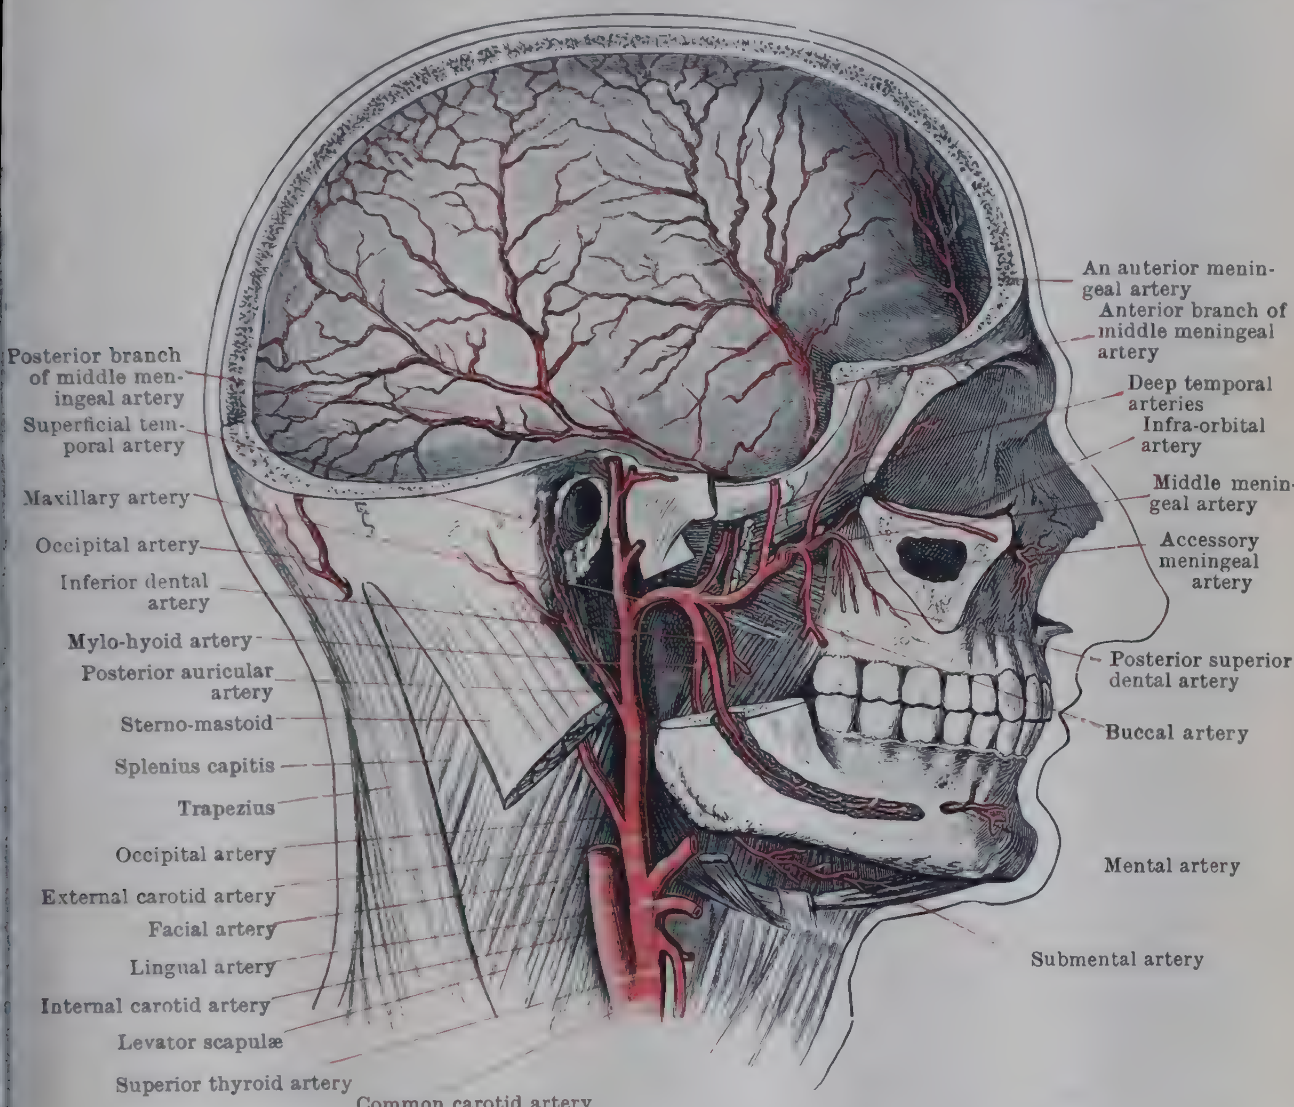

FIG. 1078.—EXTERNAL CAROTID, MAXILLARY, AND MENINGEAL ARTERIES.

tube. They anastomose with branches of the superior thyroid, lingual, and facial arteries. A small inconstant branch sometimes replaces the ascending palatine branch of the facial artery. When present, it springs from the upper part of the ascending pharyngeal artery, pierces the pharyngo-basilar fascia above the superior constrictor muscle, and descends into the soft palate with the levator palati muscle.

One or more small **meningeal** branches enter the cranium by the anterior condylar canal, the jugular foramen, or the foramen lacerum, and supply the dura mater. They anastomose with branches of the middle meningeal and vertebral arteries.

The **inferior tympanic** is a small artery which accompanies the tympanic branch of the glosso-pharyngeal nerve to the tympanic cavity, where it anastomoses with the other tympanic arteries.

(7) The **superficial temporal artery** (Fig. 1076), one of the terminal branches of the external carotid, begins between the upper part of the parotid gland and the back of the neck of the mandible, and ends in the scalp, from 1 to 2 inches (25 to 50 mm.) above the zygomatic arch, by dividing into anterior and posterior branches.

Course.—The artery pierces the deep fascia, ascends over the posterior root of the zygoma, and enters the superficial fascia of the temporal region. It is accompanied by the auriculo-temporal nerve, which is behind it, and by the superficial temporal vein, which is usually superficial to it. As it crosses the zygoma it is covered by the skin alone, and it may easily be compressed against the subjacent bone.

Branches.—Small **parotid** branches supply the upper part of the gland, and some twigs go to the *mandibular joint*.

Small **auricular** branches ramify on the lateral surface of the auricle and supply the external auditory meatus.

The **transverse facial artery** is a branch of moderate size which emerges from under cover of the upper part of the anterior border of the parotid gland. It runs forwards across the masseter, below the zygomatic arch and above the parotid duct, accompanied by zygomatic branches of the facial nerve, which may lie either above or below it. It supplies the parotid gland, the masseter, parotid duct, and the skin, and it ends in branches which anastomose with the infra-orbital and buccal branches of the maxillary artery and with muscular branches of the facial artery.

The **middle temporal artery** usually arises below the zygomatic arch, and runs upwards over it; it then pierces the temporal fascia, passes behind or through the posterior fibres of the temporal muscle, and ascends in the temporal fossa, grooving the skull-wall and anastomosing with the deep temporal branches of the maxillary artery.

The **zygomatic** branch may spring directly from the superficial temporal, but it is frequently a branch of the middle temporal. It runs forwards, above the zygomatic arch between the two layers of the temporal fascia. It supplies branches to the orbicularis oculi, and anastomoses, through the zygomatic bone and round the lateral orbital margin, with the lacrimal and palpebral branches of the ophthalmic artery.

The **anterior branch** runs forwards and upwards, in a tortuous course, through the superficial fascia of the scalp towards the frontal eminence, lying at first upon the temporal fascia, and then upon the epicranial aponeurosis. It supplies the frontal belly of the occipito-frontalis and the orbicularis oculi, and anastomoses with the lacrimal and supra-orbital branches of the ophthalmic artery, with the posterior terminal branch of the superficial temporal, and with its fellow of the opposite side.

The **posterior branch**, less tortuous than the anterior, runs upwards and backwards in the superficial fascia of the scalp. It anastomoses in front with the anterior terminal branch, behind with the posterior auricular and occipital arteries, and across the median line with its fellow of the opposite side. It supplies the skin and fascia, and the anterior and superior muscles of the auricle.

(8) The **maxillary artery** begins between the upper part of the parotid gland and the back of the neck of the mandible and ends in the pterygo-palatine fossa (Figs. 1078, 1079).

Course and Relations.—The maxillary artery has many important relations, in the consideration of which it is convenient to divide the vessel into three parts. The **first part** extends from the back of the neck of the mandible into the infratemporal fossa, as far as the lower border of the lateral pterygoid muscle. It lies between the spheno-mandibular ligament and the neck of the mandible, along with the auriculo-temporal nerve and the maxillary vein. The **second part** is in the infratemporal fossa, and runs upwards and forwards. It may lie on the lateral or the medial side of the lower head of the lateral pterygoid muscle either between the temporal and lateral pterygoid muscles or between the lateral pterygoid and the branches of the mandibular nerve. The **third part** passes between the upper and the lower heads of the lateral pterygoid, and through the pterygo-maxillary fissure into the pterygo-palatine fossa.

Branches.—*From the first part.*—The **deep auricular artery** passes upwards in the parotid gland to the external auditory meatus. It supplies also the mandibular joint and the superficial surface of the tympanic membrane. It anastomoses with branches of the superficial temporal and posterior auricular arteries.

The **anterior tympanic artery** is a variable and small branch. It runs upwards and backwards, traverses the squamo-tympanic fissure, and enters the tympanum near its lateral wall. In the tympanic cavity it anastomoses with tympanic branches from the internal carotid and ascending pharyngeal arteries, and with the posterior

ympanic branch of the stylo-mastoid artery, forming with the latter, in young subjects circular anastomosis around the tympanic membrane.

Middle Meningeal Artery.—This is the largest of the meningeal arteries; it is also y far the most important branch of the maxillary artery as it is a frequent source of æmorrhage after injury to the skull. It ascends between the lateral pterygoid muscle and the spheno-mandibular ligament and lies on the lateral surface of the tensor palati, which separates it from the pharyngo-tympanic tube; it passes between the two roots of the auriculo-temporal nerve and through the foramen spinosum, and enters the middle cranial fossa. Before it enters the skull it lies behind the mandibular nerve, nd is accompanied by a vein which descends through the foramen spinosum. In the middle cranial fossa it passes for a short distance forwards, in a groove on the greater wing f the sphenoid, in the outer layer of the dura mater, and divides into anterior and posterior terminal branches.

Branches.—A small **superficial petrosal** branch arises from the middle meningeal soon after it nters the cranium. It passes through the hiatus for the greater superficial petrosal nerve and anastomoses with the stylo-mastoid branch of the posterior auricular artery; it gives branches to he facial nerve and the wall of the tympanic cavity.

Minute branches supply the ganglion and the roots of the trigeminal nerve.

A small **superior tympanic artery** reaches the tympanic cavity through the canal for the tensor tympani, which muscle it supplies, or through the petro-squamous suture.

The **anterior terminal branch**, the larger and more important of the two, passes upwards along the greater wing of the sphenoid to the antero-inferior angle of the parietal bone, where it is often enclosed in a bony canal; it is continued upwards, a short distance behind the anterior border of the parietal bone, almost to the vertex of the skull, sending branches forwards and backwards. An occasional branch from the anterior terminal branch enters the orbit through the superior orbital fissure and anastomoses with the lacrimal artery.

The **posterior terminal branch** passes backwards from the greater wing of the sphenoid to the squamous part of the temporal bone, whence it sends branches upwards to the vertex and backwards to the occiput.

The anterior and posterior branches of the middle meningeal artery and their ramifications are separated from the bone by corresponding veins (p. 1341).

By means of its various branches the middle meningeal artery anastomoses—with its fellow of the opposite side; with the accessory meningeal artery; with meningeal branches from the occipital, ascending pharyngeal, ophthalmic, and lacrimal arteries; with the stylo-mastoid branch of the posterior auricular, in the temporal bone; and, through the skull-wall, with the middle and deep temporal arteries.

An **accessory meningeal artery** may arise either directly from the first part of the maxillary or from the middle meningeal artery. It enters the middle fossa of the skull through the foramen ovale, and supplies the trigeminal ganglion and the dura mater.

The **inferior dental artery** is a branch of moderate size which passes downwards, between the spheno-mandibular ligament and the ramus of the mandible, to the mandibular foramen. It is accompanied by the inferior dental nerve, which lies in front of it. Entering the foramen it descends with the nerve in the mandibular canal and, after giving off the mental artery, is continued in the bone to the median plane, where it anastomoses with its fellow of the opposite side.

Branches.—Before it enters the mandibular foramen it gives off a small **lingual** twig, which accompanies the lingual nerve and supplies the buccal mucous membrane. The **mylo-hyoid artery** is a small branch which arises immediately above the foramen. It pierces the spheno-mandibular ligament, and descends, with the mylo-hyoid nerve, in the mylo-hyoid groove to the floor of the mouth, where it anastomoses, on the superficial surface of the mylo-hyoid muscle, with the submental branch of the facial artery.

In the mandibular canal branches are given off to the molar teeth, to the premolar teeth, and, beyond the point of origin of the mental artery, to the canine and incisor teeth. The **mental artery**, which passes through the mental foramen, emerges beneath the depressor labii inferioris and anastomoses with its fellow of the opposite side, and with the inferior labial and submental arteries.

From the second part.—The **masseteric artery** is a small branch which passes laterally, through the mandibular notch, to the deep surface of the masseter muscle. It anastomoses in the substance of the muscle with branches of the facial and transverse facial arteries.

There are two **deep temporal arteries**—anterior and posterior. They ascend, in the temporal fossa, between the temporal muscle and the squamous part of the temporal bone, supplying the muscle and anastomosing with the middle temporal and lacrimal arteries, and, through the substance of the temporal bone, with the middle meningeal artery.

Small **pterygoid branches** supply the medial and lateral pterygoid muscles.

The **buccal artery** is a long, slender branch which passes obliquely forwards and downwards with the buccal nerve. It supplies the buccinator muscle, the skin and mucous membrane of the cheek, and it anastomoses with branches of the facial artery.

From the third part.—One or more **posterior superior dental arteries** descend, in the infratemporal fossa, on the posterior surface of the maxilla, and end in branches which supply the molar and premolar teeth and the mucous lining of the maxillary sinus; they also give twigs to the gums and to the buccinator muscle.

An **infra-orbital artery** arises in the pterygo-palatine fossa. It enters the orbit through the inferior orbital fissure and runs forwards, in the infra-orbital groove and canal, to the infra-orbital foramen, through which it emerges on the face, deep to the levator labii superioris. In the infra-orbital groove it gives branches to the inferior rectus and inferior oblique muscles of the orbit and to the lacrimal gland. In the infra-orbital canal it gives small twigs to the canine and incisor teeth (*ant. sup. dental arteries*) and to the walls of the maxillary sinus. In the face it sends branches upwards to the lower eyelid, to the lacrimal sac, and to the frontal process of the maxilla ; those anastomose with branches of the ophthalmic and facial arteries ; other branches run downwards to the upper lip, where they anastomose with the superior labial artery, and laterally into the cheek to unite with the transverse facial and the buccal arteries.

The **greater palatine artery** runs downwards, through the pterygo-palatine fossa and the greater palatine canal, to the roof of the mouth. As it descends it gives off the artery of the pterygoid canal and several small twigs (*lesser palatine arteries*) which pass through the lesser palatine canals to supply the soft palate, and to anastomose with the ascending palatine and tonsillar branches of the facial and with the ascending pharyngeal artery. The greater palatine artery runs forwards in the roof of the mouth, medial to the alveolar process and lateral to the accompanying nerve. Its delicate terminal portion ascends through the incisive canal and anastomoses in the nasal septum with a branch of the spheno-palatine artery. In its course forwards in the roof of the mouth the greater palatine artery supplies the gums and the mucous membrane of the hard palate, and also the palatine and maxillary bones.

The **artery of the pterygoid canal** is a long, slender branch, usually given off from the greater palatine ; it runs backwards through the pterygoid canal with the corresponding nerve and supplies branches to the upper part of the pharynx, to the levator and tensor palati muscles, and to the pharyngo-tympanic tube. One of the latter branches passes along the wall of the tube to the tympanic cavity, where it anastomoses with the other tympanic arteries.

The **pharyngeal branch** is a small artery which runs backwards, with the pharyngeal branch of the spheno-palatine ganglion, through the palatino-vaginal canal to the roof of the pharynx. It supplies the mucous lining of the upper and posterior part of the roof of the nose, the roof of the pharynx, the sphenoidal sinus, and the lower part of the pharyngo-tympanic tube.

The **spheno-palatine artery** is the continuation of the maxillary artery. It passes medially, through the spheno-palatine foramen, into the nose, where it gives off (*a*) a branch to the sphenoidal sinus, and (*b*) a branch which may replace the pharyngeal artery. Then it divides into nasal branches. The *posterior lateral nasal* branches supply the lateral wall of the nasal cavity and the sinuses which open through it, and they anastomose with the posterior and anterior ethmoidal arteries and the lateral nasal branch of the facial. The *posterior septal nasal* branch accompanies the long spheno-palatine nerve across the roof of the nasal cavity and downwards and forwards in the groove on the vomer. It anastomoses with the greater palatine artery and the septal branch of the superior labial.

INTERNAL CAROTID ARTERY

The **internal carotid artery** (Figs. 1076, 1078–1080) springs from the common carotid opposite the upper border of the thyroid cartilage, and ends in the middle fossa of the skull, in the vallecula of the cerebrum below the anterior perforated substance, where it divides into the anterior and middle cerebral arteries (Fig. 1079).

Course.—From its origin in the carotid triangle it ascends to the base of the skull, lying first medial to the sterno-mastoid, and then medial to the posterior belly of the digastric and the styloid process and its muscles. At first it lies postero-lateral to the external carotid, but as it ascends it gradually passes to the

medial side of that artery, from which it is separated by the styloid process, the stylo-pharyngeus muscle, the glosso-pharyngeal nerve, the pharyngeal branch of the vagus and a portion of the parotid gland.

At the base of the skull it enters the carotid canal, in which it ascends, anterior to the tympanum and the cochlea; then it turns antero-medially to the apex of

the petrous temporal bone, where it enters the foramen lacerum, through which it ascends, along the side of the body of the sphenoid, into the middle cranial fossa.

In the middle fossa it runs forwards, in the lateral wall of the cavernous sinus, to the lesser wing of the sphenoid; there it turns backwards along the medial border of the anterior clinoid process, which it grooves. At the tip of the process it turns upwards and laterally to the point where it divides below the anterior perforated substance of the cerebrum (Fig. 1079).

Relations.—Three main parts of the artery require separate consideration.

In the Neck.—Posterior to the artery are the longus capitis, the prevertebral fascia and the sympathetic trunk, which separate it from the transverse processes of the cervica vertebræ. *Postero-lateral* to it are the internal jugular vein and the vagus nerve; th accessory and glosso-pharyngeal nerves also are postero-lateral to the artery for short distance in the upper part of the neck, where they intervene between it and th internal jugular vein. *Medial* or deep to the internal carotid is the external carotid artery for a short distance below, and afterwards the wall of the pharynx, the ascendin

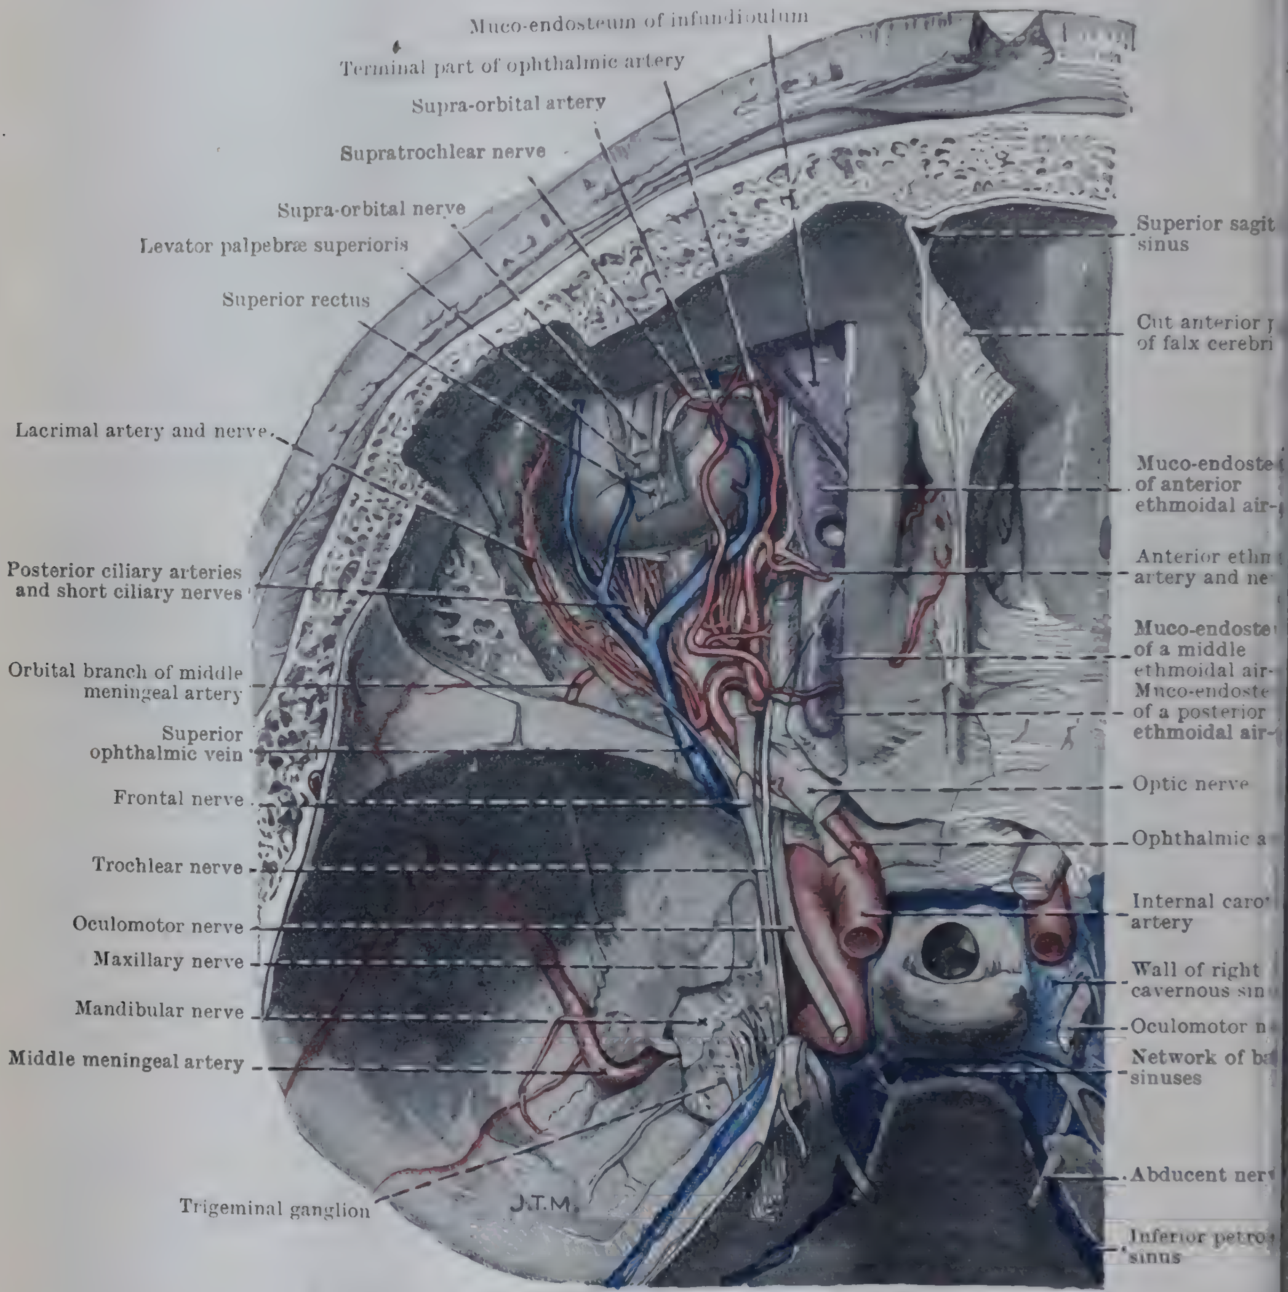

FIG. 1080.—DISSECTION OF ORBIT AND MIDDLE CRANIAL FOSSA.

On the right side the trochlear nerve has been removed, and in the left orbit portions of the structures above the ophthalmic artery have been taken away.

pharyngeal artery, the pharyngeal plexus of veins, and the external and internal laryngea nerves. Just before it enters the temporal bone the levator palati muscle is anter medial to it. *Lateral* or superficial to it are the sterno-mastoid, skin, and fasciæ, an it is crossed under cover of the sterno-mastoid, from below upwards, by the hypoglossa nerve, the occipital artery, and the posterior auricular artery. It is also crosse superficially, between the last-mentioned arteries, by the digastric and stylo-hyoid muscles which separate it from the parotid gland, and below the digastric it is covered by th lower part of the gland. Passing obliquely across its antero-lateral surface, an separating it from the external carotid artery, are the following structures—the styl pharyngeus, the styloid process (or the stylo-glossus muscle), and the glosso-pharyngea nerve, the pharyngeal branch of the vagus, and some sympathetic twigs.

In the Carotid Canal.—The artery, as it passes upwards, is antero-inferior to the cochlea nd the tympanum, postero-medial to the pharyngo-tympanic tube and the canal for ne tensor tympani, and below the trigeminal ganglion. The thin lamina of bone which eparates it from the tympanum is frequently perforated, and the lamina between it nd the trigeminal ganglion is often absent. In its course through the canal it is ccompanied by small veins and sympathetic nerves. The veins receive tributaries rom the tympanum, and communicate above with the cavernous sinus and below with he internal jugular vein. The nerves are branches of the superior cervical ganglion nd constitute the internal carotid plexus.

As it enters the cranial cavity the internal carotid artery pierces the external layer f the dura mater and passes between the lingula and the sixth cranial nerve laterally, nd the petrosal process of the body of the sphenoid medially.

In the Cranial Cavity.—The artery runs forwards, in the lateral wall of the cavernous inus, in relation with the oculomotor, trochlear, the ophthalmic division of the trigeminal, nd the abducent nerves laterally, and with the endothelial wall of the sinus medially. When it reaches the lower root of the lesser wing of the sphenoid it turns upwards to the nedial side of the anterior clinoid process, pierces the inner layer of the dura mater and he arachnoid, and comes into close relation with the inferior surface of the optic nerve, mmediately behind the optic foramen. It then runs backwards below the optic nerve, nd on the medial side of the anterior clinoid process which it frequently grooves; nclining laterally, it passes between the optic and oculomotor nerves, and finally urns upwards, a short distance from the corresponding lateral border of the optic hiasma, to end in the vallecula below the anterior perforated substance by dividing into ts two terminal branches—the anterior and middle cerebral arteries.

Carotid sinus.—The carotid sinus includes the root of the internal carotid artery, and may be limited to it (see p. 1255).

Variations.—The internal carotid artery is rarely absent, but its absence has been noted on one side (more commonly the left) and on both sides. Occasionally it springs from the arch of the aorta, and in its course through the neck it may vary in length and in tortuosity. One or more of the branches usually derived from the external carotid artery may arise from it, and it sometimes gives off a large meningeal branch to the posterior fossa of the skull. Its posterior communicating branch may replace the posterior cerebral artery; on the other hand, the upper part of the internal carotid may be absent, and the posterior communicating artery, springing from the posterior cerebral, may become the middle cerebral artery.

Branches of Internal Carotid Artery

Branches are given off from the internal carotid in the temporal bone and in the cranium, but no constant branches are given off in the neck.

In the Temporal Bone.—(1) A **carotico-tympanic branch**, very small, perforates the posterior wall of the carotid canal, and anastomoses in the tympanum with the tympanic branches of the stylo-mastoid, maxillary, and ascending pharyngeal arteries.

A small, inconstant branch accompanies the nerve of the pterygoid canal and anastomoses with the artery of the canal.

In the Cranium.—Small branches are distributed to the walls of the cavernous sinus, to the oculomotor, trochlear, trigeminal, and abducent nerves, to the trigeminal ganglion and to the dura mater of the middle cranial fossa.

One or two small branches supply the *hypophysis cerebri* (see p. 824).

(2) The **ophthalmic artery** (Figs. 1079, 1080) springs from the antero-medial side of the internal carotid immediately after it has pierced the dura and arachnoid on the medial side of the anterior clinoid process. It passes forwards and laterally, below the optic nerve, through the optic foramen into the orbital cavity. In the orbit it runs forwards, for a short distance, on the lateral side of the optic nerve, and it is in relation laterally with the ciliary ganglion and the lateral rectus muscle; turning upwards and medially, it crosses, between the optic nerve and the superior rectus, to the medial wall of the orbit, where it turns forwards to end near the front of the orbit by dividing into the supratrochlear and dorsal nasal arteries. It is accompanied at first by the naso-ciliary nerve and then by the infratrochlear nerve.

Variations.—The ophthalmic artery, as it traverses the orbit, may pass either above or below the optic nerve. It (or its lacrimal branch) is occasionally replaced by a branch of the middle meningeal artery.

Branches.—The branches of the ophthalmic artery are numerous. The **posterior cilia** arteries, usually six to eight in number, run forwards at the sides of the optic nerve; they so divide into numerous branches which pierce the fascial sheath of the eyeball and the posteri part of the sclera; the majority terminate in the choroid coat of the eye as the *short posteri ciliary arteries*, but two of larger size—the *long posterior ciliary arteries*—run forwards, one each side of the eyeball almost in the horizontal plane, between the sclera and the choroi to the periphery of the iris, where they divide. The resulting branches anastomose wi anterior ciliary arteries to form the *greater arterial circle* at the periphery of the iris, fr which secondary branches run inwards and anastomose together in a *lesser arterial circle* near t pupillary border of the iris.

The **central artery of the retina** arises in, or close to, the optic foramen and enters t dural sheath of the optic nerve. It pierces the infero-medial aspect of the nerve about half-w along its intra-orbital course, and runs with its companion vein in its centre to the retina whe it breaks up into terminal branches (see p. 1172). It is an 'end-artery' and the most importa branch of the ophthalmic.

Small **meningeal branches**, of which one arises from the lacrimal artery, pass backwar through the superior orbital fissure into the middle fossa of the cranium, where they anastomc with the middle and accessory meningeal arteries and with meningeal branches of the intern carotid artery.

The **lacrimal artery** arises from the ophthalmic on the lateral side of the optic nerv It runs forwards with the lacrimal nerve, along the upper border of the lateral rectus, to t upper lateral corner of the orbit, where it gives off branches to the lacrimal gland. In course it gives off *muscular branches* to the lateral and superior recti, and twigs whi accompany the zygomatico-temporal and zygomatico-facial branches of the zygomatic ner to the temporal fossa and the face respectively. The lacrimal artery gives off also *anter ciliary arteries* to the eyeball, and it ends in the *lateral palpebral arteries* which supply t conjunctiva and the eyelids.

The **muscular** branches are arranged in two sets: one supplies the upper and lateral orbi muscles, the other the lower and medial muscles. They anastomose with muscular branches fr the lacrimal and the supra-orbital arteries, and they give off *anterior ciliary arteries*.

The **anterior ciliary arteries** arise from muscular branches of the ophthalmic and from t lacrimal artery. They pierce the sclera behind the corneo-scleral junction and join the grea arterial circle of the iris. They give off small *episcleral arteries*, which pass forwards on t surface of the sclera to the corneo-scleral junction and give off in turn minute *anter conjunctival arteries*, which loop back in the conjunctiva to anastomose with posterior co junctival branches of the palpebral arteries. (For the circulation in the Eye and its access organs, see the Section on Organs of the Senses and Fig. 984, p. 1165.)

The **supra-orbital artery** is given off as the ophthalmic artery crosses above the optic ner It passes round the medial borders of the superior rectus and levator palpebræ muscles, and ru forwards, between the levator and the periosteum, to the supra-orbital notch or foram accompanying the frontal nerve and its supra-orbital branch. Passing through the notch reaches the scalp, and, after it has perforated the frontalis muscle, it anastomoses with the sup trochlear and superficial temporal arteries.

Anterior and **posterior ethmoidal arteries** arise from the ophthalmic as it runs forwa along the medial wall of the orbit. They pass medially, between the superior oblique a the medial rectus. The posterior, which is much the smaller of the two, traverses the poster ethmoidal canal and supplies the posterior ethmoidal sinuses and the posterior and upper part the lateral wall of the nasal cavity. The anterior ethmoidal artery passes through the anter ethmoidal canal with the anterior ethmoidal nerve, enters the anterior fossa of the skull a crosses the cribriform plate of the ethmoid to the nasal slit, passes through an aperture at t lateral side of that slit into the nasal cavity, where it descends, with the nasal continuation the anterior ethmoidal nerve, in a groove on the inner surface of the nasal bone, and, final passes between the lateral cartilage and the lower border of the nasal bone to the tip the nose. It gives off meningeal branches in the anterior cranial fossa and supplies anterior and middle ethmoidal cells, the frontal sinus, the nasal muco-periosteum, and the sk on the dorsum of the nose.

Medial palpebral arteries, upper and lower, are given off near the termination of ophthalmic. They are distributed to the upper and lower eyelids, and they anastomose with supra-orbital and infra-orbital arteries, and with the **lateral palpebral arteries**, which arise fr the lacrimal, to form the *superior* and *inferior palpebral arches*. The palpebral arteries give *posterior conjunctival arteries*, which anastomose with the anterior conjunctival branches of anterior ciliary arteries.

The **dorsal nasal artery** passes out of the orbit above the medial palpebral ligament pierces the palpebral fascia and ends on the side of the nose by anastomosing with the termi part of the facial artery.

The supratrochlear artery pierces the palpebral fascia at the upper and medial part of orbit, and ascends, with the supratrochlear nerve, in the superficial fascia of the anterior a medial part of the scalp, anastomosing with its fellow of the opposite side and with the sup orbital artery.

(3) The **posterior communicating artery** arises from the internal carotid near termination, and forms part of the *circulus arteriosus* (p. 1275). It runs backwar below the optic tract and anterior to the cerebral peduncle, and, passing above the ocu

tor nerve, joins the posterior cerebral artery. It gives branches to the optic chiasma, optic tract, the cerebral peduncle, the interpeduncular region, the internal capsule, l the thalamus. The posterior communicating artery varies much in size; it may be all on one or both sides, and sometimes it is very large on one side. Occasionally it laces the origin of the posterior cerebral artery from the basilar; and it sometimes ses from the middle cerebral artery.

(4) The **anterior choroid artery** is a small branch which also arises near the termina- n of the internal carotid; it passes backwards and laterally, between the cerebral luncle and the uncus, to the lower and anterior part of the choroid fissure, which it ers; and it ends in the choroid plexus of the inferior horn of the lateral ventricle. supplies the optic tract, the cerebral peduncle, the uncus, the posterior part of the ernal capsule, the tail of the caudate nucleus, part of the lentiform nucleus, and the ygdaloid nucleus. It anastomoses with the posterior choroid artery on the surface, the lateral geniculate body and helps to supply it (Abbie, 1933).

(5) The **anterior cerebral artery** is the smaller of the two terminal branches the internal carotid. It passes forwards and medially, above the optic iasma and in front of the lamina terminalis, to enter the longitudinal fissure of

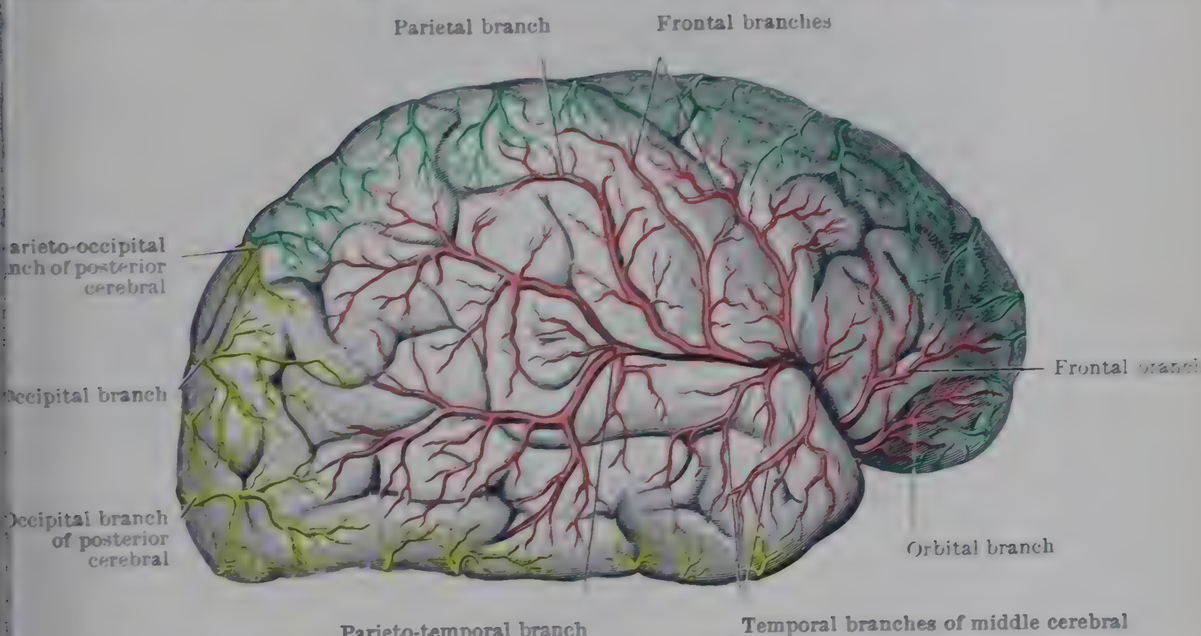

Fig. 1081.—Distribution of Cerebral Arteries on Supero-Lateral Surface of Right Cerebral Hemisphere.

The anterior cerebral artery is coloured *green*, the middle cerebral *red*, and the posterior cerebral *yellow*.

e cerebrum; it continues upwards and forwards along the rostrum of the rpus callosum, turns round the genu, and runs backwards in the longitudinal sure on the upper surface of the corpus callosum or in the sulcus cinguli; and ends by turning upwards on the medial surface of the hemisphere in front of e parieto-occipital sulcus and dividing into branches which pass over the supero- edial margin of the hemisphere. As it enters the longitudinal fissure it is closely nnected with its fellow of the opposite side by a wide but short **anterior com- unicating artery**, and from that point the two arteries run side by side, though parated by the arachnoid mater and, in the posterior part of their course, by the lge of the falx cerebri.

Branches.—Branches of all the cerebral arteries are distributed both to the interior the cerebrum and to the cerebral cortex; they therefore form two distinct groups which not communicate with one another—(*a*) **central**, (*b*) **cortical**.

The branches of the anterior cerebral are as follows:

Central Branches.—These are a small group of slender arteries which pass upwards to the base of the brain, in front of the optic chiasma; they pierce the lamina rminalis and the rostrum of the corpus callosum, and supply the head of the caudate ucleus, the anterior part of the lentiform nucleus and internal capsule, the anterior lumns of the fornix, the septum lucidum, and the anterior commissure. These branches re known as the **antero-medial central arteries**.

Cortical Branches.—The area supplied by these is seen in Figs. 1081, 1082; it

includes the corpus callosum. One or more small **orbital branches** supply the media half of the orbital surface and the olfactory lobe.

Several **frontal branches** are distributed to the medial surface of the frontal lobe, to the gyrus cinguli, to the superior and middle frontal gyri on the supero-lateral surface of the hemisphere, and to the upper part of the pre-central gyrus.

Parietal branches supply the precuneus, and the upper parts of the post-centra gyrus and the superior parietal lobule.

Branches of the anterior cerebral artery thus supply the upper parts of the motor and sensory areas of the cortex.

Variations.—The anterior cerebral may arise from the corresponding artery of the opposite side by enlargement of the anterior communicating artery; or there may be an additiona anterior cerebral artery, the third vessel arising from the anterior communicating artery.

(6) The **middle cerebral artery** is the larger of the two terminal branches of the internal carotid artery and is in more direct continuation with it. It passes

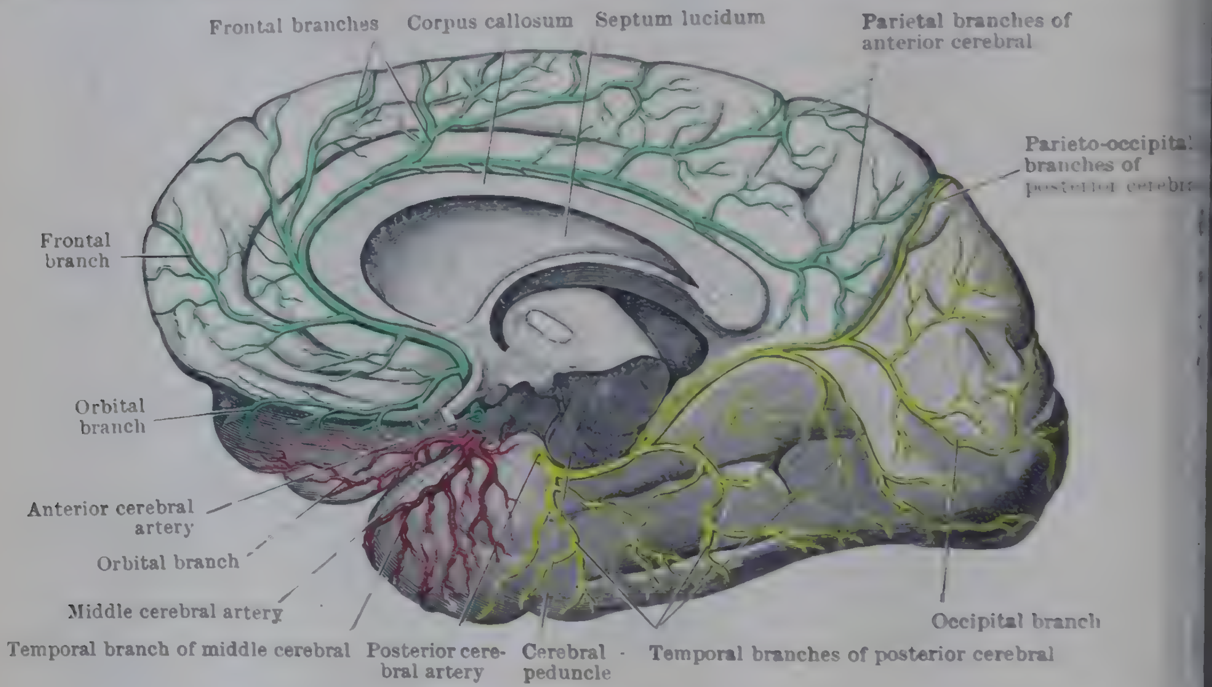

FIG. 1082.—DISTRIBUTION OF CEREBRAL ARTERIES ON MEDIAL AND TENTORIAL SURFACES OF RIGHT CEREBRAL HEMISPHERE.

The anterior cerebral artery is coloured *green*, the middle cerebral *red*, and the posterior cerebral *yellow*.

laterally, in the stem of the lateral sulcus, to the surface of the insula, where i divides into numerous parietal and temporal cortical branches.

Branches.—*Central branches* are numerous and very variable in size. They aris at the base of the brain and pierce the anterior perforated substance. They constitut the **antero-lateral central arteries**, and are arranged in two sets, known as the media and the lateral striate arteries.

The **medial striate arteries** pass upwards through the globus pallidus of the lentiforn nucleus and the internal capsule to end in the caudate nucleus. They supply th anterior parts of the lentiform and caudate nuclei and of the internal capsule.

The **lateral striate arteries** pass upwards through the putamen of the lentiforn nucleus, and between it and the external capsule, and they form two sets—an anteric and a posterior; both sets traverse the lentiform nucleus and the internal capsule, bu the anterior arteries terminate in the caudate nucleus, and the posterior in the thalamu One of the anterior set, which passes in the first instance round the lateral side of th lentiform nucleus and afterwards through its substance, is larger than its companions; is said to be the one that most frequently ruptures, and is known as the "artery c cerebral hæmorrhage".

Cortical branches are given off as the middle cerebral artery passes over the surface c the insula at the bottom of the lateral sulcus. They supply the gyri of the insula, tl deep surfaces of its opercula, and a considerable area of the frontal, parietal an temporal lobes (Figs. 1081, 1082).

One or two **orbital branches** run forwards and laterally, and are distributed to the ateral part of the orbital surface of the frontal lobe and to the inferior frontal gyrus.

Several **frontal branches** turn round the upper margin of the lateral sulcus, and re distributed to the inferior and middle frontal gyri, and to the greater part of the re-central gyrus.

Two main **parietal branches** emerge from the lateral sulcus and pass upwards and ackwards, supplying the post-central gyrus and the superior and inferior parietal lobules.

The **temporal branches** pass out of the lateral sulcus, and turn downwards to supply he greater part of the lateral surface of the temporal lobe.

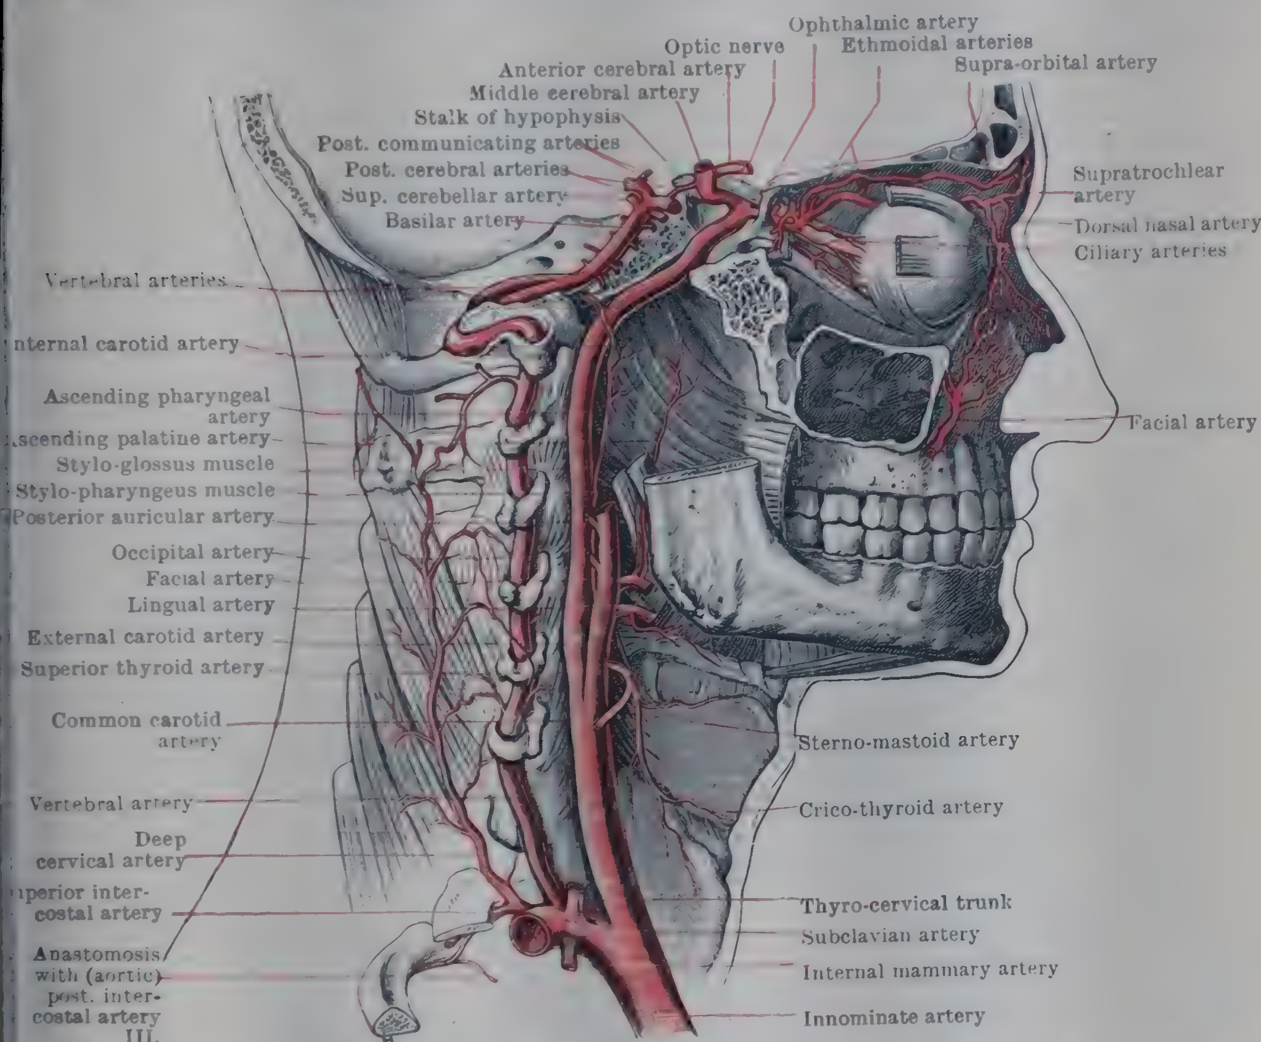

Fig. 1083.—Carotid, Subclavian, and Vertebral Arteries and their Main Branches.

A common parieto-temporal branch, continuing the main stem of the middle cerebral artery, emerges, as a rule, from the posterior end of the lateral sulcus; and divides into parietal and temporal branches (Fig. 1081).

VERTEBRAL ARTERY

The **vertebral artery** (Figs. 1083 and 1084) is the first branch given off from the subclavian trunk; it arises from the upper and posterior part of the parent stem, opposite the interval between the scalenus anterior and the longus cervicis muscles, and terminates at the lower border of the pons by uniting with its fellow of the opposite side to form the basilar artery.

Course and Relations.—The vertebral artery is divisible into four parts.

The **first part** runs upwards and backwards, between the scalenus anterior and the longus cervicis, to the foramen in the transverse process of the sixth cervical vertebra. Behind it are the transverse process of the seventh cervical vertebra, the anterior primary rami of the seventh and eighth cervical nerves, and also, a little to its medial side near its origin, the inferior cervical ganglion of the sympathetic trunk. Numerous sympathetic nerve-fibres are closely related to it, including communicating cords between the middle and inferior cervical ganglia

which pass in front and behind it. It is covered by the vertebral and internal jugular veins, and it may be crossed in front by the inferior thyroid artery. On the left side the terminal part of the thoracic duct also passes anterior to it.

The **second part** runs upwards through the foramina in the transverse processes of the upper six cervical vertebræ. As far as the second cervical vertebra its course is almost vertical; as it passes through the transverse process of the axis, however, it is directed obliquely upwards and laterally to the atlas. It is surrounded by a plexus of sympathetic nerve-fibres, and also by a plexus of veins. The artery lies anterior to the trunks of the cervical nerves, and medial to the intertransverse

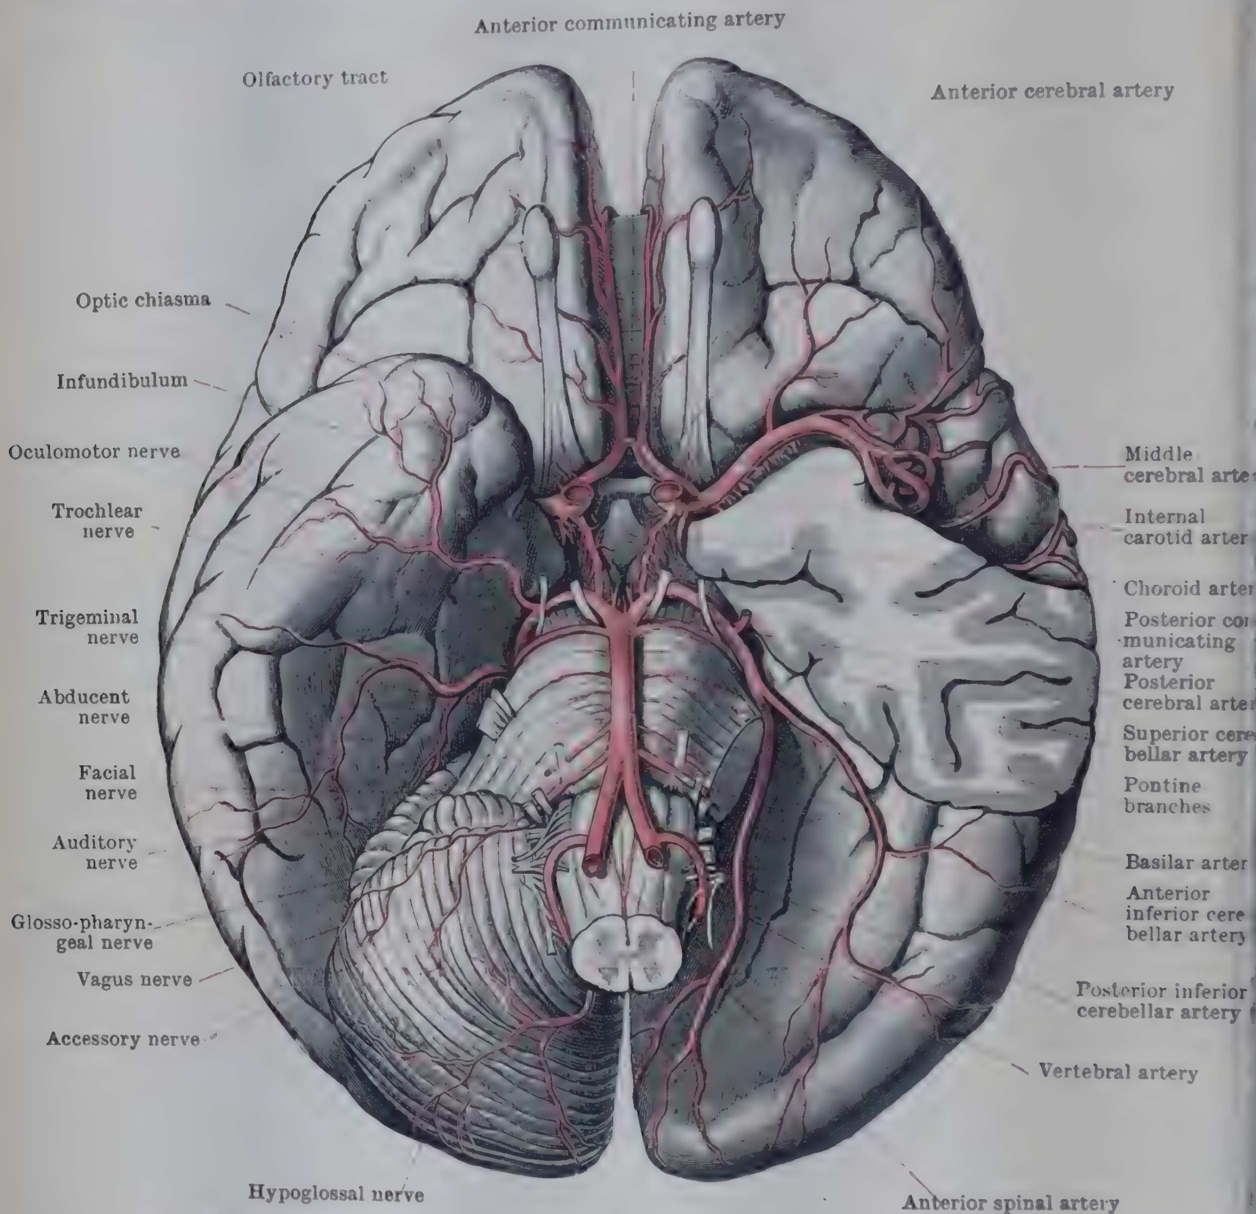

FIG. 1084.—ARTERIES OF BASE OF BRAIN SHOWING THE CIRCULUS ARTERIOSUS.

muscles. The **third part** emerges from the foramen transversarium of the atlas, between the anterior primary ramus of the first cervical nerve medially and the rectus capitis lateralis laterally, and runs almost horizontally backwards and medially, behind the lateral mass of the atlas. In that part of its course it enters the suboccipital triangle, where it lies in the groove on the upper surface of the posterior arch of the atlas. It is separated from the bone by the first cervical nerve, and is overlapped superficially by the superior and inferior oblique muscles. It leaves the triangle by passing anterior to the thickened (sometimes ossified) edge of the posterior atlanto-occipital membrane and enters the vertebral canal.

The **fourth part** pierces the spinal dura mater and the arachnoid mater immediately below the skull and then runs upwards in front of the first dentation of the ligamentum denticulatum into the cranial cavity through the foramen magnum.

it passes in front of the roots of the hypoglossal nerve, and, inclining to the front of the medulla oblongata, reaches the lower border of the pons, where it unites with its fellow of the opposite side to form the basilar artery (Fig. 1084).

Variations.—The vertebral artery may have a double origin—one from the subclavian, and one from the inferior thyroid artery or from the aorta.

The right vertebral may arise from the common carotid or from the arch of the aorta. Occasionally it springs from the descending aorta, an arrangement associated with the persistence of the dorsal roots of the fourth and fifth right arches.

The left vertebral artery not infrequently springs from the arch of the aorta, arising between the left common carotid and left subclavian arteries; that is evidently due to the absorption of the stem of the seventh intersegmental artery into the aortic arch. Very exceptionally the left vertebral is a branch of an intercostal artery.

In its course upwards either vertebral artery may enter the foramen transversarium of any of the lower six cervical vertebræ. If it does not enter one of the lowest of those foramina, it has probably been formed in part from the precostal instead of from the postcostal anastomosing channels.

The artery may enter the vertebral canal with the second cervical nerve instead of with the first, or, after leaving the foramen transversarium of the third vertebra, it may divide into two branches, one of which accompanies the second and the other the first cervical nerve; the two branches unite together again in the vertebral canal to form a single trunk.

Sometimes, though rarely, it gives off superior intercostal and inferior thyroid branches. The upper end of one of the vertebrals is sometimes very small, or it may end in small terminal branches; in the latter case the basilar artery is formed by the direct continuation of the opposite vertebral.

Branches.—**Muscular branches** which vary in number and size arise from the vertebral artery in the cervical part of its course. They supply the deep muscles of the neck and the suboccipital muscles, and anastomose with the deep and ascending cervical arteries and with the descending branch of the occipital artery.

Spinal branches pass from the *second part* of the vertebral artery through the intervertebral foramina into the vertebral canal, where they give off twigs which run along the roots of the spinal nerves to reinforce the anterior and posterior spinal arteries; they supply the bodies of the vertebræ and the intervertebral discs and anastomose with corresponding arteries above and below.

One or two small **meningeal branches** are given off before the vertebral artery pierces the dura mater. They ascend into the posterior fossa of the skull, where they anastomose with meningeal branches of the occipital and ascending pharyngeal arteries, and occasionally with branches of the middle meningeal artery.

The **posterior spinal artery** springs most commonly from the posterior inferior cerebellar branch of the vertebral (Stopford, 1916), but occasionally it arises from the vertebral directly. It runs downwards over the side of the medulla oblongata, giving branches to the fasciculi cuneatus and gracilis, and then on the spinal cord, along the line of the posterior nerve-roots. It is a slender artery, but is continued to the lower part of the spinal cord by means of reinforcements from the spinal branches of the vertebral and posterior intercostal arteries. These anastomose to form two more or less continuous longitudinal vessels, one in front of and the other behind the posterior nerve-roots, which finally end by joining the anterior spinal artery. Branches are given off to the posterior grey horn and others which anastomose in the pia mater before entering the lateral and posterior white columns.

The **anterior spinal artery** arises near the termination of the vertebral. It runs obliquely downwards and medially on the front of the medulla oblongata, and unites with its fellow of the opposite side in front of the decussation of the pyramids to form a single median trunk, which descends in the pia mater of the spinal cord under the linea splendens, and is continued as a fine vessel along the filum terminale. As it descends it is reinforced by anastomosing twigs from the spinal branches of the vertebral, posterior intercostal, and lumbar arteries, and it gives off branches which pass into the anterior median fissure of the spinal cord and divide to supply the grey matter, including the base of the posterior horn, of both sides. Branches from the right and left arteries and from the median vessel supply the anterior and medial parts of the medulla oblongata, including the hypoglossal nucleus and the hypoglossal triangle on the floor of the fourth ventricle (Stopford, 1916; Shellshear, 1927).

The **posterior inferior cerebellar artery** is the largest branch of the vertebral. It arises near the lower end of the olive and pursues a very tortuous course backwards round the medulla oblongata, at first between the rootlets of the hypoglossal nerve, and then upwards behind the rootlets of the vagus and glosso-pharyngeal nerves, loops backwards

and downwards from the lower border of the pons along the infero-lateral boundary o the fourth ventricle, and then turns outwards into the vallecula of the cerebellum, wher it divides into lateral and medial terminal branches. The trunk of the artery give branches to the medulla oblongata and to the choroid plexus of the fourth ventricle. Som of these branches supply the nuclei of the glosso-pharyngeal, vagus, and accessor nerves, the spino-thalamic, spino-cerebellar, rubro-spinal, and olivo-cerebellar tracts, an possibly also the vestibular root of the auditory and the spinal tract of the fifth nerv (Bury & Stopford, 1913). A special branch goes to supply the dentate nucleus of th cerebellum (Shellshear, 1922). The medial terminal branch runs backwards between th inferior vermis and the hemisphere of the cerebellum: it supplies the vermis, and anasto moses with its fellow of the opposite side. The lateral terminal branch passes to the lowe surface of the hemisphere and anastomoses with the superior cerebellar artery.

Basilar Artery.—The basilar artery is formed by the junction of the tw vertebral arteries; it begins at the lower border of the pons and ends a its upper border by bifurcating into the two posterior cerebral arteries.

Course and Relations.—It runs upwards, in the median part of the cistern pontis, in a shallow groove on the front of the pons, behind the sphenoidal sectio of the basi-cranial axis and between the two abducent nerves.

Variations.—The basilar artery may be double in part of its extent, or its lumen may b divided by a more or less complete septum. It may end in one instead of two posterior cerebr arteries, the missing vessel being supplied by the enlargement of the posterior communicatin branch of the internal carotid.

Branches.—A series of pairs of small **pontine branches** supply the pons, the midd cerebellar peduncles, and the roots of the trigeminal nerves.

The **internal auditory arteries** are a pair of long slender branches. Each intern auditory may spring either from the basilar or from the anterior inferior cerebellar arter of the same side (Stopford, 1916). It enters the corresponding internal auditory meat with the facial and auditory nerves, and is distributed to the internal ear.

The **anterior inferior cerebellar arteries** arise, one on each side, from the middle o the basilar artery. They pass backwards, on the anterior parts of the lower surfac of the hemispheres of the cerebellum, and anastomose with the posterior inferior cerebell arteries.

The **superior cerebellar arteries** arise near the termination of the basilar. Each pass laterally, at the upper border of the pons, directly below the oculomotor nerve of th same side, and, after turning round the lateral side of the cerebral peduncle, belo the trochlear nerve, it reaches the upper surface of the cerebellum, where it divide into a medial and a lateral branch. The medial branch supplies the upper part of th vermis, and the superior medullary velum. The lateral branch is distributed over th upper surface of the cerebellar hemisphere; it anastomoses with the inferior cerebell arteries.

The **posterior cerebral arteries** (Figs. 1079 and 1084) are the two termin branches of the basilar. Each runs backwards and upwards between the cerebr peduncle and the uncus and parallel to the superior cerebellar artery, fro which it is separated by the oculomotor and trochlear nerves. It is connecte with the internal carotid by the posterior communicating artery; it gives branche to the inferior surface of the cerebrum, and is continued backwards beneath th splenium of the corpus callosum to the calcarine sulcus, where it divides int occipital and parieto-occipital branches. It supplies the tentorial surface of th hemisphere, the medial and lateral surfaces of the occipital lobe, and the inferi temporal gyrus (Figs. 1081, 1082).

Variations.—The size of the posterior cerebral artery and the size of the posterior commun cating artery vary inversely, and the posterior cerebral may arise entirely from the intern carotid. It may be double, the extra vessel arising from either the basilar or the posteri communicating artery.

Branches.—*Central.*—A set of small **postero-medial central arteries** pass, on th medial side of the corresponding cerebral peduncle, to the posterior perforated substanc They supply the peduncle, the posterior part of the thalamus, the mamillary bodies, an the walls of the third ventricle.

A set of small **postero-lateral central arteries** pass round the lateral side of th

duncle. They supply the quadrigeminal and medial geniculate bodies, the pineal body, e peduncle, and the posterior part of the thalamus.

A set of small **posterior choroid branches** pass through the upper part of the choroid sure; they enter the posterior part of the tela choroidea of the third ventricle, and end the choroid plexus. They supply also the lateral geniculate body and the adjacent arts of the fornix and the thalamus.

Cortical.—Several **temporal branches** supply the uncus, the hippocampal gyrus, the edial and lateral occipito-temporal gyri, and the lingual gyrus.

The **occipital branches**, one of which continues the line of the main artery along the lcarine sulcus, supply the cuneus, the lingual gyrus, and the occipital pole; they are pecially associated with the supply of the visual area of the cortex of the brain.

The **parieto-occipital branch** passes along the corresponding sulcus and supplies he cuneus and precuneus.

Circle Of Willis

Circulus Arteriosus (Fig. 1084).—The cerebral arteries of opposite sides are itimately connected together at the base of the brain by anastomosing channels. hus, the two anterior cerebral arteries are connected with each other by the anterior ommunicating artery, whilst the two posterior cerebral arteries are in continuity rough the basilar artery, from which they arise. There is also a free anastomosis n each side between the carotid system of cerebral arteries and the vertebral ystem by means of the posterior communicating arteries, which connect the nternal carotid trunks and posterior cerebral arteries. It is probable that this free nastomosis equalizes the flow of blood to the various parts of the cerebrum, and rovides for the continuation of a regular blood-supply if one or more of the main runks should be obstructed.

These vessels form the so-called **circulus arteriosus**, described by Willis (1664) in classical work on the brain and therefore long known as the "circle of Willis". It s situated at the base of the brain in the interpeduncular cistern and encloses the ollowing structures: the posterior perforated substance, the mamillary bodies, the uber cinereum, the infundibulum, and the optic chiasma. The "circle" is irregu-arly polygonal in outline, and is formed behind by the termination of the basilar and y the two posterior cerebral arteries, postero-laterally by the posterior communicat-ng arteries and the internal carotids, antero-laterally by the anterior cerebral rteries, and in front by the anterior communicating artery.

Variations.—The posterior communicating artery is the most variable part of the "circle". It may be absent on one side or it may be larger than usual, so that the posterior cerebral artery arises mainly or even entirely from the internal carotid. The anterior communicating artery (which may be double or triple) also varies in size, and there may be corresponding reduction in size of the origin of one of the anterior cerebral arteries from the internal carotid.

ARTERIES OF UPPER LIMB

The main arterial stem of the Upper Limb passes through the root of the neck, traverses the axilla, and is continued through the upper arm to the forearm. In the forearm its extent is short, for it ends opposite the neck of the radius by bifurcating into the radial and ulnar arteries, which run through the forearm to the hand. That portion of the common trunk which lies in the root of the neck is known as the **subclavian artery**, the part in the axilla is termed the **axillary artery**, whilst the remaining part is called the **brachial artery**.

SUBCLAVIAN ARTERIES

The right subclavian artery (Figs. 1062, 1069, 1071, and 1076) is one of the two branches of the innominate artery, and it begins behind the sterno-clavicular joint; the left artery arises from the arch of the aorta opposite the left margin of the manubrium sterni.

The right artery is about 3 inches (75 mm.) long; it lies in the root of the neck. The left artery is about 4 inches (100 mm.) long; it is situated first in the superior mediastinum of the thorax and then in the root of the neck. In the root of the neck each artery arches laterally across the front of the cervical pleura and behind the scalenus anterior muscle; it is divided into three parts, which lie

respectively to the medial side, behind, and to the lateral side of the muscle. Th extent to which the arch rises above the level of the clavicle varies from half a inch to an inch. The first parts of the subclavian arteries differ from each othe both in extent and relations. The relations of the second and third parts ar similar on the two sides.

The **first part of the left subclavian artery** springs from the arch of th aorta, half an inch behind the origin of the left common carotid and on the lef side of the trachea. It ascends almost vertically, in the superior mediastinum, t the root of the neck, where it arches upwards and laterally to the medial borde of the scalenus anterior muscle.

Relations.—(A) **As it ascends.**—*Posterior.*—Left pleura and lung, laterally medially, first the œsophagus and the thoracic duct, and then fatty tissue and the longu

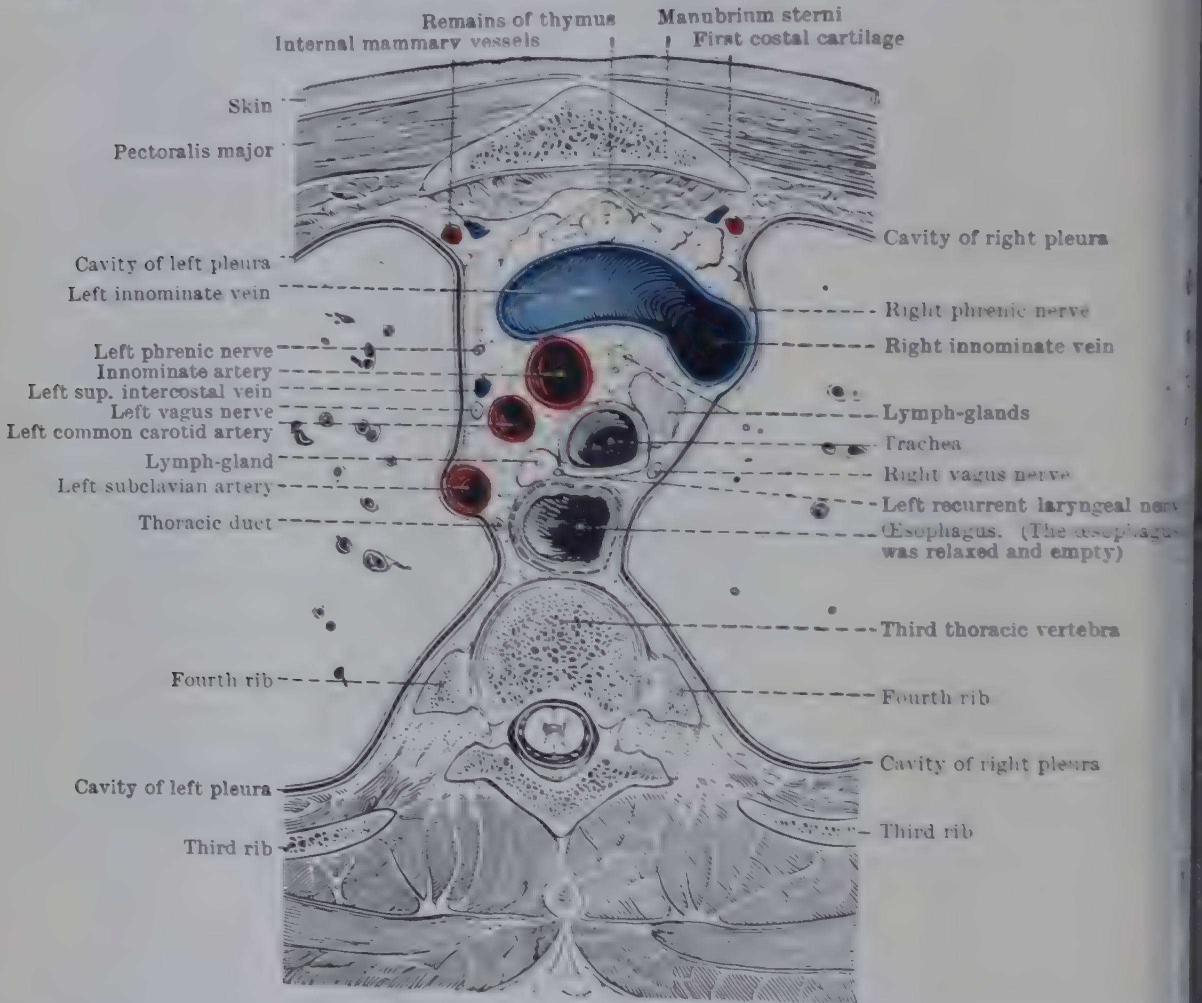

FIG. 1085.—TRANSVERSE SECTION OF THORAX OF YOUNG MAN THROUGH JUNCTION OF INNOMINATE VEINS. The section is in the Plane A-A, FIG. 1109, p. 1330.

cervicis muscle. *Anterior.*—The left vagus, the cardiac branch of the left superic cervical sympathetic ganglion, the inferior cardiac branch of the left vagus, the lef phrenic nerve, and the left common carotid artery, in front of which some distance awa is the left innominate vein. It is overlapped by the left lung and pleura. *Medial.*— From below upwards, the trachea, and, some fatty areolar tissue and perhaps a lympl gland intervening, the left recurrent laryngeal nerve, the œsophagus and the thoraci duct. *Lateral.*—The left pleura and lung, the lung being grooved by it.

(B) **As it runs laterally.**—*Posterior.*—The apex of the left lung and the cervica pleura covered by the suprapleural membrane. *Anterior.*—The vertebral and interna jugular veins; the phrenic nerve and the thoracic duct: the sterno-thyroid and stern hyoid muscles; the anterior jugular vein; and the sterno-mastoid.

The **first part of the right subclavian artery** (Fig. 1071) extends from th back of the right sterno-clavicular joint to the medial border of the scalenu anterior. Thus, it is limited to the root of the neck.

Relations.—*Posterior.*—Behind that part of the artery are the recurrent laryngeal rve, the posterior part of the ansa subclavia, and the apex of the right lung covered the cervical pleura and suprapleural membrane. *Inferior.*—The recurrent laryngeal rve curves backwards *below* it and intervenes between it and the pleural sac. *Anterior.*— front it is in relation with the right vagus, the cardiac branches of the vagus and the mpathetic, the anterior portion of the ansa subclavia, the internal jugular and vertebral ins, and more superficially the sterno-hyoid and sterno-thyroid muscles, the anterior gular vein, and the sterno-mastoid muscle. The right common carotid artery also is in ont of it at its origin.

The **second part of the subclavian artery**, on *each side*, extends from the edial to the lateral border of the scalenus anterior, behind which it lies.

Relations.—*Posteriorly* and *below* it is in relation with the pleural sac and supra- eural membrane. *Anteriorly* it is covered by the scalenus anterior and the sterno- astoid muscles. The scalenus anterior separates it from the subclavian vein, which lies a slightly lower level, from the transverse cervical and suprascapular arteries, from e anterior jugular vein, and, on the right side, from the phrenic nerve.

The **third part of the subclavian artery** is the most superficial portion. extends downwards and laterally from the lateral border of the scalenus anterior the outer border of the first rib, lying partly in the posterior triangle of the eck and partly behind the clavicle and the subclavius muscle.

Relations.—It rests upon the upper surface of the first rib. Immediately *posterior* it is the lowest trunk of the brachial plexus, which separates it from the scalenus edius muscle. *Anterior* to it, and at a slightly lower level, lies the subclavian vein. The ternal jugular vein crosses the medial part of that portion of the artery, and receives e transverse cervical and suprascapular veins; those vessels also pass in front of the rtery, which is thus covered superficially by venous trunks; it is also crossed vertically, ehind the veins, by the nerve to the subclavius muscle. The lateral section of that part f the artery lies behind the clavicle and the subclavius muscle. It is crossed in ont by the suprascapular artery, but the layer of deep cervical fascia which binds the ferior belly of the omo-hyoid to the posterior border of the subclavian groove tervenes between the two vessels. More superficially the third part of the artery is overed by the superficial layer of the deep fascia, the superficial fascia (containing the upraclavicular nerves and the platysma), and the skin.

Variations.—The variations in origin of the subclavian arteries have already been entioned (pp. 1251-1252). Other interesting modifications are met with in respect of its position nd branches.

The subclavian artery may reach as high as 1½ inches (4 cm.) above the clavicle, though as a ule it does not reach more than half that distance. On the other hand, it may not rise even o the level of the upper border of the clavicle. The differences appear to be associated with lescent of the clavicle and sternum, which occurs as age increases.

The artery may pass in front of or through the scalenus anterior instead of behind it, or he vein may accompany it behind the muscle.

The branches of the subclavian artery may be modified with reference to their points of origin; hus, those of the first part may be farther medial or lateral than usual, the suprascapular r some other branch of the thyro-cervical trunk may arise separately from the third part f the subclavian, and not uncommonly the deep branch of the transverse cervical artery s a branch of that part. The variations of the vertebral artery have already been described; hose of the thyro-cervical trunk and its branches are numerous but not important.

Branches of Subclavian Artery

(1) The **vertebral artery** is distributed almost entirely to the head and neck, and its chief function is to supply the posterior part of the brain. Its description has therefore been given with that of the other cerebral arteries (see p. 1271).

(2) The **thyro-cervical trunk** (Figs. 1071 and 1083) arises close to the medial border of the scalenus anterior, from the upper and front part of the subclavian artery. After a very short upward course, it ends, under cover of the internal jugular vein, by dividing into three branches—the inferior thyroid, the transverse cervical, and the suprascapular.

(A) The **inferior thyroid artery** (Fig. 1071) ascends along the anterior border of the scalenus anterior, and turns medially, opposite the cricoid cartilage,

to the middle of the posterior border of the corresponding lobe of the thyroid gland; it then curves medially and downwards, and descends to the lower end of the lobe, where it divides into ascending and inferior terminal branches.

Relations.—*Posterior* are the vertebral artery and the longus cervicis muscle; the recurrent laryngeal nerve passes either in front of or behind the vessel, behind the thyroid gland. It is covered *anteriorly* by the carotid sheath, which contains the common carotid artery, the internal jugular vein, and the vagus nerve; the middle cervical ganglion of the sympathetic lies in front of the artery, which often passes through a loop of the sympathetic trunk as it runs medially; and on the left side the thoracic duct also passes in front of it.

Branches.—Numerous small **muscular** branches pass to adjacent muscles.

The **ascending cervical artery** usually springs from the inferior thyroid as it turns medially, but it may arise separately from the thyro-cervical trunk. It ascends, parallel with and medial to the phrenic nerve, in the groove between the longus capitis and the scalenus anterior, to both of which it gives *muscular branches.* It also gives off *spinal branches* which pass through the intervertebral foramina to the vertebral canal. It anastomoses with branches of the vertebral, occipital, ascending pharyngeal, and deep cervical arteries.

Small **pharyngeal branches** supply the lower part of the pharynx; small **œsophageal branches** anastomose with the œsophageal branches of the thoracic aorta; and **tracheal branches** anastomose on the trachea with branches of the superior thyroid and with the bronchial arteries.

An **inferior laryngeal artery** accompanies the recurrent laryngeal nerve to the lower part of the larynx. It enters the larynx at the lower border of the inferior constrictor, gives branches to the laryngeal muscles and mucous membrane, and anastomoses with the laryngeal branch of the superior thyroid artery.

Inferior and ascending terminal **glandular branches** supply the posterior and lower parts of the thyroid gland, and anastomose with branches of the superior thyroid artery and with their fellows of the opposite side. Small branches are given to the parathyroid glands.

(B) The **transverse cervical artery** (Figs. 1076 and 1087) arises from the thyro-cervical trunk and runs upwards and backwards across the posterior triangle of the neck to the anterior border of the trapezius; there it divides into a superficial and a deep branch. It is very variable in size.

Immediately after its origin, under cover of the internal jugular vein, it crosses the scalenus anterior, lying superficial to the phrenic nerve and under cover of the sterno-mastoid muscle; on the left side it is also crossed, superficially, by the terminal part of the thoracic duct. Passing from beneath the sterno-mastoid, it enters the lower part of the posterior triangle of the neck, where it lies upon the trunks of the brachial plexus, and as it runs upwards and backwards to its termination it passes deep to the inferior belly of the omo-hyoid.

The superficial branch may be a separate vessel which springs from the thyro-cervical trunk and takes the course described, whilst the deep branch arises from the third part of the subclavian artery and lies at a lower level. In such cases the upper of the two vessels is called the *superficial cervical artery* and the lower the *descending scapular artery.*

Branches.—The **superficial branch**, usually a slender artery, passes beneath the trapezius; it sends branches upwards and downwards on the deep surface of the muscle where they anastomose with twigs from the descending branch of the occipital artery.

The **deep branch** runs downwards, deep to the levator scapulæ and the rhomboid muscles, close to the medial border of the scapula. It runs parallel with and a short distance lateral to the nerve of the rhomboids, and it sends branches into the supraspinous, infraspinous, and subscapular fossæ, which anastomose with branches of the suprascapular and subscapular arteries. It also sends branches backwards, through and between the rhomboid muscles, which anastomose with the posterior branches of posterior intercostal arteries.

(C) The **suprascapular artery** springs from the thyro-cervical trunk and ends in the infraspinous fossa of the scapula.

It begins behind the internal jugular vein, crosses the scalenus anterior

nd the phrenic nerve, and is covered superficially by the sterno-mastoid; on he left side it lies behind the thoracic duct also. Continuing laterally behind the lavicle and crossing superficial to the third part of the subclavian artery and the ords of the brachial plexus, it reaches the suprascapular notch and passes over he suprascapular ligament. It then descends, with the suprascapular nerve,

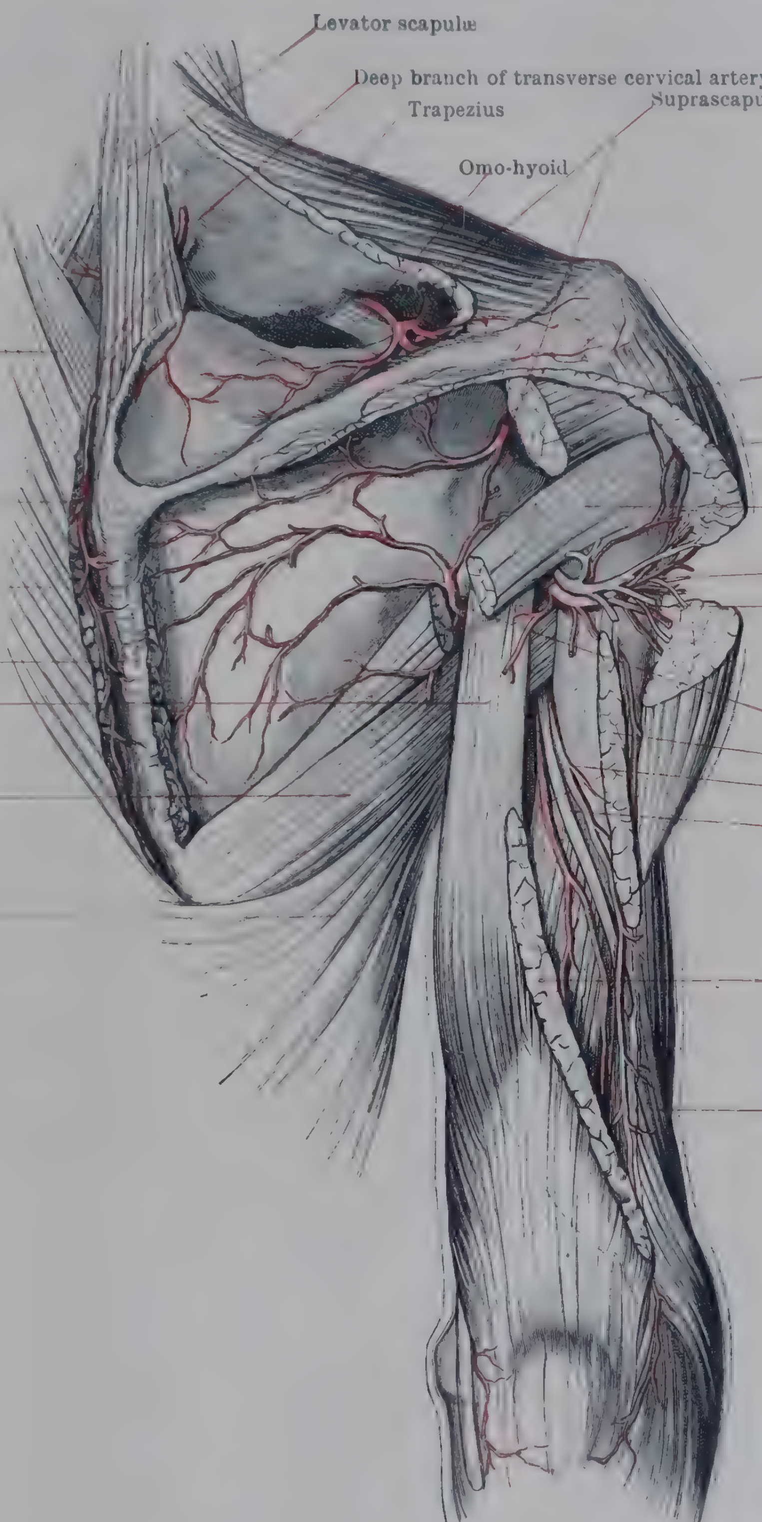

Fig. 1086.—Anastomosing Arteries on Dorsum of Scapula and Posterior Humeral Circumflex and Profunda Brachii Arteries.

through the supraspinous fossa and deep to the supraspinatus muscle, and after passing through the spino-glenoid notch, deep to the spino-glenoid ligament, it ends in the infraspinous fossa.

Branches.—The trunk of the artery gives branches to the adjacent muscles, a branch that passes superficial to the sternal end of the clavicle and an **acromial branch**, which ramifies over the acromion, anastomosing with the acromial branches of the acromio-thoracic and the posterior circumflex arteries.

As the artery passes over the suprascapular ligament, it gives off a branch into t subscapular fossa, which anastomoses with the branches of the subscapular artery a the deep branch of the transverse cervical artery.

In the supraspinous and infraspinous fossæ its branches anastomose also with the de branch of the transverse cervical; and in the infraspinous fossa they anastomose addition with the circumflex scapular artery.

The chief **muscular branches** of the suprascapular artery supply the supraspinat infraspinatus, and subscapularis muscles. The artery also supplies branches to the stern clavicular, acromio-clavicular, and shoulder joints, and nutrient arteries to the clavi and the scapula.

(3) The **internal mammary artery** (Figs. 1071, 1083) arises from the lower a anterior part of the subclavian, at the medial border of the scalenus anterior a usually immediately below the origin of the thyro-cervical trunk. It terminat behind the sternal end of the sixth intercostal space by dividing into t musculo-phrenic and superior epigastric arteries.

The artery passes at first downwards, forwards, and medially, lying upon t pleura, and behind the innominate vein, the sternal end of the clavicle, and t cartilage of the first rib; the right artery is crossed obliquely, from the lateral the medial side, by the phrenic nerve, which usually passes in front of it. Fro the cartilage of the first rib it descends vertically, about half an inch from t border of the sternum, and lies, in the upper part of its course, in front of the pleu and, in the lower part, in front of the sterno-costalis muscle. It is cover in front by the cartilages of the upper six ribs, the intervening anterior intercos membrane and internal intercostal muscles, and is crossed by the terminal portio of the intercostal nerves. It is accompanied by lymph-vessels and lymph-glan, and by two venæ comitantes, which unite at the level of the third costal cartila to form a single trunk which runs on the medial side of the artery to end in t innominate vein in the thorax.

Variations.—The internal mammary artery, though usually a branch of the first part of t subclavian, is very variable in origin. It may arise from the second or third part, or fr the thyro-cervical trunk, or it may spring from the aorta, or from the innominate or axill arteries. All these variations are due to obliteration of the normal origin and the openi up of anastomoses. The internal mammary artery sometimes descends in front of the cartila of one or more of the lower true ribs; and occasionally it gives off a *lateral costal branch* wh descends on the inner side of the chest-wall, close to the mid-axillary line—a point of importa in the operation of paracentesis. Occasionally a bronchial artery may arise from the inter mammary, and one or several small branches may pass to the lower end of the trachea.

Branches.—The **pericardiaco-phrenic artery** is a long slender branch which is giv off from the upper part of the internal mammary. It accompanies the phrenic ner to the diaphragm, where it anastomoses with the phrenic and musculo-phrenic arteri In its course downwards this artery gives off numerous small branches to the ple and pericardium, which anastomose with offsets of the mediastinal and pericard branches of the aorta and internal mammary arteries, and also with the bronch arteries, forming a wide-meshed *subpleural plexus* (Turner. 1865).

Numerous small **mediastinal branches** pass into the mediastinum and supply the ba of the sternum, the areolar tissue and lymph-glands, the thymus and the pericardiu The *thymic branches* are larger and more important in the child.

The **anterior intercostal arteries** are two in number in each of the upper six int costal spaces. They pass laterally and lie for a short distance between the ple (or the sterno-costalis) and the internal intercostal muscles; they then pass between t internal intercostal muscles and the innermost intercostals (see p. 428), and end anastomosing with the posterior intercostal arteries and their collateral branches.

The **perforating branches**, one in each of the upper six intercostal spaces, are sm vessels which pass forwards, with the anterior cutaneous branches of the intercos nerves, piercing the internal intercostal muscle, the anterior intercostal membrane, a the pectoralis major. They end in the skin and subcutaneous tissue. They supply tw to the sternum, and those in the second, third, and fourth spaces, usually the largest the series, give off *mammary branches* which are of special importance in the female arteries of supply to the mammary gland.

The **musculo-phrenic artery**, the lateral terminal branch of the internal mamma runs downwards and laterally, from the sixth intercostal space to the tenth cos

ilage. In the upper part of its course it lies upon the thoracic surface of the hragm, but it pierces the diaphragm about the level of the eighth costal cartilage, and on its abdominal surface. It gives off *muscular branches* to the diaphragm which tomose with phrenic branches of the thoracic aorta and with the phrenic arteries; it supplies two **anterior intercostal arteries** to each of the seventh, eighth, and h intercostal spaces. These are distributed in the same manner as the corresponding nches of the internal mammary artery, and end by anastomosing with the posterior rcostal arteries and their collateral branches.

The **superior epigastric artery**, the medial terminal branch of the internal mammary, ends into the anterior wall of the abdomen. It leaves the thorax, between the sternal costal origins of the diaphragm, and enters the sheath of the rectus abdominis scle, lying first behind the muscle and then in its substance. It ends by anasto-sing with branches of the inferior epigastric artery. It gives *muscular branches* the rectus, to the other muscles of the abdominal wall, and to the diaphragm. ll cutaneous branches pierce the rectus and the anterior wall of its sheath; these mpany the anterior terminal branches of the lower intercostal nerves and end in the cutaneous tissues and skin of the middle portion of the anterior abdominal wall. mall branch which supplies adjacent muscle and skin crosses the front of the xiphoid cess to anastomose with its fellow of the opposite side, and branches of small size pass kwards in the falciform ligament to the liver, where they anastomose with branches he hepatic artery.

(4) The **costo-cervical trunk** (Fig. 1083) springs from the back of the second rt of the subclavian artery on the right side and from the first part on the left e. It runs upwards and backwards, over the cervical pleura and the apex of e lung, to the neck of the first rib, where it divides into the deep cervical and perior intercostal arteries.

Branches.—The **deep cervical artery** runs backwards into the back of the neck, sing below the eighth cervical nerve, and between the transverse process of the seventh vical vertebra and the neck of the first rib. In the back of the neck it ascends ween the semispinalis capitis and semispinalis cervicis muscles, and it ends by astomosing with the descending branch of the occipital artery; it anastomoses also h branches of the ascending cervical and vertebral arteries. It supplies the adjacent iscles; and it sends a *spinal* branch into the vertebral canal through the intervertebral amen between the last cervical and the first thoracic vertebræ; this branch anasto-ses with the spinal branches of the vertebral and posterior intercostal arteries.

The **superior intercostal artery** descends, in front of the neck of the first rib, between e first thoracic nerve laterally and the sympathetic trunk medially. At the lower rder of the neck of the rib, it gives off the posterior intercostal artery of the first ace; then, after crossing in front of the neck of the second rib, it becomes the posterior ercostal artery of the second intercostal space. The **first two posterior intercostal teries** run laterally, each in its own space, lying first between the pleura and the sterior intercostal membrane, and then between the innermost intercostal and the internal ercostal muscle (see p. 448). They end by anastomosing with anterior intercostal anches of the internal mammary artery, and their branches are distributed in the same anner as those of the other posterior intercostal arteries (p. 1294).

Variations.—The **deep cervical artery** may arise directly from the subclavian trunk, and e **superior intercostal artery** may be absent, its place being taken by branches from the aorta. e superior intercostal is sometimes formed from a postcostal instead of a precostal primitive annel; in such cases it passes between the necks of the ribs and the transverse processes of e vertebræ instead of, as usual, in front of the necks of the ribs.

AXILLARY ARTERY

The **axillary artery** is the direct continuation of the subclavian artery, and it comes the brachial artery.

It begins at the outer border of the first rib, at the apex of the axilla. It asses downwards along the lateral wall of the space, *i.e.*, along the medial side of the houlder joint and the humerus, to the lower border of the teres major, where it ecomes the brachial artery. A line drawn from the middle of the clavicle to e medial border of the prominence of the coraco-brachialis muscle, when the

arm is abducted until it is at right angles with the side, indicates the positic and direction of the artery.

The position and direction, and to a certain extent the relations of th axillary artery, are modified, however, by changes in the position of the upp limb. With the arm hanging by the side the axillary artery describes curve with the concavity directed downwards and medially, and the vein lies alor its medial side. When the arm is at right angles with the side, the axillary arte

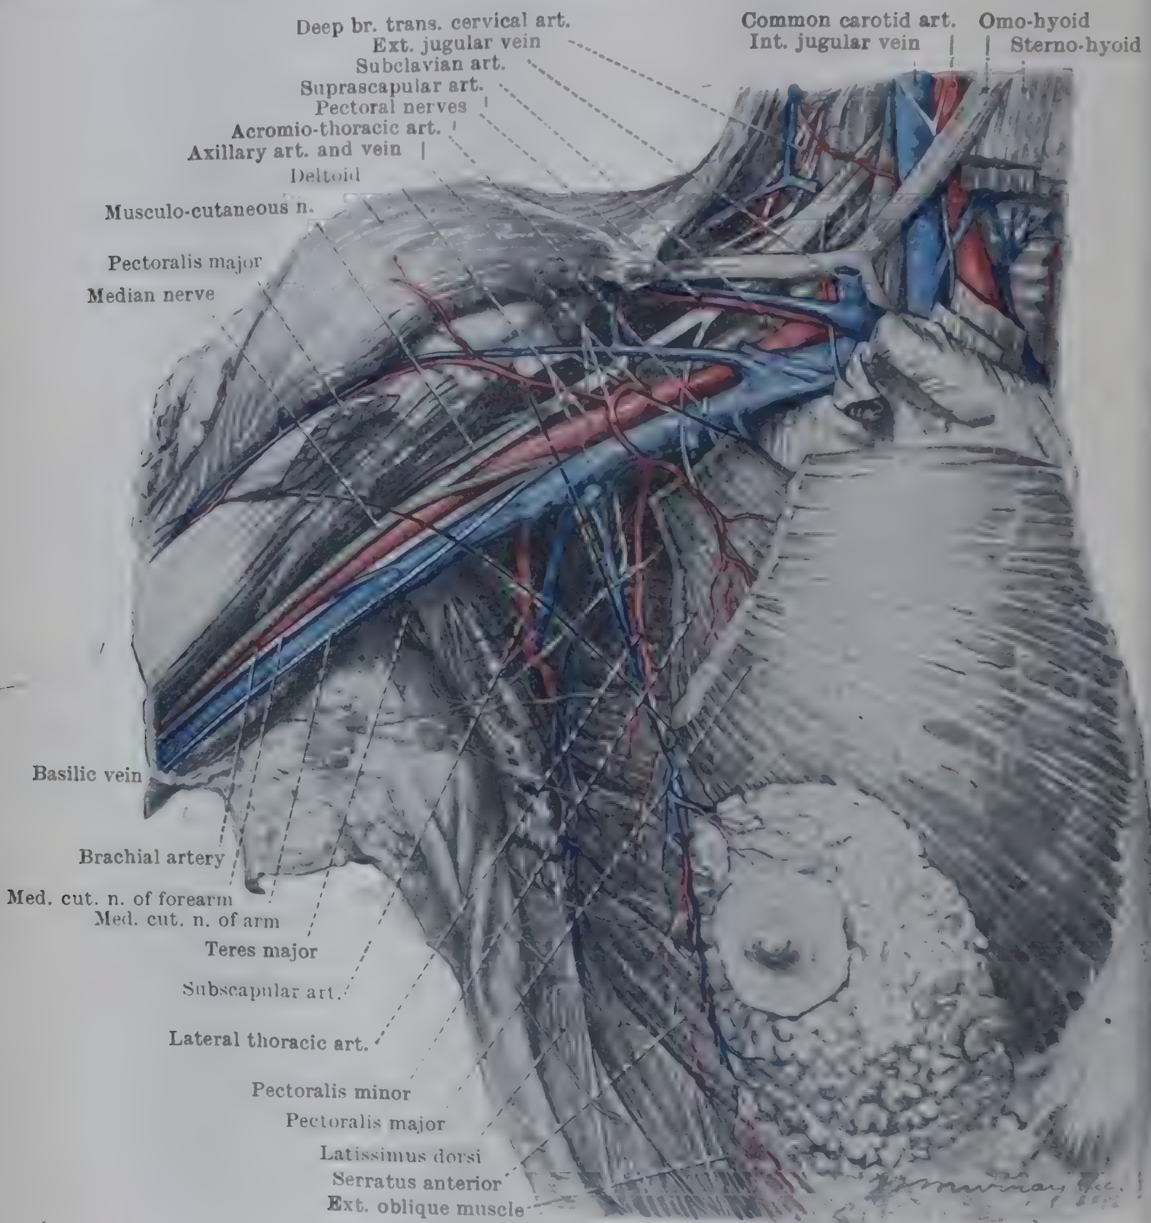

Fig. 1087.—Axillary Artery and its Branches.

The middle third of the clavicle has been removed, and the arm has been slightly abducted and rota laterally. Parts of the pectoralis major and minor have been removed; the positions of the low border of the pectoralis major and both borders of the pectoralis minor are indicated by broken bl lines.

is almost straight; it lies closer to the lateral wall of the axilla, and the ve overlaps it antero-medially. When the arm is raised above the level of t shoulder the axillary artery is curved over the head of the humerus, with t convexity of the curve below, and the vein lies still more in front of it.

For descriptive purposes the artery is divided into three parts: the fir part lies above the pectoralis minor, the second behind, and the third pa below it.

Though it is the usual custom to describe three parts of the axillary arte —a division which is of practical interest in so far as it emphasizes the fact th the axillary artery is surgically accessible above the pectoralis minor—it is to noted that the upper border of the pectoralis minor may be so nearly in line wi

e outer border of the first rib, at the point where the axillary artery begins, at the first part of the artery is exceedingly short.

Relations of First Part.—The first part of the artery is enclosed, together with e vein and the cords of the brachial plexus, in a prolongation of the cervical fascia iown as the *axillary sheath*. *Posterior.*—Behind the sheath are the upper serraon of the serratus anterior, the contents of the first intercostal space, and the nerve serratus anterior, which descends vertically between the artery and the muscle; ithin the sheath, the medial pectoral nerve and the medial cord of the brachial plexus e behind the artery. *Anterior.*—It is covered in front by the clavi-pectoral fascia. his fascia intervenes between the artery and the cephalic vein, the branches of the teral pectoral nerve, the branches of the acromio-thoracic artery with their accomınying veins, and the clavicular part of the pectoralis major muscle, superficial to hich are the deep fascia, the supraclavicular nerves descending from the cervical lexus, the platysma in the superficial fascia, and the skin. Posterior to the claviectoral fascia the artery is crossed by a loop of communication between the lateral nd medial pectoral nerves. *Lateral.*—Above and to the lateral side are the lateral nd posterior cords of the brachial plexus and the lateral pectoral nerve. *Medial.*—elow and to the medial side is the axillary vein, the medial pectoral nerve intervening.

Relations of Second Part.—*Posterior.*—Behind the second part of the artery are ne posterior cord of the brachial plexus and the fatty areolar tissue which separates it from ne subscapularis muscle. *Anterior.*—In front is the pectoralis minor, and, more supercially, the pectoralis major, the fasciæ and skin. *Lateral.*—To the lateral side lies the lateral ord of the brachial plexus. *Medial.*—On the medial side the medial cord of the plexus es in close relation to the artery, and intervenes between it and the axillary vein.

Relations of Third Part.—*Posterior.*—The third part of the artery rests upon ne lower part of the subscapularis, the latissimus dorsi, and the teres major. It is eparated from the subscapularis by the circumflex and radial nerves, and from the atissimus dorsi and teres major by the radial nerve alone. *Anterior.*—It is crossed in ront by the medial ~~head~~ of the median nerve. In its upper half it lies under cover f the lower part of the pectoralis major, the fasciæ and skin, whilst its lower part, hich is superficial, is covered by skin and fasciæ only. *Lateral.*—To the lateral side e the median and musculo-cutaneous nerves and the coraco-brachialis muscle. *Medial.*—o the medial side is the axillary vein. The two vessels are, however, separated by two f the chief branches of the medial cord of the brachial plexus—the medial cutaneous erve of the forearm in front and the ulnar nerve behind. The medial cutaneous erve of the arm lies medial to the vein, and the venæ comitantes of the brachial rtery ascend along the medial side to end in the axillary vein at the lower border of the ubscapularis muscle.

Variations.—The **axillary artery** does not vary much in its origin or course. Its relaions may be modified by the existence of a muscular or tendinous "axillary arch", which, assing from the latissimus dorsi to the pectoralis major, crosses the distal part of the artery uperficially; and there may be an anomalous arrangement of its branches. Occasionally the ubscapular, circumflex humeral, profunda brachii and ulnar collateral arteries arise from the xillary by a common stem. In those cases the chief branches of the brachial plexus are grouped ound the common stem instead of round the axillary artery. The arrangement is due to the ersistence of a different part of the original vascular plexus.

Sometimes the axillary artery divides into the radial and ulnar arteries, and more rarely the common interosseous artery may spring from it. Obviously there is no brachial artery when the adial and ulnar arteries are formed by the division of the axillary; its place is taken by he two abnormal vessels which, as a rule, are separated by the median nerve as they run hrough the arm; the radial is usually more superficial than the ulnar, and crosses laterally in front of it at the bend of the elbow.

Branches of Axillary Artery

(1) The **superior thoracic artery** is a small branch which arises from the first part of the axillary at the lower border of the subclavius. It runs downwards and medially, across the first intercostal space, and pierces the medial part of the clavi-pectoral fascia. It supplies branches to the adjacent muscles; and it anastomoses with branches of the suprascapular, the internal mammary, and the acromio-thoracic arteries.

(2) The **acromio-thoracic artery** (Fig. 1087) arises near the upper border of

the pectoralis minor, from the second part of the axillary artery. It is a very s
trunk, of considerable width, which passes forwards, pierces the clavi-pectoral fas
and ends, deep to the clavicular portion of the pectoralis major, by dividing
four terminal branches—acromial, clavicular, deltoid, and pectoral.

The **acromial branch** runs upwards and laterally, across the tip of the cora
process, to the acromion; it anastomoses with the deltoid branch, with the acro
branches of the suprascapular, and with the posterior circumflex humeral artery.

The **clavicular branch** is a long slender artery which runs upwards and medially
the sterno-clavicular joint, anastomosing with the superior thoracic, with branche
the suprascapular, and with the first perforating branch of the internal mammary ar
It supplies the adjacent muscles and the sterno-clavicular joint.

The **deltoid branch** descends, in the groove between the pectoralis major and del
muscles, where it lies by the side of the cephalic vein, as far as the insertion of
deltoid. It anastomoses with the acromial branch and with the anterior circumflex hum
artery; and it gives branches to the pectoralis major and deltoid muscles and to the s

The **pectoral** is a large branch which descends between the two pectoral muscles
both of which it gives branches, and it anastomoses with the intercostal and lat
thoracic arteries.

(3) The **lateral thoracic artery** arises from the second part of the axill
and descends, along the lateral border of the pectoralis minor, to anastomose w
the intercostal and subscapular arteries and with the pectoral branch of t
acromio-thoracic. It supplies the adjacent muscles, and sends *external mamm
branches* to the lateral part of the mammary gland.

(4) The **subscapular artery** is the largest branch of the axillary. It ar
from the third part of the artery opposite the lower border of the subscapul
along which it descends, giving branches to the muscle and to the medial
of the axilla. After a short course it gives off the circumflex scapular art
and then, accompanied by the nerve to the latissimus dorsi, continues along
lateral border of the scapula to the wall of the thorax, where it anastom
with the lateral thoracic artery, with branches of the intercostal arteries, and w
the deep branch of the transverse cervical. A large muscular branch enters
latissimus dorsi with its nerve at a well-defined neuro-vascular hilum (p. 409).

The **circumflex scapular artery** is frequently larger than the continuation of the pa
trunk. It arises about 1½ inches from the origin of the subscapular artery, and pa
backwards into the triangular space which lies between the subscapularis muscle ab
the teres major below, and the long head of the triceps laterally. Turning round
usually grooving the lateral border of the scapula, under cover of the teres mino
enters the infraspinous fossa, where it breaks up into branches which anastomose
the deep branch of the transverse cervical artery and the suprascapular artery.
the triangular space the artery gives off two branches; one passes into the subscap
fossa and anastomoses there with the same two arteries; the other runs downward
the inferior angle of the scapula, between the teres major and minor muscles. S
branches are given also to the deltoid and long head of triceps.

(5) The **posterior circumflex humeral artery** arises from the third part of
axillary artery and passes backwards, accompanied by the circumflex nerve, thro
the quadrangular space, which is bounded by the teres minor and subscapu
muscles above, the teres major below, the long head of the triceps medially, and
humerus laterally. It turns round the surgical neck of the humerus, under cove
the deltoid muscle, and ends in numerous branches which supply a large portio
the deltoid and anastomose with the anterior circumflex humeral and acro
thoracic arteries. As a rule it is only slightly smaller than the subscapular arte

Branches.—**Muscular branches** are given to the adjacent muscles, and a br
ascends, through the deltoid, to the acromion, where it anastomoses with the acro
branches of the suprascapular and acromio-thoracic arteries. A *descending branch*
downwards along the lateral head of the triceps to anastomose with the ascending br
of the profunda brachii artery; frequently this communication is enlarged so
the posterior circumflex humeral appears to take origin from the profunda brachii.
artery also supplies articular branches to the shoulder joint, and nutrient branche
the proximal end of the humerus.

5) The **anterior circumflex humeral artery** is a small branch; it is given om the third part of the axillary close to, or in common with, the posterior nflex. It passes laterally, deep to the coraco-brachialis and the two heads of iceps, around the front of the surgical of the humerus, and it ends by tomosing with the posterior humeral mflex. It gives muscular branches to adjacent muscles, one of which runs wards along the tendon of insertion ne pectoralis major. At the bicipital ve it gives off a well-marked branch h ascends along the tendon of the long of the biceps to the shoulder joint.

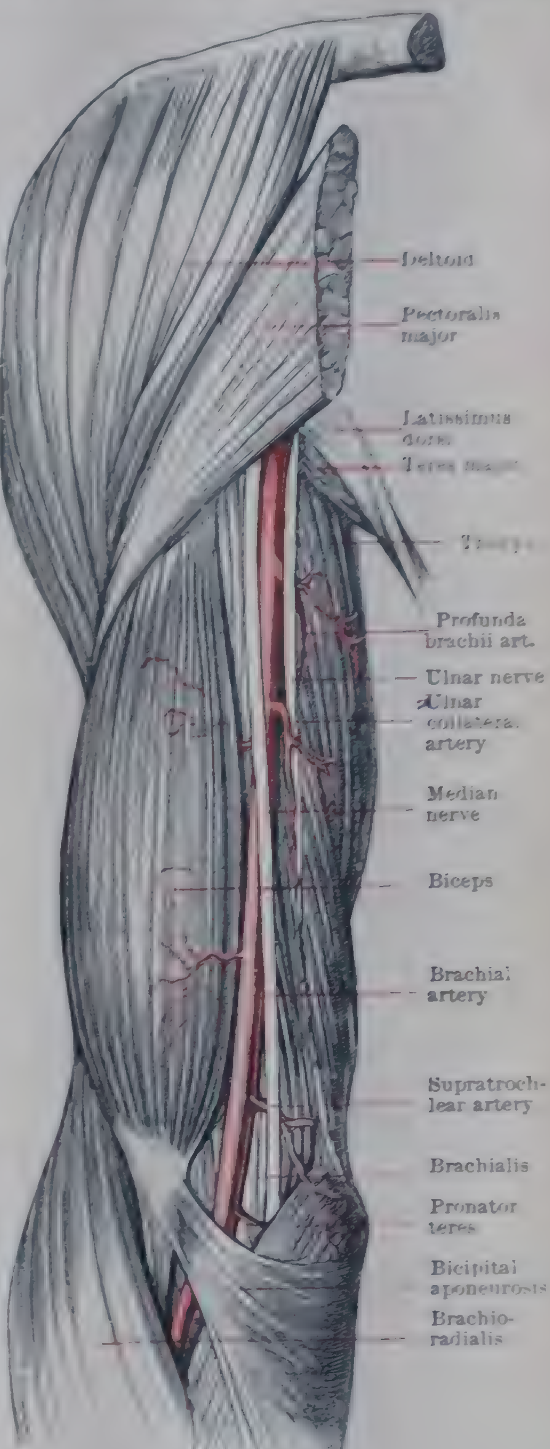

Fig. 1088.—Brachial Artery and its Branches.

BRACHIAL ARTERY

The **brachial artery** is the direct con- ation of the axillary. It begins at the r border of the teres major, and ends, he cubital fossa, opposite the neck of radius, by dividing into the radial and r arteries. It runs downwards at first e medial side of the humerus and then ont of it. Its position and that of the ary artery may be indicated on the ace, when the arm is abducted, by a drawn from the middle of the clavicle he centre of the bend of the elbow.

Relations.—*Posterior.*—It lies, success- , anterior to the long head of the triceps the radial nerve and the profunda vessels vening; the medial head of the triceps; nsertion of the coraco-brachialis; and the hialis. *Anterior.*—It is overlapped *an- rly* by the medial border of the biceps; it rossed, at the middle of the arm, by the ian nerve, and, in addition, it is covered leep and superficial fascia and skin. In cubital fossa a thickened portion of the fascia, called the bicipital aponeurosis, rates it from the median cubital vein and anterior branch of the medial cutaneous e of the forearm, both of which lie in the rficial fascia. *Lateral.*—To the *lateral side* in relation, proximally, with the median e, and, distally, with the biceps. *Medial.*— he *medial side* it is in relation, in the proxi- part of its extent, with the basilic vein, medial cutaneous nerve of the forearm, the ial cutaneous nerve of the arm, and the ulnar nerve, and in the distal part with the ian nerve. Two venæ comitantes, a medial and a lateral, accompany the artery, and munications between them pass across the vessel.

Variations.—The brachial artery is rarely prolonged beyond its usual point of bifurcation; uncommonly, however, it bifurcates at a higher level. Of the two terminal branches of radial, one may divide into radial and common interosseous, the other forming the ulnar; e may divide into radial and ulnar, whilst the other is the common interosseous. nally the brachial artery ends by dividing into three branches—viz., the radial, the ulnar, the common interosseous. The common interosseous was the original trunk (p. 1375 and 1135).

High division " of the brachial artery occurs most commonly in the proximal third of the r arm, and least commonly in the distal third; the resulting trunks are often united near bend of the elbow by a more or less oblique anastomosis.

When there is high division of the brachial artery the radial branch may pierce the deep fascia of the arm near the bend of the elbow and descend in the forearm in the superficial fascia; or it may run deeper and pass behind the tendon of the biceps. The ulnar branch sometimes runs, on the medial intermuscular septum, towards the medial epicondyle, and then laterally towards the middle of the bend of the elbow, behind a band of fascia from which the proximal fibres of the pronator teres arise, or behind the supracondylar process of the humerus if it is present. More commonly the ulnar branch descends towards the medial epicondyle and crosses superficial to the flexor muscles or deep to the palmaris longus; and in a few cases it is subcutaneous. Rarely the ulnar artery accompanies the ulnar nerve behind the medial epicondyle; it has then obviously been formed by enlargement of the ordinary ulnar collateral and posterior ulnar recurrent arteries.

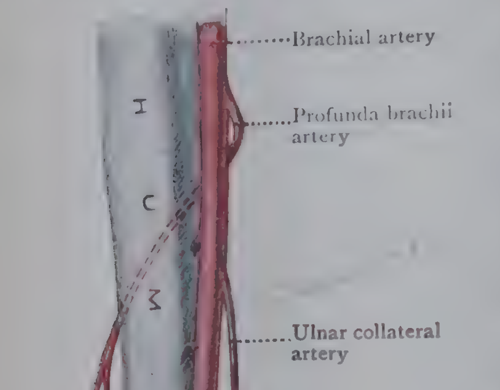

Fig. 1089.—Diagram of Anastomosis around Elbow Joint. (Cf. Pl. LXXXI p. 1296.)

Instead of following its usual course along the brachialis muscle, the brachial artery may accompany the median nerve behind a supracondylar process (p. 255), or ligament, as in many carnivora; it may pass in front of the median nerve instead of behind it. It may give off a "vas aberrans" or a median artery, and any of its ordinary branches may be absent.

The vas aberrans given off from the brachial artery usually ends in the radial artery, sometimes in the radial recurrent, and rarely in the ulnar artery.

Branches of Brachial Artery

(1) The **profunda brachii artery** is a large branch which arises from the postero-medial side of the brachial soon after its origin. It runs downwards and laterally in the groove for the radial nerve, and divides at the back of the humerus into two descending branches—anterior and posterior. Not infrequently the division takes place at a higher level, and the artery appears double. The *anterior descending branch* accompanies the radial nerve through the lateral intermuscular septum and then descends between the brachio-radialis and the brachialis to the front of the lateral epicondyle, where it anastomoses with the radial recurrent artery. The *posterior descending branch* continues downwards behind the lateral intermuscular septum to the back of the lateral epicondyle, where it anastomoses with the interosseous recurrent and supratrochlear arteries.

Behind the humerus one of the descending branches gives off: (*a*) a slender twig which descends with the nerve to the anconeus muscle in the medial head of the triceps to the back of the elbow where it anastomoses with the supratrochlear artery; (*b*) a *nutrient branch* which enters a foramen on the posterior surface of the humerus; and (*c*) an *ascending branch* which anastomoses with the descending branch of the posterior circumflex humeral artery.

(2) **Muscular branches** are given to the adjacent muscles; one for the main supply of the biceps divides, each branch entering, with the corresponding branch of the nerve, a distinct neuro-vascular hilum on the deep surface of a belly.

(3) A small **nutrient branch** arises from the middle of the brachial and enters the nutrient foramen on the antero-medial surface of the humerus.

(4) The **ulnar collateral artery** is smaller than the profunda, with which it sometimes arises by a common trunk; usually, however, it springs from the postero-medial side of the middle of the brachial artery. It runs downwards and backwards with the ulnar nerve, through the medial intermuscular septum, and then, passing more vertically, reaches the back of the medial epicondyle of the humerus, where it ends by anastomosing with the posterior ulnar recurrent and supratrochlear arteries.

(5) The **supratrochlear artery** arises from the medial side of the brachial artery about two inches above its bifurcation. It runs medially between the median nerve and the brachialis. It then pierces the medial intermuscular septum and turns laterally between the medial head of the triceps and the posterior surface of the bone to reach the lateral epicondyle. It supplies the adjacent muscles and it anastomoses in front of the medial epicondyle with the anterior ulnar recurrent, behind the medial epicondyle with the posterior ulnar recurrent and the ulnar collateral, on the back of the humerus with the twig from the profunda which follows the nerve to the anconeus, and behind the lateral epicondyle with the posterior descending branch of the profunda and with the interosseous recurrent artery (Pl. LXXXI, p. 1296).

RADIAL ARTERY

The **radial artery** (Figs. 1090 and 1091) is the smaller of the two terminal branches of the brachial artery, but it is in more direct line with the parent trunk. It begins in the cubital fossa opposite the neck of the radius, and it ends in the palm of the hand by anastomosing with the deep branch of the ulnar artery and thus completing the deep palmar arch.

The trunk is divisible into **three parts**. The *first part* lies in the forearm. It runs downwards and slightly laterally to the apex of the styloid process of the radius. The *second part* curves round the lateral side of the wrist, and across the scaphoid and trapezium, to reach the proximal end of the first interosseous space. The *third part* passes forwards through the first interosseous space to the palm of the hand, where it joins the deep branch of the ulnar artery.

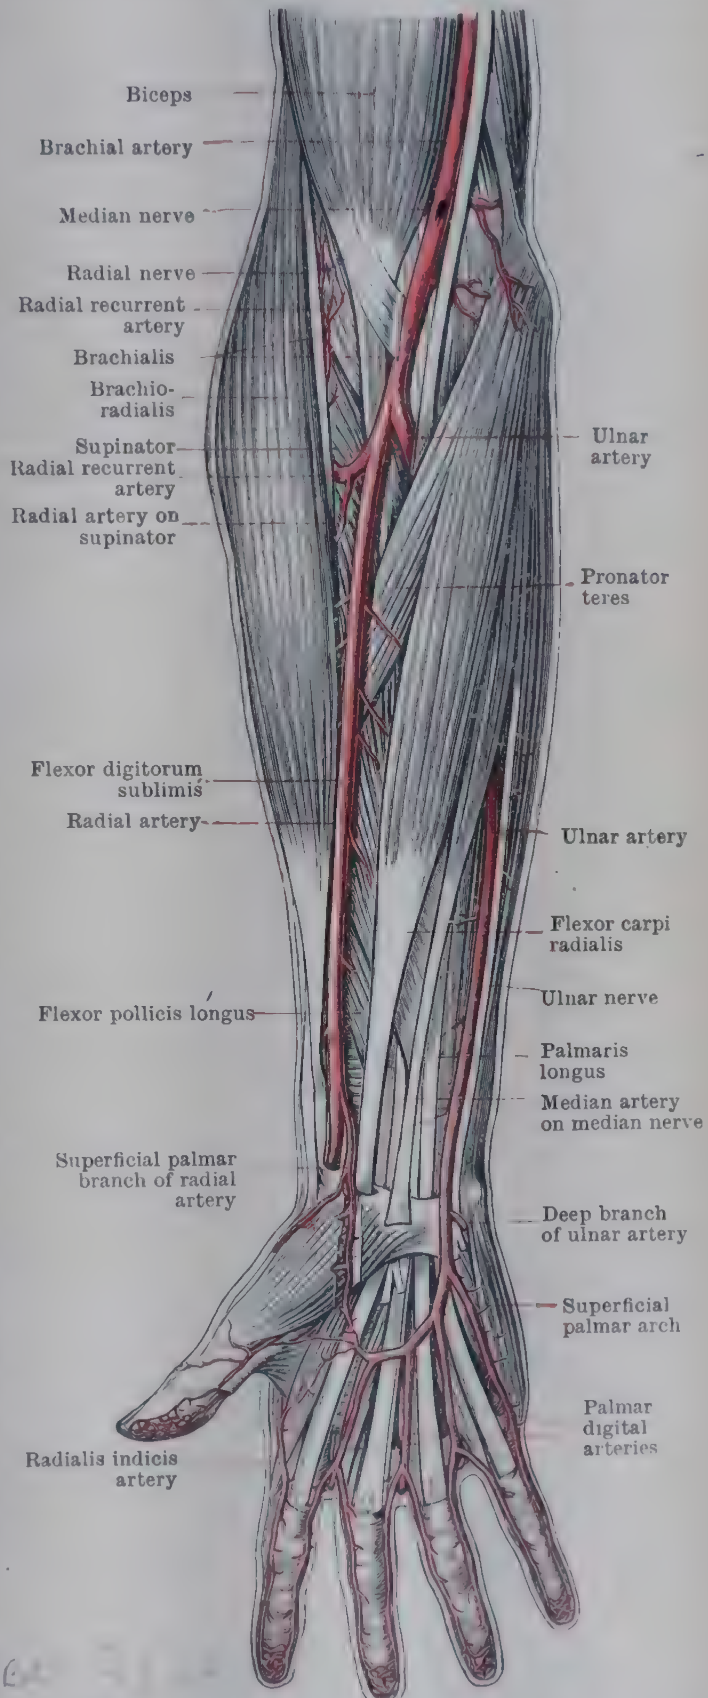

Fig. 1090.—Superficial Dissection of Forearm and Hand, showing Radial and Ulnar Arteries and Superficial Palmar Arch with its Branches.

Relations of First Part.—*Posterior.*—It passes successively across the following structures: the tendon of insertion of the biceps, the supinator, the pronator teres, the radial portion of the flexor digitorum sublimis, the flexor pollicis longus, the pronator quadratus, and the lower end of the radius.

Anterior.—The artery is covered superficially, in the proximal half, by the border of the brachio-radialis; in the remainder of its extent it is covered only by skin and fasciæ.

To the *radial side* are the brachio-radialis and the radial nerve. The nerve lies

near to the middle third of the artery. To the *ulnar side* are the pronator ter proximally, and the flexor carpi radialis, distally. Two venæ comitantes lie along tl sides of the artery.

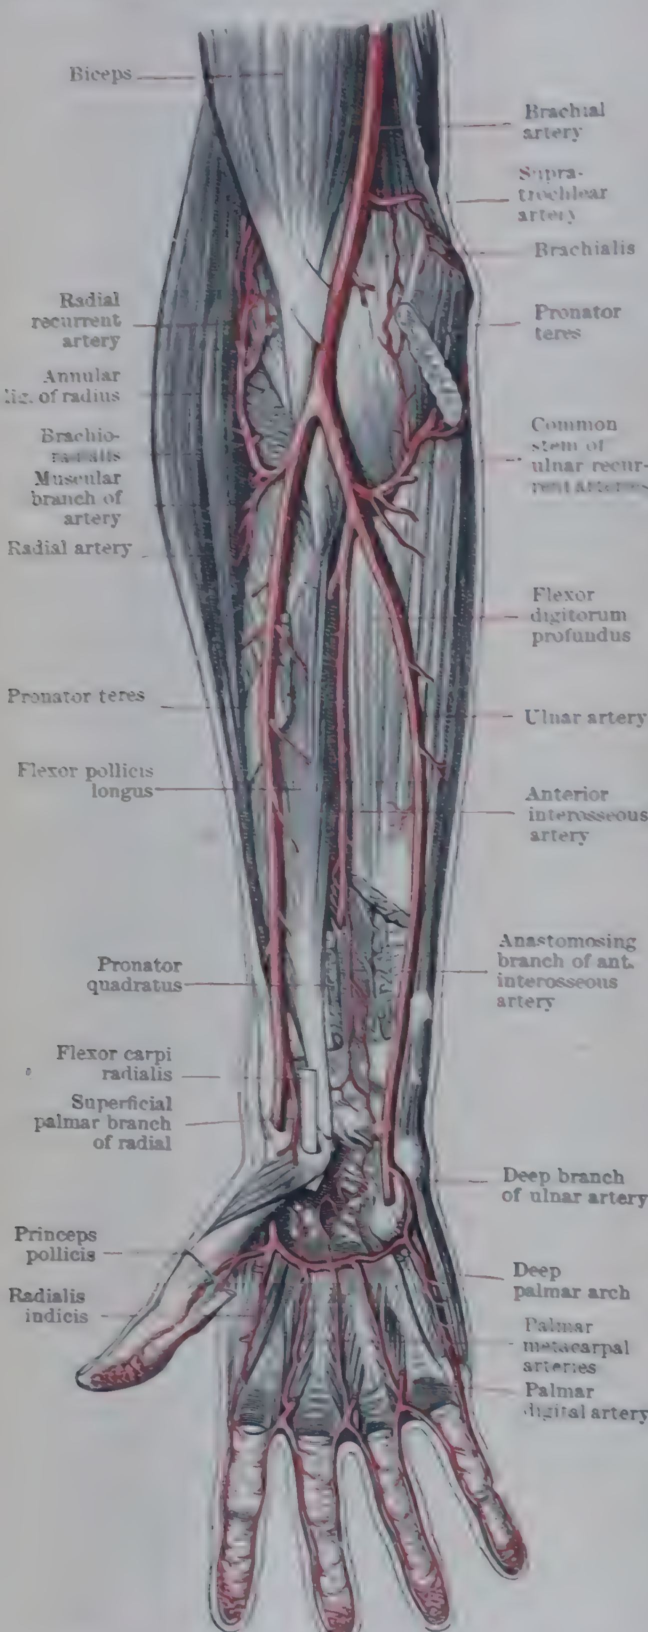

Fig. 1091.—Deep Dissection of Forearm and Hand, showing Radial and Ulnar Arteries and Deep Palmar Arch with its Branches.

Branches of First Part.—Tl **radial recurrent artery** arises in tl cubital fossa, where it springs fro the lateral side of the radial, on tl surface of the supinator. It runs t wards the radial border of the forear passes between the radial nerve and i posterior interosseous branch, and th runs upwards to the lateral epicond of the humerus, where it anastomos with the anterior descending branch the profunda brachii. The radial recu rent supplies numerous branches to t adjacent muscles.

Muscular branches supply t muscles on the radial side of the fo arm.

The **superficial palmar bran** (Fig. 1090) is a slender vessel whi arises a short distance above the wr and runs downwards across the b of the thumb. It usually pierces t superficial muscles of the thenar em ence, and ends either in their substan or by uniting with the ulnar artery complete the *superficial palmar arch.*

An **anterior carpal branch** pas medially, between the synovial shea of the flexor tendons and the rad attachment of the anterior radio-car ligament. It anastomoses with t anterior carpal branch of the ulnar arte to form the *anterior carpal arch*, and receives communications from the a terior interosseous artery and from t deep palmar arch.

Relations of Second Part. As it curves round the radial si and the dorsum of the wrist, the rad artery lies upon the lateral ligame of the wrist, and upon the scaph bone and the trapezium. It is cross by the tendons of the abductor polli longus, the extensor pollicis brevis, a the extensor pollicis longus; more sup ficially it is covered by skin, and fascia, which contains the commenceme of the cephalic vein and some filame of the radial nerve.

Branches of Second Part (F 1092).—The **posterior carpal bran** runs medially on the distal row of t carpus, deep to the extensor tendo and joins the posterior carpal branch the ulnar artery to complete the *poster* *carpal arch.* From the arch three **dorsal metacarpal arteries** run downwards on t second, third, and fourth dorsal interosseous muscles, and divide opposite the heads the metacarpal bones, each into two **dorsal digital arteries** which supply the adjac sides of the fingers and anastomose with the palmar digital arteries.

Two *dorsal digital arteries of the thumb* and a *radial dorsal digital artery of*

r take independent origin from the radial artery; the former run along the dorsal ders of the thumb and anastomose with the palmar digital branches of the princeps cis; the latter, from which the adjacent vessel of the thumb may arise, runs downwards the ulnar head of the first dorsal interosseous muscle to reach the radial border of index finger.

Each dorsal metacarpal artery is connected with the deep palmar arch by a *proximal rating branch* which passes through the proximal part of the corresponding interosseous e, and with a digital branch from the superficial palmar arch by a *distal perforating branch* ch passes through the distal part of the space. The first dorsal metacarpal (which runs on second dorsal interosseous muscle) may arise direct from the radial or in common with the terior carpal branch.

Relations of Third Part.—The third part of the radial artery passes between two heads of the first dorsal interosseous muscle to reach the palm, where it turns dially, deep to the oblique head of the adductor pollicis, and, after passing through proximal fibres of the transverse head, or between the two heads of that muscle, it tes with the deep branch of the ulnar artery, completing the *deep palmar arch*.

Branches of Third Part.—The **princeps pollicis artery** is given off as soon as radial artery enters the palm. It runs downwards, on the palmar aspect of the first tacarpal bone, between the adductor and the opponens pollicis, and under cover of the g flexor tendon. Near the distal end of the bone it divides into two *palmar digital teries*, which run along the sides of the thumb and anastomose with the dorsal digital teries (Pl. LXXXII, p. 1297).

The **radialis indicis artery** is a branch which descends between the ulnar head of the st dorsal interosseous muscle and the adductor pollicis and along the radial side the index finger to its tip. It supplies the adjacent tissues, and not uncommonly it astomoses with the superficial palmar arch.

Variations.—The **radial artery** may be absent, its place being taken by branches of the nar or interosseous arteries. Its origin may be higher than usual, from the axillary, or from e brachial. It may end in muscular branches in the forearm, or as the superficial palmar, or carpal branches; the distal portion of the artery is then usually replaced by branches of the nar or interosseous arteries. Occasionally the radial divides some distance proximal to the ist into two terminal branches, one of which gives off the carpal branches, and becomes e superficial palmar, whilst the other crosses superficial to the extensor tendons and passes to e back of the wrist.

The radial artery may run a superficial course, or, and especially when it arises at a more stal level than usual, it may pass deep to the pronator teres and the radial origin of the flexor gitorum sublimis. Sometimes it passes to the back of the wrist across the brachio-radialis, and may lie superficial to the extensor tendons of the thumb, instead of deep to them.

Its branches may be diminished or increased in number. The radial recurrent may spring om the brachial or ulnar arteries, or may be represented by several branches from the proximal rt of the radial. The radial dorsal digital artery of the index finger may be large, and ay replace the princeps pollicis and the radialis indicis. The posterior carpal branch and rsal metacarpal arteries may be replaced—the former by branches of the interosseous arteries of e forearm, and the latter by the proximal perforating branches of the deep palmar arch.

The princeps pollicis and radialis indicis arteries may be absent, their places being taken ther by branches of the superficial palmar arch or by the radial dorsal digital artery of the dex.

ULNAR ARTERY

The **ulnar artery** (Figs. 1090 and 1091) is the larger terminal branch, but is n less direct line with the brachial artery. It begins in the cubital fossa, pposite the neck of the radius, and ends in the palm of the hand, where it nastomoses with the superficial palmar branch of the radial artery to form the uperficial palmar arch.

From its origin it runs obliquely, downwards and medially, deep to the muscles hat arise from the medial epicondyle, to the junction of the proximal and middle hirds of the forearm, where it comes into relation with the ulnar nerve. It then uns straight, on the radial side of the ulnar nerve, to the wrist, where it passes n to the front of the flexor retinaculum and ends there, at the radial side of the isiform bone, by dividing into its *deep branch* and the *superficial palmar arch* Pl. LXXXII, p. 1297).

Relations—*Posterior.*—In succession it lies in front of the distal part of the brachialis, he flexor digitorum profundus, and the flexor retinaculum. *Anterior.*—It is crossed, in

the oblique part of its course, by the pronator teres, the median nerve (which is separated from the artery by the ulnar head of the pronator teres), the flexor digitorum sublimis the flexor carpi radialis, and the palmaris longus. In the middle third of the forearm it is overlapped by the flexor carpi ulnaris, and in the distal third it is covered by skin and fasciæ only. For a short distance above the wrist the palmar cutaneous branch of the ulnar nerve lies in front of it. On the flexor retinaculum it may be bound down by a fascial slip which passes from the superficial surface of the retinaculum to the pisiform bone and the tendon of the flexor carpi ulnaris. Two communicating venæ comitantes lie one on each side of the artery. On the *radial side* there is also, in its distal two-thirds, the flexor digitorum sublimis. On its *ulnar side* are the flexor carpi ulnaris and the ulnar nerve.

Branches.—The **anterior ulnar recurrent artery** is a small branch which arises in the cubital fossa, frequently in common with the posterior ulnar recurrent. It runs upwards, under cover of the pronator teres, to the front of the medial epicondyle and anastomoses with branches of the supratrochlear artery.

The **posterior ulnar recurrent artery**, larger than the anterior, arises in the cubital fossa from the ulnar side of the ulnar artery; it ascends, on the flexor profundus and under cover of the muscles which arise from the medial epicondyle, to the back of that prominence, where it passes between the humeral and ulnar heads of the flexor carpi ulnaris and anastomoses with the ulnar collateral and supratrochlear arteries. It gives branches to the adjacent muscles and to the elbow joint.

The **common interosseous artery** is a short trunk which springs from the postero-lateral side of the ulnar artery in the distal part of the cubital fossa. It passes backwards towards the proximal border of the interosseous membrane, and divides into anterior and posterior interosseous branches.

The **anterior interosseous artery** runs downwards on the anterior surface of the interosseous membrane, between the adjacent borders of the flexor pollicis longus and the flexor digitorum profundus, to the proximal border of the pronator quadratus, where it pierces the interosseous membrane; it then continues downwards, first on the posterior surface of the membrane, deep to the extensor pollicis longus and extensor indicis, and then on the distal end of the radius, in the groove for the extensor digitorum; and it ends on the back of the carpus by joining the posterior carpal arch. It is accompanied on the front of the interosseous membrane by the anterior interosseous nerve, and on the back of the membrane by an articular filament of the posterior interosseous nerve.

Branches.—It supplies **muscular branches** to the adjacent muscles, and gives *nutrient* branches to the radius and ulna. A slender *communicating* branch passes distally, deep to the pronator quadratus and on the interosseous membrane, to anastomose with the anterior carpal arch. After it has passed to the back of the forearm, it anastomoses with the posterior interosseous artery. The **median artery** is a long, slender branch which arises from the proximal part of the anterior interosseous and runs with the median nerve to the palm, where it anastomoses with recurrent branches of the superficial palmar arch.

The **posterior interosseous artery** is usually smaller than the anterior interosseous. It passes to the back of the forearm between the proximal border of the interosseous membrane and the oblique cord, and then between the supinator and the abductor pollicis longus, after which it descends between the superficial and deep muscles on the back of the forearm giving branches to them. It ends in the distal part of the back of the forearm by dividing into small branches, which anastomose with the anterior interosseous artery and so with the posterior carpal arch. As it crosses the abductor pollicis longus it is accompanied by the posterior interosseous nerve, but in the remainder of its course it is separated from the nerve by the deep muscles.

Branches.—An **interosseous recurrent artery** is given off at the distal border of the supinator. It runs upwards, on the posterior surface of the supinator, under cover of the anconeus, to the back of the lateral epicondyle of the humerus, where it anastomoses with the posterior descending branch of the profunda brachii and with branches of the supratrochlear artery. **Muscular branches** supply the adjacent muscles, and the artery also supplies the skin on the back of the forearm and the wrist.

The **anterior carpal branch** of the ulnar artery is a small branch given off above the flexor retinaculum; it passes towards the radial side, deep to the flexor tendons and their sheaths, on the anterior radio-carpal ligament, and anastomoses with the anterior carpal branch of the radial to form the anterior carpal arch.

The **posterior carpal branch** arises from the ulnar side of the ulnar artery, immediately proximal to the pisiform bone. It passes, deep to the tendons of the flexor and

ensor carpi ulnaris, to the back of the carpus, where it unites with the posterior carpal anch of the radial to form the posterior carpal arch.

The **deep branch of the ulnar artery** descends between the abductor and flexor giti minimi, and, turning wards the radial side, deep the flexor, the opponens, and e long flexor tendons and their eaths, it joins the radial tery to complete the *deep lmar arch.*

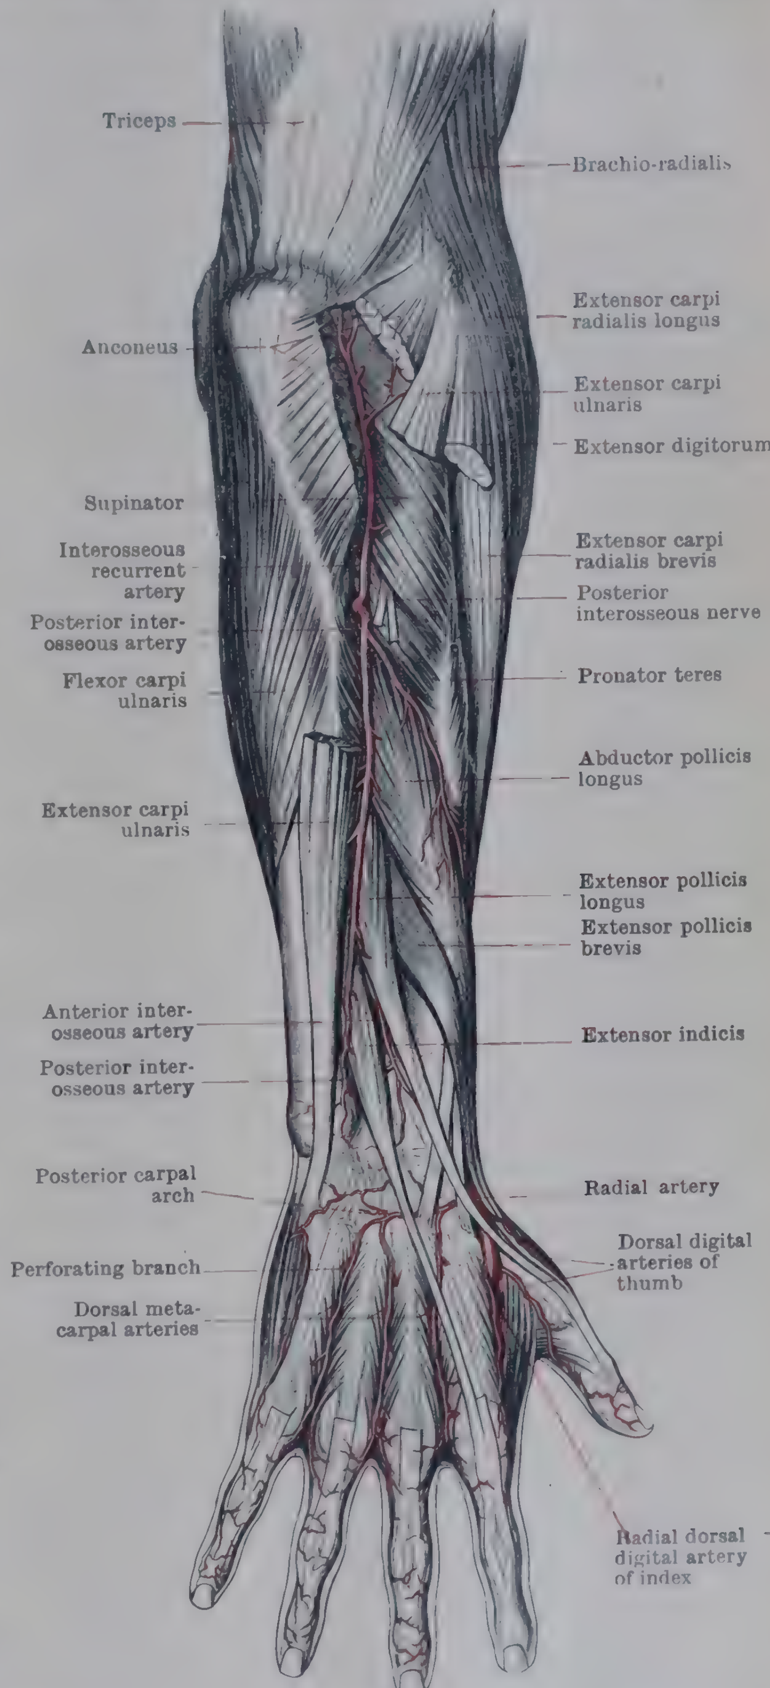

Fig. 1092.—Posterior Interosseous Artery and Second Part of Radial Artery, with their Branches.

Variations.—The **ulnar artery** ay be absent, being replaced by e median artery or the anterior terosseous artery, and it may end the deep palmar arch instead of the superficial. It rarely arises ore distally than usual, and hen it arises higher up it most ommonly passes superficial to the uscles which spring from the edial epicondyle. Moreover, it ien frequently has no interosseous ranch, the latter vessel spring-ng from the radial artery. In xplanation it may be noted that ie anterior interosseous artery is he original continuation of the rachial. Even when it begins at ie usual level the ulnar artery iay pass superficial to the muscles hat arise from the medial epi-ondyle, and its interosseous and ecurrent branches then spring rom the radial artery.

The **interosseous arteries** may rise separately from the ulnar nstead of by a common inter-sseous trunk. The recurrent oranches of the ulnar may spring rom the common interosseous, vhich itself may be a branch of he radial.

The **median artery**—the com-panion artery of the median ierve—usually a branch of the nterior interosseous, may spring from the axillary, brachial, or ulnar rteries; it may be much larger han usual (Pl. LXXXI, p. 1296), ind it may end either by breaking ip into digital arteries or by join-ng one or more digital branches of he superficial palmar arch or the irch itself.

ARTERIAL ARCHES OF WRIST AND HAND

The **anterior carpal arch** (Fig. 1091) lies on the radial attachment of the anterior radio-carpal ligament, deep to the long flexor tendons and their synovial sheaths. It is formed by the union of the anterior carpal branches of the radial and ulnar arteries, and it receives a communicating branch from the anterior interosseous artery and recurrent branches from the deep palmar arch. Branches from it supply the ligaments and synovial membranes of the radio-carpal and intercarpal joints.

The **posterior carpal arch** (Fig. 1092) lies on the back of the distal row of the carpus deep to the extensor tendons and their sheaths. It is formed by the union of the posterior carpal branches of the radial and ulnar arteries, and receives the terminal branches of the anterior and posterior interosseous arteries. It supplies adjacent joints and gives off three **dorsal metacarpal arteries.**

The **superficial palmar arch** (Fig. 1090) is the main terminal branch of the ulnar artery. It extends from the ball of the little finger to the ulnar border of the flexor pollicis brevis, and reaches distally to a line drawn across the palm at the level of the distal border of the fully abducted thumb. It is completed on the radial side by the superficial palmar branch of the radial, or by the radialis indicis or the princeps pollicis artery. It is accompanied by venæ comitantes and it is covered by the skin and superficial fascia and the palmar aponeurosis, and, on the ulnar side of the palm, by the palmaris brevis. It is in contact dorsally with the flexor and opponens digiti minimi, and with the palmar digital branches of the ulnar and median nerves, as well as with the flexor tendons and the lumbrical muscles. It is often irregular in its appearance (Pl. LXXXII, p. 1297).

Branches.—Four **palmar digital arteries** arise from the convex side of the arch. The most ulnar of the four passes along the ulnar border of the little finger, accompanied by a palmar digital branch of the ulnar nerve; the other three pass downwards, each between two flexor tendons and superficial to a palmar digital nerve and a lumbrical muscle, towards the interdigital clefts, where, at the level of the base of the proximal phalanges, it divides into two branches which supply the contiguous sides of the fingers bounding the cleft. As the branches pass along the sides of the fingers they lie behind the corresponding digital nerves and supply branches to the joints, to the flexor tendons and their sheaths, and to the skin and subcutaneous tissues on the palmar surfaces of the fingers; they give off dorsal branches also which anastomose with the dorsal digital arteries and supply the tissues on the dorsal surfaces of the middle and distal phalanges. Some of the dorsally directed branches form a plexus in the matrix of the nail. In the pulp of the finger-tips anastomosing twigs join to form arches from which numerous branches are given off to the skin and subcutaneous fat. For a note on the arterio-venous anastomoses found in the distribution of these arteries, see p. 1246.

Each of the three palmar digital arteries which pass to interdigital clefts is joined, just before it divides, by a palmar metacarpal artery from the deep palmar arch and a distal perforating branch from a dorsal metacarpal artery. The digital artery to the ulnar side of the little finger is joined by a branch which arises either from the medial palmar metacarpal artery or from the deep palmar arch.

The **deep palmar arch** (Fig. 1091) extends from the base of the metacarpal bone of the little finger to the proximal end of the first interosseous space. It is formed by the terminal part of the radial artery and its anastomosis with the deep branch of the ulnar. It is from half to three-quarters of an inch (12 to 18 mm.) proximal to the level of the superficial palmar arch. It lies deeply in the palm, in contact with the proximal ends of the shafts of the metacarpal bones and on the origin of the interossei muscles, and deep to the long flexor tendons and their synovial sheaths.

Branches.—The **palmar metacarpal arteries** are three vessels which pass downwards over the interosseous muscles of the three ulnar interosseous spaces, deep to the flexor tendons. They end by joining the palmar digital arteries immediately before these vessels divide.

Three small **perforating branches** pass backwards through the interosseous spaces, between the heads of the second, third, and fourth dorsal interosseous muscles, and join the dorsal metacarpal arteries.

Small *recurrent branches* pass upwards to join the anterior carpal arch, and other small branches are distributed to the adjacent joints

Variations.—The **superficial palmar arch** is sometimes absent; its branches are then given off from the deep arch. Or it may be larger than usual, and it may be completed on the radial side by the radialis indicis, the princeps pollicis, or the median artery.

The **deep palmar arch** is much more rarely absent than the superficial arch. When absent its branches are supplied by the superficial arch, the proximal perforating branches of the dorsal metacarpal arteries, or the anterior carpal arch.

BRANCHES OF DESCENDING THORACIC AORTA

The branches given off from the descending thoracic aorta are distributed iefly to the walls of the thorax and to the thoracic viscera. They contribute so to the supply of the spinal cord and its membranes, of the vertebral column, d of the upper part of the abdominal wall. The branches, which are numerous d for the most part arranged in pairs, are as follows:—

Visceral
- Bronchial
- Œsophageal
- Pericardial
- Mediastinal

Parietal
- Posterior intercostal
- Subcostal
- Phrenic
- The vas aberrans

Visceral Branches of Descending Thoracic Aorta

The **bronchial arteries** are usually two in number—an upper and a lower— nd both pass to the left lung. The *upper left bronchial artery* arises from the ront of the aorta opposite the fifth thoracic vertebra; the *lower left bronchial rtery* usually takes origin at a slightly lower level. Both vessels are directed ownwards and laterally to the back of the bronchus which they accompany, nd, dividing similarly, they follow its ramifications in the lung. They not only upply the walls of the bronchial tubes and the substance of the lungs, but also ive branches to the broncho-pulmonary lymph-glands, the pulmonary vessels, he pericardium, and the œsophagus. (See also p. 720.)

As a rule there is only one *right bronchial artery*. It arises from the third ight posterior intercostal artery (*i.e.*, the first right intercostal branch of the aorta) fter that artery has crossed behind the œsophagus; and in its course and distribution it corresponds to the bronchial arteries of the left side. It may, however, rise from the upper left bronchial artery or, more rarely, directly from the aorta.

Variations.—The **bronchial arteries** obviously correspond to splanchnic arteries and their continuations to diverticula from the walls of the gut; therefore the usual origin of the right bronchial artery must result from the persistence of an anastomosis between a splanchnic artery and the first part of a somatic intersegmental artery; the origin of the right from the upper left bronchial artery, which sometimes occurs, is due to the fusion of the roots of two splanchnic arteries. The occasional origin of a bronchial vessel from an internal mammary artery can result only from the persistence and enlargement of an anastomosis between a splanchnic artery and the ventral branch of a somatic segmental artery. The origin of a bronchial branch from a subclavian artery may have the same or a different significance on opposite sides of the body. A bronchial artery which arises from the left subclavian artery corresponds with the origin of the right bronchial artery from the third right posterior intercostal artery; it is due to the persistence of an anastomosis between a splanchnic artery and the root of a somatic intersegmental artery. The origin of a bronchial artery from a right subclavian artery may be due to a similar cause; it may, on the other hand, be due to the enlargement of an anastomosis between a splanchnic branch of the descending aorta and a splanchnic branch of the fourth right aortic arch. A bronchial artery occasionally arises from the inferior thyroid; that is due to the persistence and enlargement of an anastomosis between splanchnic arteries.

Nakamura (1924) has analysed the variations in the origin of the bronchial arteries; Berry, Brailsford & Daly (1931) surveyed the problem of anastomoses between pulmonary and bronchial vessels from the historical point of view; Berry (1935), using injection methods, found no anastomoses between pulmonary and bronchial arteries; but Hudson, Moritz & Wearn (1932) have shown that there are numerous anastomoses between the bronchial and other arteries, including the coronary arteries of the heart. See also the reference to the subpleural plexus of Turner on p. 1280.

The **œsophageal branches** are usually four or five small branches that spring from the front of the aorta and pass forwards to the œsophagus, in the walls of which they ramify, anastomosing above with branches of the left bronchial and inferior thyroid arteries, and below with œsophageal branches of the left gastric and the phrenic arteries.

The **pericardial branches** are three or four small irregular vessels which are distributed on the surface of the pericardium.

Small **mediastinal branches** pass to the fatty areolar tissue and the lymph-glands in the posterior mediastinum.

Parietal Branches of Descending Thoracic Aorta

Posterior Intercostal Arteries.—Nine pairs of posterior intercostal art (III-XI) arise from the back of the aorta—usually separately but, not commonly, a pair may take origin by a common trunk. They are distribute the lower nine intercostal spaces, to the vertebral column, to the contents of vertebral canal, and to the muscles and skin of the back. The first three on side give branches to the mammary gland also. The arteries of opposite closely correspond, but, since the upper part of the descending thoracic lies on the left of the vertebral column, most of the right posterior in costal arteries cross the front of the column, behind the œsophagus, the tho duct, and the vena azygos, and are longer than the left arteries. In other res the course of each artery is almost identical. As each artery runs backw and laterally, across the side of the vertebral column, to an intercostal spa passes behind the pleura, and is crossed by the sympathetic trunk. The l arteries are crossed by the splanchnic nerves also, and those on the left side crossed by the superior or inferior hemiazygos vein.

As each artery passes laterally, between the necks of two adjacent ribs, it asc to the upper border of the space to which it belongs, and, passing either behi in front of the corresponding intercostal nerve, reaches the angle of the r rib where it enters the costal groove, in which it is continued along the space. the space, as far as the angle of the rib, it lies between the pleura and the post intercostal membrane. Then it is continued forwards between the innermost i costal and the internal intercostal muscles (see p. 448). In the costal groove artery lies between the corresponding vein above and the intercostal nerve be and it ends by anastomosing with an anterior intercostal branch of the inte mammary or of the musculo-phrenic artery. The lower two posterior interc arteries, on each side, extend beyond their spaces into the abdominal wall, anastomose with branches of the superior epigastric, subcostal and lumbar arte The first right intercostal branch of the aorta (posterior intercostal artery frequently gives off the right bronchial artery.

Branches.—The **posterior branch** arises as the intercostal artery reaches the passes backwards, between the necks of the ribs which bound the space, medial to superior costo-transverse ligament, and then, accompanied by the posterior primary r of a spinal nerve, between the adjacent transverse processes, to the vertebral groove, w it divides into medial and lateral terminal branches. The medial branch passes backw and medially, either over or through the multifidus, giving branches to the muscles bet which it passes and to the vertebral column. The lateral branch runs laterally u cover of the longissimus thoracis to the interval between it and the costalis. *Mus branches* supply the muscles and *cutaneous branches* pass to the skin of the back. *spinal branch* passes through the corresponding intervertebral foramen, and enters vertebral canal, to the contents and walls of which it is distributed. Twigs from the s branches run medially, on the roots of the spinal nerve, to supply the membranes c spinal cord and reinforce the anterior and posterior spinal arteries. Others anast with twigs from adjacent arteries on the backs of the bodies of the vertebræ to a series of vertical arches connected by short transverse anastomoses; from anastomosing arteries branches of supply enter the bodies of the vertebræ through vascular foramina. Similar though less regular anastomoses are formed on the pos wall of the vertebral canal, and they assist in the supply of the laminæ, articular proc and the roots of the spines of the vertebræ (p. 1388, and Fig. 1147).

A **collateral branch** arises near the angle of the rib. It descends and forwards along the lower border of the intercostal space, to anastomose in front wi anterior intercostal branch of the internal mammary or musculo-phrenic artery. collateral branches of the lower two intercostal arteries, on each side, are incons when present they are small, and end in the abdominal wall.

Several **nutrient branches** supply the rib above, and **muscular branches** to the adj muscles are given off by both the main trunk and its collateral branch.

A **lateral cutaneous** branch accompanies the lateral cutaneous branch of the costal nerve. Those of the third, fourth, and fifth spaces give a ***mammary branch*** t mammary gland; these branches anastomose with branches of the lateral thoracic internal mammary arteries.

In addition to the secondary branches above named, the trunk of the third posterior rcostal artery anastomoses with the superior intercostal, and may supply the whole he greater part of the second intercostal space. Longitudinal anastomoses between acent trunks and also between adjacent posterior branches of posterior intercostal eries sometimes exist near the necks of the ribs, or near the transverse processes.

The **subcostal arteries** are in series with the posterior intercostal arteries, l are distributed in the same manner. The trunk runs along the lower border the twelfth rib in company with the subcostal nerve. It passes below the eral arcuate ligament to the abdomen, and there crosses in front of the quadratus nborum, and behind the kidney. It next pierces the aponeurosis of origin of the nsversus abdominis, and runs between the transversus and the internal oblique scles, anastomosing with the lower intercostal arteries, with the lumbar arteries, d with branches of the superior epigastric artery.

Variations.—Variations of the **posterior intercostal arteries** are not very common, but they significant and interesting. Corresponding vessels of opposite sides may arise from a mon stem which has been formed by the fusion of the roots of two somatic intersegmental eries after or simultaneously with the fusion of the primitive dorsal aortæ. The number of ercostal arteries may be reduced, one artery supplying two or more intercostal spaces; in such es the roots of origin of some of the somatic intersegmental arteries in the thoracic region ve disappeared, and the precostal anastomoses between their ventral branches have persisted. Occasionally the number of the intercostal arteries is increased, an additional artery being en to the second intercostal space, which is usually supplied by the superior intercostal ery; that is brought about by the persistence of the root of the tenth somatic intersegmental ery and the disappearance of the precostal anastomosis between the ventral branches of the th and tenth somatic intersegmental arteries. Very rarely the third posterior intercostal ery sends a branch upwards between the necks of the ribs and the transverse processes of the per thoracic region; that branch supplies the upper intercostal spaces, the superior intercostal ery being small or absent, and it ends by becoming the deep cervical artery. It is due to persistence of the postcostal anastomoses in the upper thoracic region, and is a repetition of a ndition regularly present in some carnivores.

Phrenic branches are given off from the lower part of the thoracic aorta. They e small vessels which ramify on the upper and posterior surfaces of the diaphragm, d anastomose with the pericardiaco-phrenic and musculo-phrenic branches of the ternal mammary arteries.

The **vas aberrans** is a variable and inconstant branch of the thoracic aorta; represents the dorsal roots of the fourth and sixth right aortic arches of the nbryo. When present it arises from the front and right side of the upper part of e descending aorta near the upper left bronchial artery, and passes upwards and the right behind the œsophagus; it frequently anastomoses with the right perior intercostal artery, and it may be enlarged and form the first part of e right subclavian artery.

BRANCHES OF ABDOMINAL AORTA

The branches of the abdominal portion of the aorta are distributed almost ntirely to the walls and contents of the abdominal cavity, but some supply nall branches to the vertebral column and to the contents of the vertebral canal, nd others are prolonged into the true pelvis. They are divisible into visceral nd parietal groups, both of which include paired and single (unpaired) vessels.

Visceral	**Paired**	Suprarenal
		Renal
		Testicular or Ovarian
	Single	Cœliac
		Superior mesenteric
		Inferior mesenteric
Parietal	**Paired**	Phrenic
		Lumbar
		Common iliac
	Single	Median sacral

Paired Visceral Branches of Abdominal Aorta

There are three pairs of **suprarenal arteries**—the superior, middle, and inferior. Of these only the middle arise directly from the aorta; the superior spring from he phrenic arteries, and the inferior from the renal arteries.

The **middle suprarenal arteries** are a pair of small branches which arise, behind the pancreas, from the sides of the aorta, close to the origin of the superior mesenteric artery. They run, one on each side, laterally and upwards, upon the crura of the diaphragm just above the renal arteries, to the suprarenal glands, to which they are distributed. They anastomose with the superior and inferior suprarenal arteries.

The **renal arteries** (Fig. 1096) arise, one on each side, from the aorta, about half an inch below the origin of the superior mesenteric artery and opposite the second lumbar vertebra.

Both arteries, on account of the functional nature of the kidneys, are of large size, and the right is frequently slightly lower in position than the left. Each artery runs almost transversely to the hilum of the corresponding kidney. It passes anterior to the crus of the diaphragm and the psoas muscle. The left artery lies posterior to the pancreas; the right vessel passes behind the inferior vena cava, the head of the pancreas, and the second part of the duodenum. The renal vein usually lies below and anterior to the artery, but near the kidney the vein not infrequently occupies a posterior position.

On reaching the hilum of the kidney each artery divides into three branches, two of which pass in front of the pelvis of the ureter and between it and the renal vein, and the third behind the pelvis. In the renal sinus these primary branches break up into numerous secondary branches which enter the kidney substance between the pyramids. Their intimate distribution is described on p. 735.

Branches.—Each renal artery gives off small **ureteric branches to the upper part of the ureter, which anastomose with branches of the testicular or ovarian arteries,** and an **inferior suprarenal artery, which passes upwards to the lower part of the suprarenal gland.**

Small branches, which anastomose with the lumbar arteries, are also given to the aortic **lymph-glands and to the renal fat.**

Variations.—The **renal arteries** frequently deviate from the normal arrangement. They may spring from a common stem, or there may be two or more renal arteries on one or both sides. The *accessory arteries* are more common on the left than on the right side, and an accessory artery arising below the ordinary vessel is more common than one arising above it.

Accessory renal arteries may be derived not only from the aorta, but also from the common iliac or internal iliac arteries; they have been described as arising also from the phrenic, testicular, lumbar, and median sacral arteries, and even from the external iliac artery. As the kidney is developed in the region of the first sacral vertebra, and afterwards ascends to its permanent position, it is not surprising that it occasionally receives arteries from the main stem of more than one of the segments of the body through which it has passed, and it is usually found that the lower the position of the kidney in the abdomen the more likely it is to receive its arteries from the lower part of the aorta or from the common iliac arteries. The accessory renal arteries which spring from the phrenic, the testicular, and lumbar arteries can only be the result of the persistence and enlargement of anastomosing channels between the renal and either another intermediate visceral artery, or a somatic artery.

The **testicular** or **ovarian arteries** are long, slender vessels which spring from the front of the aorta a short distance below the origins of the renal arteries.

Each **testicular artery** runs downwards, on the anterior surface of the psoas major, to the deep inguinal ring, where it comes into relation with the vas deferens. It accompanies the vas deferens through the inguinal canal into the scrotum to supply the testis.

Relations.—*Posterior.*—The right artery passes in front of the inferior vena cava, and as each artery descends, on the anterior surface of the psoas major, it passes in front of the corresponding genito-femoral nerve and ureter, and the lower part of the external iliac artery.

Anterior.—Each artery is in relation anteriorly with the peritoneum; but crossing in front of the right artery and intervening between it and the peritoneum are the third part of the duodenum, the right colic and the ileo-colic vessels, and the lower parts of the superior mesenteric vessels; and the cæcum may overlap it. Crossing anterior to the left artery are the superior and inferior left colic vessels and the terminal part of the descending colon.

In the lower part of the abdominal portion of its course each testicular artery is accompanied by two veins which issue from the pampiniform plexus in the inguinal canal and enter the abdomen through the deep inguinal ring, but at a higher level the two veins fuse into a single stem which is usually lateral to the artery.

As it approaches the inguinal canal each testicular artery passes in front of the lower

PLATE LXXXI

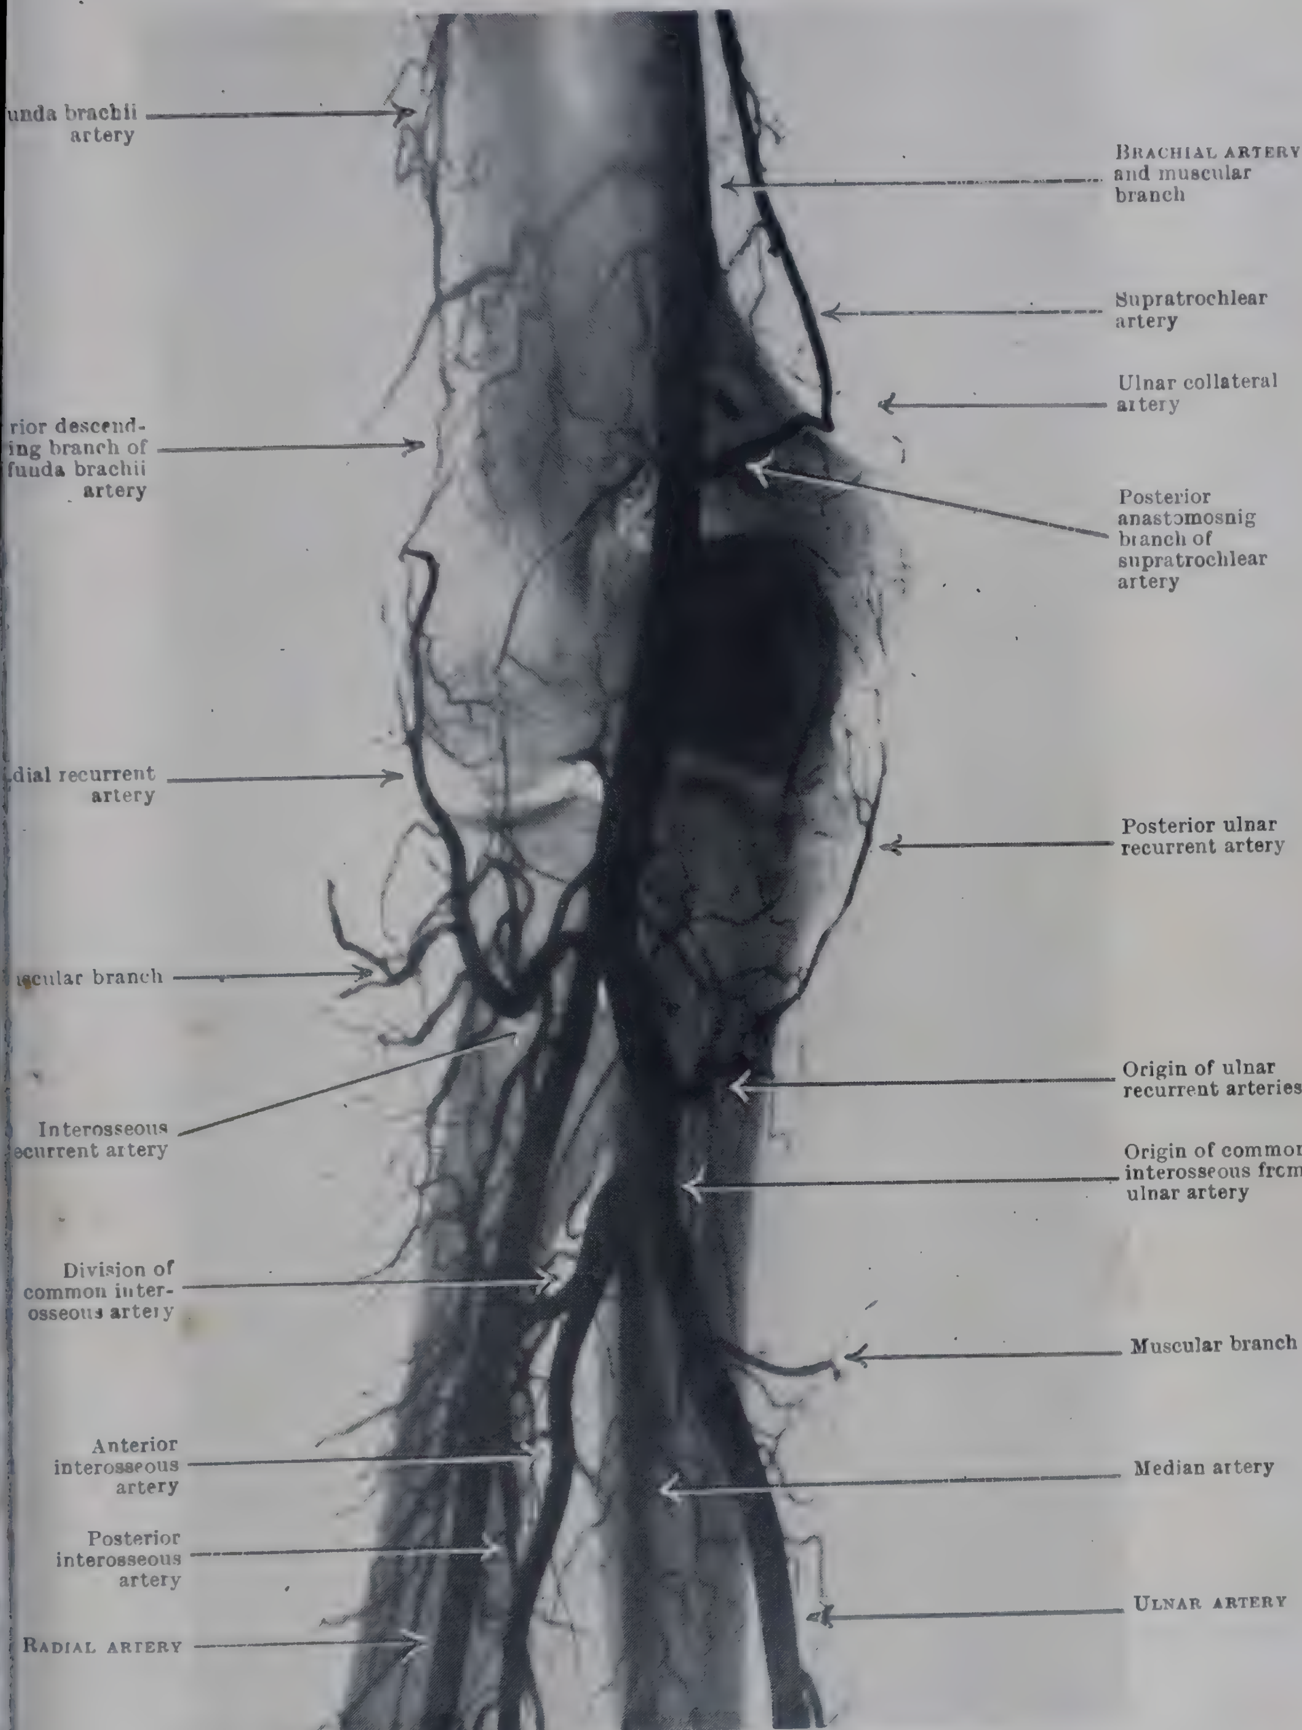

Plate LXXXI.—Radiograph of Elbow Region after radio-opaque injection of the Arteries (from positive print).

Cf. Fig. 1089, p. 1286. The median artery (p. 1291) is larger than usual.

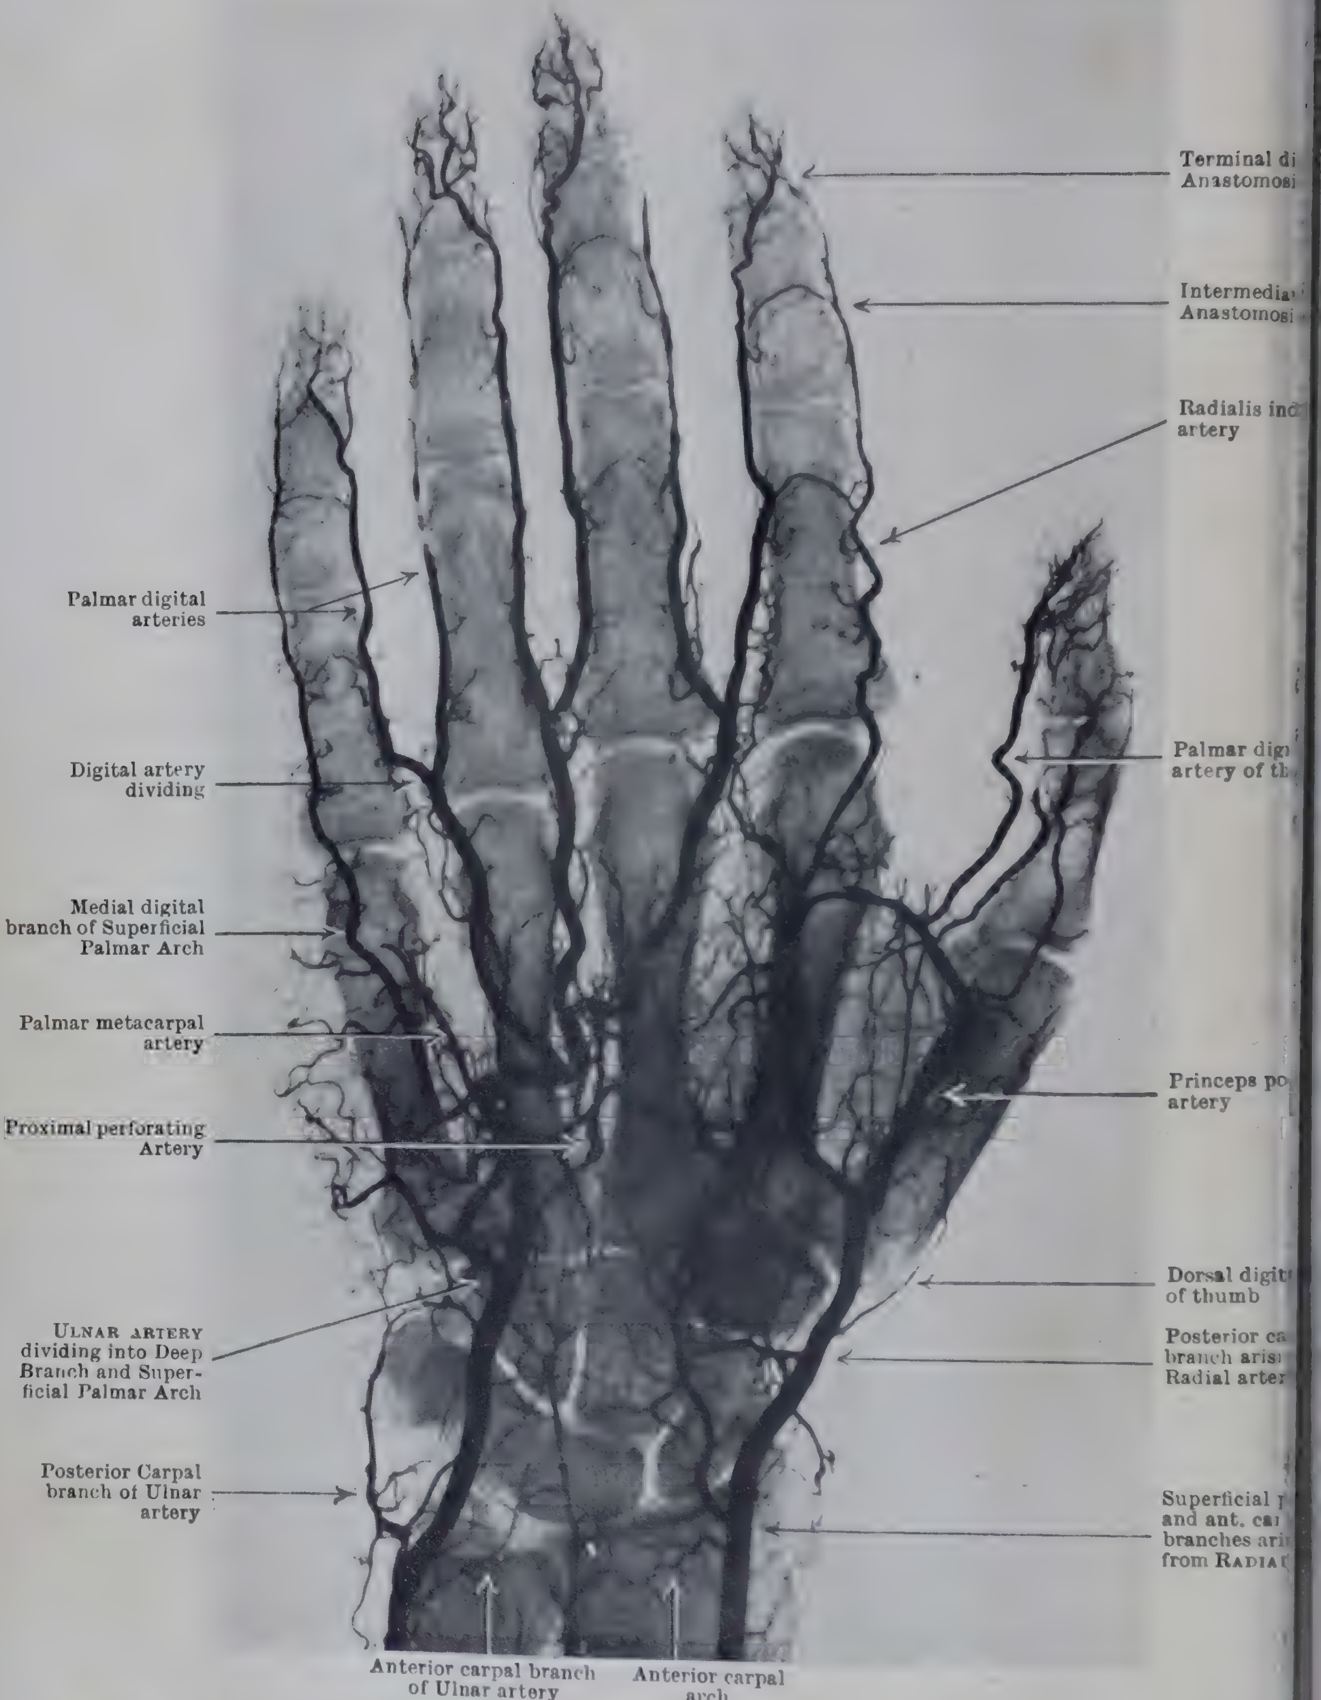

PLATE LXXXII.—RADIOGRAPH OF HAND AFTER RADIO-OPAQUE INJECTION OF THE ARTERIES (from positive print).

Cf. Figs. 1090-1092, pp. 1287-1291. The superficial palmar arch is irregular and appears to be completed by a branch of the princeps pollicis artery (see p. 1292).

end of the external iliac artery; and as it runs downwards and medially, in the canal, it is accompanied by the vas deferens, and is more or less enclosed in the meshes of the pampiniform venous plexus. At the lower end of the canal it passes through the superficial inguinal ring and descends to the scrotum, lying antero-lateral to the vas deferens and in close association with the anterior group of testicular veins. At the upper end of the testis it breaks up into branches, some of which are distributed to the testis and others to the epididymis. It anastomoses with the artery to the vas deferens and the cremasteric artery. (For details, see p. 756.)

Branches.—In the abdominal part of its course each testicular artery gives off **ureteric branches** to the abdominal part of the ureter, and twigs to the perirenal fat, the peritoneum, and the aortic lymph-glands.

The course and the relations of each **ovarian artery**, as far as the external iliac artery, are the same as the relations of the corresponding testicular artery; but it then turns medially to enter the true pelvis by crossing the external iliac vessels an inch below the origin of the artery, and passes between the layers of the infundibulo-pelvic ligament to reach the broad ligament of the uterus. In the broad ligament it runs medially, below the uterine tube, to the level of the ovary. There it turns backwards and passes into the mesovarium, where it breaks up into terminal branches which enter the ovary through the hilum in its anterior border. As it lies in the broad ligament each ovarian artery is accompanied by the pampiniform plexus of ovarian veins. In the lower portion of the abdominal part of its course it is accompanied by two veins which issue from the pampiniform plexus at the brim of the true pelvis and unite at a higher level into a single trunk.

Branches.—In the abdominal part of its course the branches of the ovarian artery are the same as those of the testicular artery.

In the pelvic part of its course it gives branches which supply the uterine tube, the round ligament of the uterus, and anastomose with the uterine artery.

Variations.—The **testicular** or **ovarian arteries** may be double on one or both sides; the arteries of the two sides may spring from a common trunk, or each may arise from the renal, accessory renal, or suprarenal artery. The right artery may pass behind the inferior vena cava instead of in front of it. The testicular and ovarian arteries arise from the upper lumbar portion of the aorta, because the testes and ovaries are developed in and obtain their arterial supply in that region, and the vessels are elongated as the testes and ovaries descend to their permanent positions.

Single Visceral Branches of Abdominal Aorta

The **cœliac artery** (Figs. 1093 and 1096) arises from the front of the abdominal aorta, immediately below the aortic orifice of the diaphragm and between its crura. It is a short but wide vessel which runs almost horizontally forwards, below the caudate lobe of the liver, for a distance of about half an inch (12 mm.). It ends by dividing into three branches—the left gastric, the hepatic, and the splenic.

Relations.—The trunk lies behind the lesser sac of the peritoneum below the caudate lobe of the liver and above the upper border of the pancreas and the splenic vein. It is surrounded by the cœliac plexus of nerves.

Branches.—The **left gastric** is the smallest branch of the cœliac artery. It runs obliquely upwards and to the left, and reaches the lesser curvature of the stomach close to the œsophagus. It then turns sharply forwards, downwards, and to the right, and runs towards the pyloric end of the stomach to anastomose with the right gastric branch of the hepatic artery. In the first part of its course the artery lies on the left crus behind the lesser sac; it then curves over the upper border of the lesser sac (between the layers of the left gastro-pancreatic fold when that fold of peritoneum is present), and is continued between the layers of the lesser omentum.

When the left gastric artery reaches the stomach it gives off **œsophageal branches** which pass upwards on the œsophagus to anastomose with œsophageal branches of the thoracic aorta and with the phrenic artery. On the lesser curvature it often divides into two parallel vessels from which branches are distributed to both surfaces of the stomach. They anastomose with the short gastric branches of the splenic artery, and with branches of the gastro-epiploic arterial arch on the greater curvature of the stomach.

The **splenic artery** (Fig. 1093) is the largest branch of the cœliac artery. Accompanied by the splenic vein, which lies below it, it runs a tortuous course behind the stomach and the lesser sac of peritoneum along the upper border of the pancreas. It lies in front of the left suprarenal gland and the upper part of the left kidney, and passes forwards between the two layers of the lieno-renal ligament, in which it divides into five to eight terminal **splenic branches** which enter the hilum of the spleen and supply the splenic substance. For the peculiarities of the distribution of these branches, see p. 831 and Fig. 718.

Branches.—Numerous small **pancreatic** branches are given off to the pancreas. A larger branch (*pancreatica magna*), occasionally present, enters the upper border of the pancreas, about the junction of its middle and left thirds, and runs from left to right in the substance of the pancreas, a little above and posterior to the pancreatic duct. The pancreatic branches anastomose with one another and with branches of the pancreatico-duodenal arteries.

The **short gastric arteries**, four or five in number, are given off either from the end of the splenic artery or, more commonly, from some of its terminal branches. They

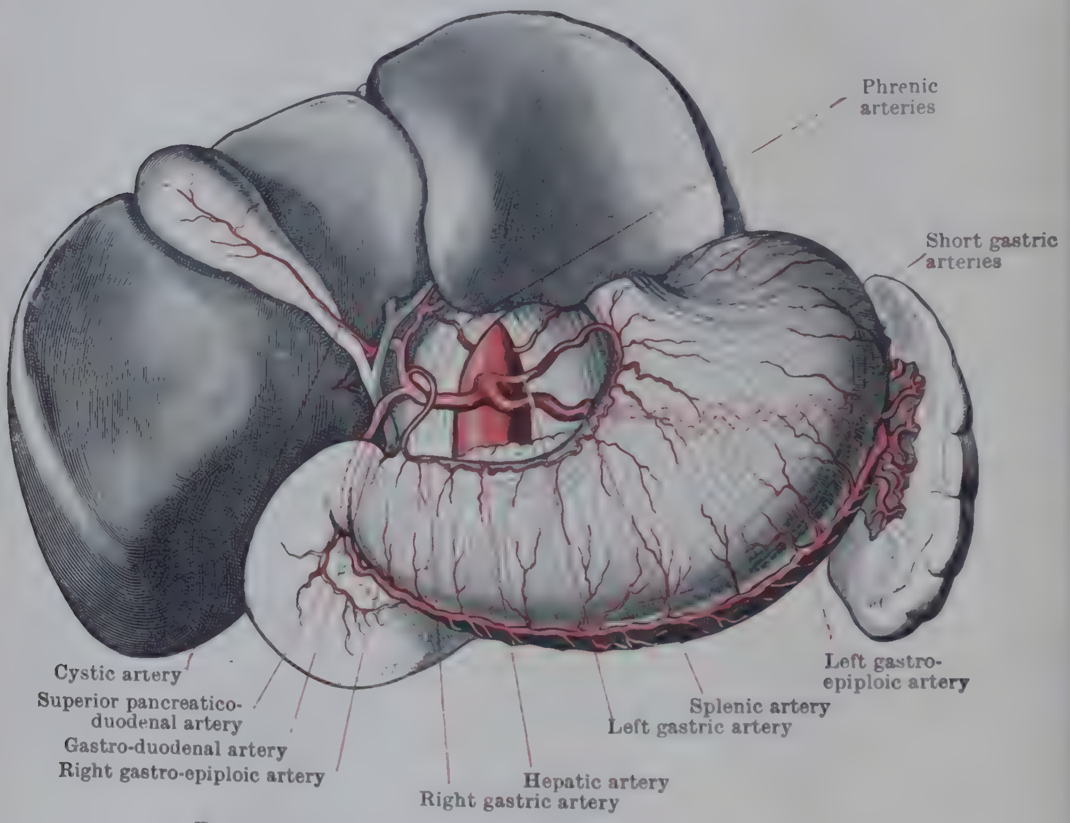

Fig. 1093.—Cœliac Artery and its Branches.

pass between the layers of the gastro-splenic ligament to the left part of the greater curvature of the stomach, and anastomose with the œsophageal, the left gastric, and the left gastro-epiploic arteries.

The **left gastro-epiploic artery** arises from the splenic, or from one of its terminal branches, and passes forwards, between the layers of the gastro-splenic ligament, to the left end of the lower part of the greater curvature of the stomach, along which it is continued, from left to right, between the anterior two layers of the greater omentum. It ends by anastomosing with the right gastro-epiploic artery. It gives off numerous branches to both surfaces of the stomach; they anastomose with the short gastric and with branches of the left and right gastric arteries. Long, slender *omental branches* pass to the omentum.

The **hepatic artery** (Fig. 1093) runs along the upper border of the head of the pancreas to the upper border of the first part of the duodenum, where it enters the lesser omentum and ascends between its layers at its free margin. In the omentum it is in front of the portal vein and to the left of the bile-duct, and near the porta hepatis it divides into right and left terminal branches.

Branches.—The **gastro-duodenal artery** arises as soon as the hepatic reaches the first part of the duodenum, descends behind it and ends opposite its lower border. In its course it lies between the neck of the pancreas and the first part of the duodenum, and anterior to the portal vein. The bile-duct is on its right side. The vessel ends by dividing into the right gastro-epiploic and superior pancreatico-duodenal arteries. The **right gastro-epiploic artery** is the larger; it passes from right to left, along the greater curvature of the stomach, between the anterior layers of the greater omentum, and unites with the left gastro-epiploic branch of the splenic artery. From the arterial arch so formed, branches pass upwards on both surfaces of the stomach to anastomose with branches of the right and left gastric arteries. *Omental branches* pass downwards in the greater omentum. The **superior pancreatico-duodenal artery** runs a short course to the right, between the duodenum and the head of the pancreas, and divides into anterior and posterior terminal branches, which descend, the former in front of and the latter behind the head of the pancreas, to anastomose with similar branches of the inferior pancreatico-duodenal artery. They supply the head of the pancreas, anastomosing in it with the pancreatic branches of the splenic artery; branches are given also to the second part of the duodenum and to the bile-duct.

The **right gastric artery** is a small branch which arises as the hepatic enters the lesser omentum. It runs between the layers of the lesser omentum to the pylorus, and then along the lesser curvature of the stomach. It gives branches to both surfaces of the stomach and ends by anastomosing with the left gastric artery. It also gives a branch to the first part of the duodenum.

Terminal Branches.—The **right branch** passes, either in front of or behind the common hepatic duct and behind the cystic duct, to the right end of the porta hepatis; there, it divides into two or more branches which enter the substance of the liver and accompany the branches of the portal vein and the hepatic duct. As it crosses the junction of the hepatic and cystic ducts, the right branch gives off the cystic artery. The **cystic artery** runs downwards and forwards, along the cystic duct, to the gall-bladder, where it divides into anterior and posterior branches; the anterior passes downwards between the gall-bladder and the visceral surface of the liver, to both of which it gives offsets; the posterior branch is distributed on the posterior surface of the gall-bladder, and lies between it and the peritoneum. The **left branch** is longer and narrower than the right. It runs to the left end of the porta hepatis, gives branches to the caudate and quadrate lobes, crosses the fissure for the ligamentum teres, and breaks up into branches which terminate in the substance of the left lobe of the liver.

Variations.—The **cœliac artery** may be absent, its branches arising separately from the aorta or from some other source. Sometimes it gives off only two branches, usually the left gastric and splenic, and occasionally it gives four branches, the additional branch being either a second left gastric artery or a separate gastro-duodenal artery. The **left gastric artery** is occasionally double; it may spring directly from the aorta, and it may give off the left hepatic or an accessory hepatic artery. The **splenic artery** may arise from the middle colic, from the left hepatic, or from the superior or inferior mesenteric artery. The **hepatic artery** may spring directly from the aorta or from the superior mesenteric artery; the left hepatic artery, or an accessory hepatic artery, arises occasionally from the left gastric artery and runs to the liver in the upper part of the lesser omentum. Other accessory hepatic arteries are not uncommon, and they originate either from the superior mesenteric, renal, or inferior mesenteric artery. (For these variations, consult Flint, 1923 and Petrén, 1929.)

The **superior mesenteric artery** (Figs. 1094, 1095, 1096) springs from the front of the aorta, about half an inch (12 mm.) below the origin of the cœliac artery and opposite the first lumbar vertebra.

It passes obliquely downwards and forwards, crossing anterior to the left renal vein, the uncinate process of the head of the pancreas, and the third part of the duodenum; on the duodenum it enters the root of the mesentery, in which it continues to descend, curving obliquely from above downwards and to the right, to the right iliac fossa, and crossing, in this part of its course, in front of the aorta, the inferior vena cava, the right ureter, and the right psoas major muscle. At its origin it lies behind the pancreas and the splenic vein; where it passes in front of the duodenum it is crossed in front by the transverse colon; and in the lower part of its extent it is behind the coils of small intestine. The superior mesenteric vein runs along its right side. It ends by anastomosing with the ileo-colic artery.

Branches.—The branches of the superior mesenteric artery supply the duodenum and the pancreas in part, the whole of the small intestine below the duodenum, and the large intestine nearly as far as the left colic flexure.

The **inferior pancreatico-duodenal artery** arises either from the trunk of the superior mesenteric, at the upper border of the third part of the duodenum, or from the first

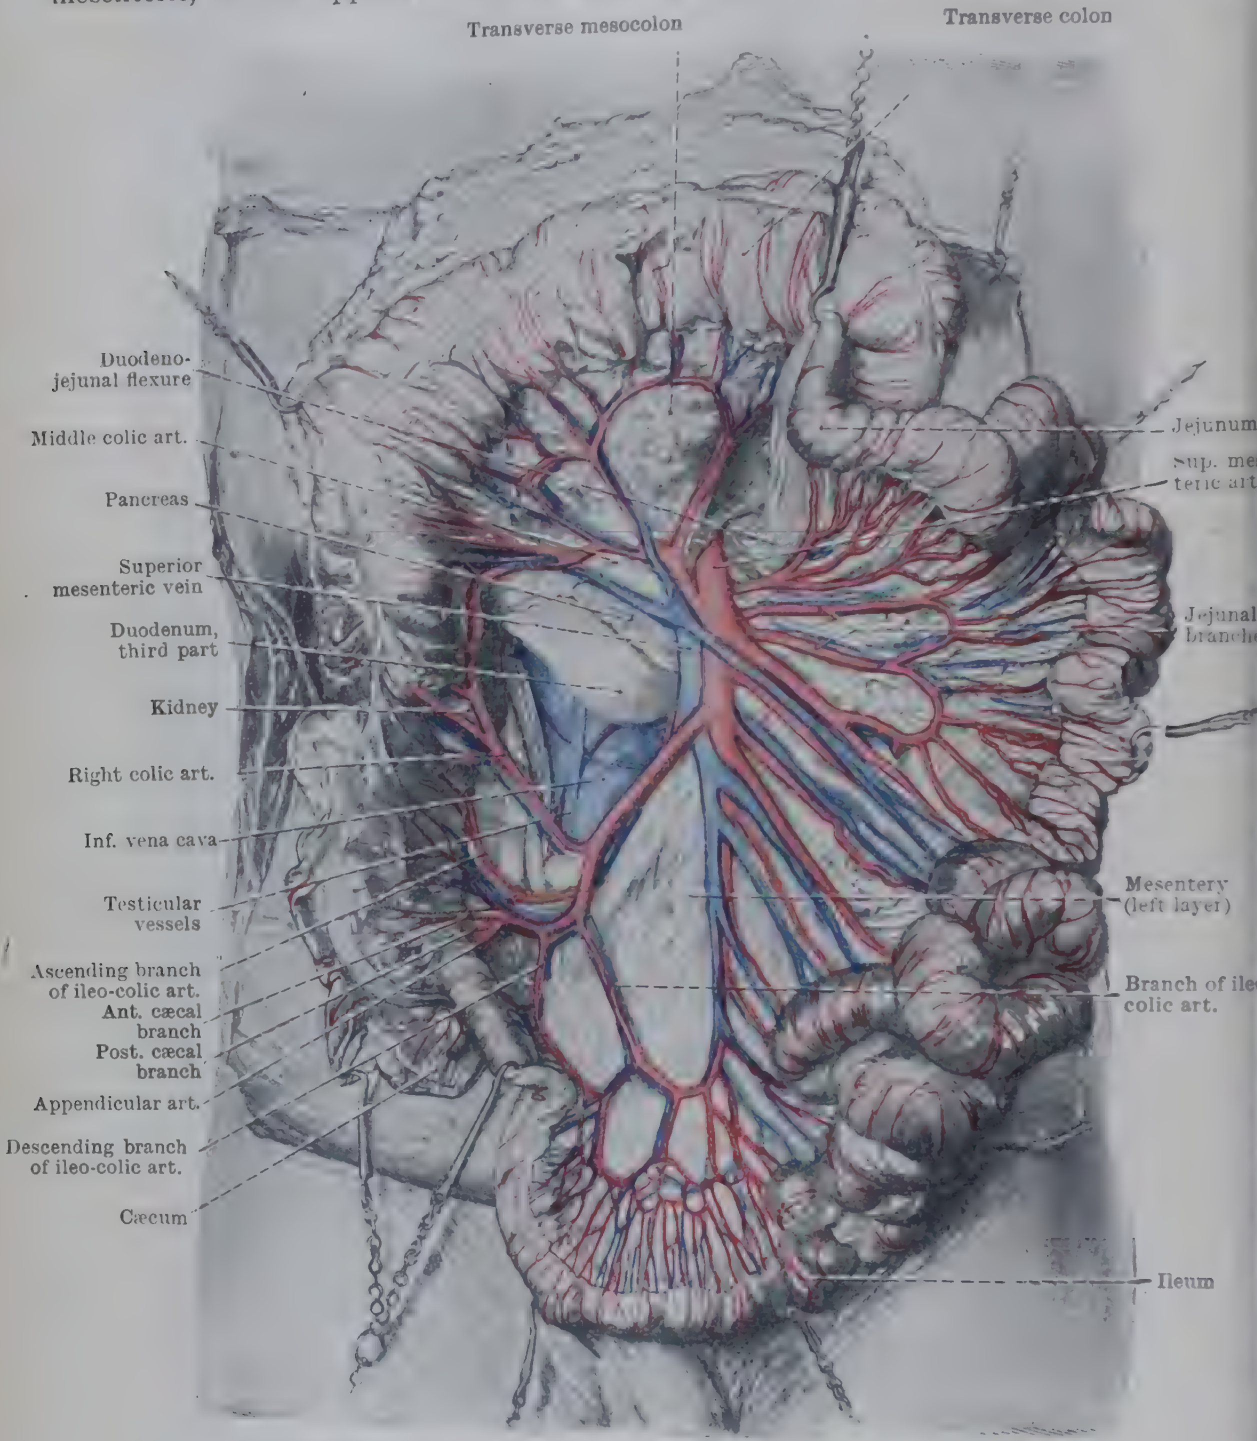

FIG. 1094.—SUPERIOR MESENTERIC ARTERY AND ITS BRANCHES.

Note the difference in the number and arrangement of the loops formed by the jejunal as contrasted with the ileal branches, that the right colic and ileo-colic arteries arise by a common trunk, and that the terminal branches of the ileo-colic are irregular.

jejunal branch. It runs to the right, between the head of the pancreas and the third part of the duodenum, and ends by dividing into two branches, anterior and posterior, which ascend, the former in front of the head of the pancreas, the latter behind it; they supply the head of the pancreas and the duodenum, and they anastomose with the similar branches of the superior pancreatico-duodenal artery.

The branches to the small intestine, varying from ten to sixteen in number, are separable into two groups—**jejunal** and **ileal**. They spring from the convexity of the superior mesenteric artery and pass obliquely forwards and downwards, between the layers of the mesentery, each dividing into two branches which anastomose with

djacent arteries to form a series of arcades from which secondary branches are given ff. The upper jejunal branches form only one or two arches, but the process of division nd union is repeated three or four times in the case of the ileal branches; thus four or ive tiers of arches are formed, in the longer, lower part of the mesentery. The branches rom the terminal arcades pass to the wall of the gut, generally to one or other side, but ccasionally a terminal branch divides and passes to both sides. According to Cokkinis (1930) the terminal branches from any one terminal arcade neither anastomose with one another nor with the branches of adjacent terminal arcades, but Ross (1947; 1950) and Doran (1950) have shown, by means of corrosion preparations, that they do in fact anastomose in the wall of the gut; these terminal branches can therefore no longer be regarded as "end-arteries". Branches from the successive arcades are given off also to the mesenteric lymph-glands.

The **ileo-colic artery** arises by a common trunk with the right colic, or separately lower down from the right side of the superior mesenteric, and passes downwards and to the right, behind the peritoneum either in front of or behind the superior mesenteric vein, towards the lower part of the ascending colon. It ends by dividing into an ascending branch which anastomoses with the lower branch of the right colic, and a descending branch which supplies the lower part of the ascending colon, sends branches to the front and back of the cæcum, gives off the appendicular artery, and ends in a branch to the lower part of the ileum which anastomoses with the end of the superior mesenteric trunk.

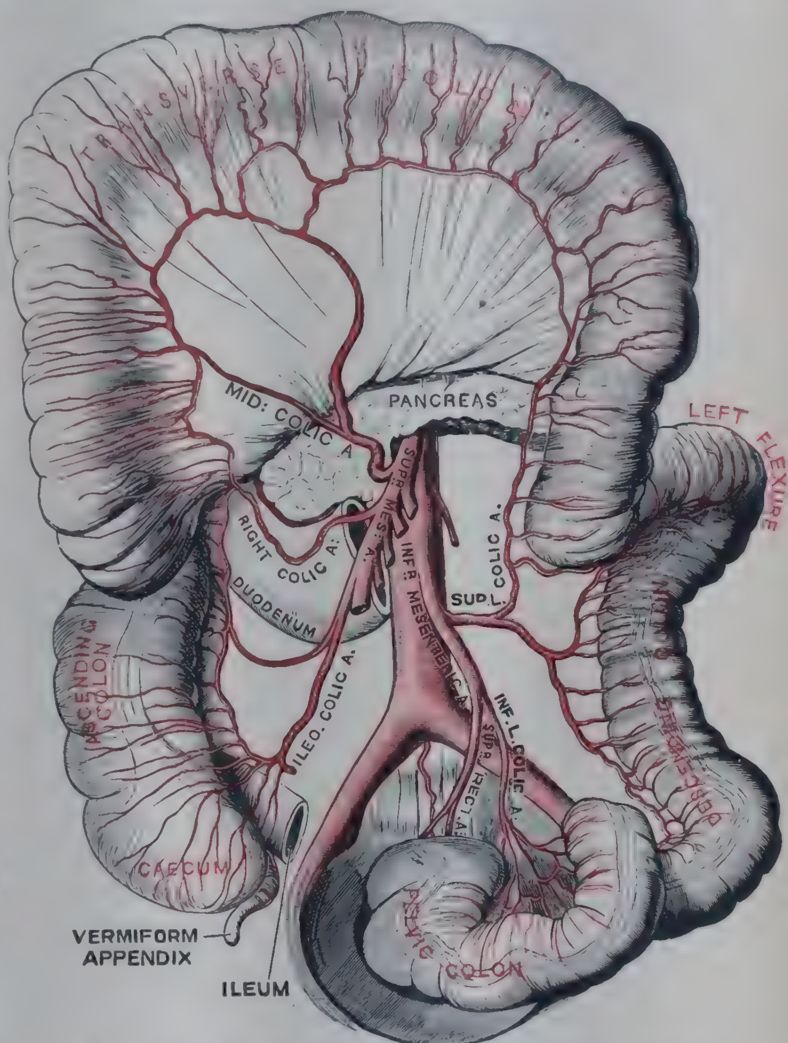

FIG. 1095.—DISTRIBUTION OF SUPERIOR AND INFERIOR MESENTERIC ARTERIES.

There are usually two inferior left colic arteries.

The *anterior cæcal* branch passes across the front of the ileo-colic junction in the fold of peritoneum called the vascular fold of the cæcum; the *posterior cæcal* branch crosses the back of the ileo-colic junction. The **appendicular artery** passes behind the terminal part of the ileum into the mesentery of the vermiform appendix; it runs near the free margin of the mesentery to the tip of the appendix and gives off a series of short branches which supply the apex of the cæcum and the appendix from its root to its tip.

The **right colic artery** springs from the right side of the superior mesenteric, either alone as the superior mesenteric crosses the duodenum (Fig. 1095), or below the duodenum in the form of a common trunk which divides into right colic and ileo-colic branches (Fig. 1094). It runs to the right, behind the peritoneum on the posterior wall of the abdomen, and in front of the right psoas major, the ureter, and the testicular or ovarian vessels, towards the ascending colon, near which it divides into an ascending and a descending branch. The former passes upwards, and anastomoses, in the transverse mesocolon, with the middle colic artery; the latter descends to anastomose with the upper branch of the ileo-colic. From the loops thus formed branches are distributed to the ascending colon and the beginning of the transverse colon.

The **middle colic artery** is a large branch which springs from the front of the superior mesenteric as it escapes from behind the pancreas. It runs downwards and forwards, in the transverse mesocolon, and ends by dividing into two branches which

anastomose with the right and left colic arteries, forming arcades. Secondary and tertiary loops are sometimes formed and the terminal branches are distributed to the transverse colon.

Variations.—The **superior mesenteric artery** may be double, and it may supply the whole of the alimentary canal from the second part of the duodenum to the end of the rectum, the inferior mesenteric artery being absent. In addition to its ordinary branches it may give off a hepatic, a splenic, a pancreatic, a gastric, a gastro-epiploic, or a gastro-duodenal branch.

The **inferior mesenteric artery** (Figs. 1095, 1096) arises from the front of the aorta towards the left side, about $1\frac{1}{2}$ inches (3-4 cm.) above the bifurcation; it passes downwards and slightly to the left, lying behind the peritoneum and in front of the aorta, and then on its left side in front of the left psoas major muscle, to the upper and left border of the left common iliac artery, where it becomes the superior rectal artery. Its vein runs close to its left side in the lower part of its course, but they are separated by an interval in the upper part.

Branches.—The **superior left colic artery** arises from the left side of the inferior mesenteric near its origin, and divides at a variable point into ascending and descending branches. The *ascending branch* runs upwards and to the left towards the left colic flexure, across the lower part of the left kidney, and divides into two branches; one enters the transverse mesocolon to end by joining the left branch of the middle colic artery, and the other passes to the upper part of the descending colon. The *descending branch*, which may arise separately or may be replaced by the lower division of the ascending branch, passes to the left and divides also into two branches; one anastomoses with the lower division of the ascending branch and supplies the descending colon above the iliac crest. The other branch supplies the descending colon below the iliac crest, and anastomoses with branches of the inferior left colic arteries. The superior left colic artery lies immediately behind the peritoneum, and crosses anterior to the ureter and the testicular or ovarian vessels.

The **inferior left colic arteries**, usually two in number, pass downwards and to the left to the lower part of the descending colon and to the pelvic colon. They lie behind the peritoneum, and in front of the psoas major, the ureter, and the upper part of the iliacus. They end by dividing into branches which anastomose with the terminal twigs of the descending branch of the superior left colic above and with branches of the superior rectal below, forming a series of arches from which branches are distributed to the colon.

The **superior rectal artery** is the direct continuation of the inferior mesenteric. It enters the mesentery of the pelvic colon, crosses the front of the left common iliac artery, descends into the true pelvis as far as the third piece of the sacrum, or, in other words, to the junction between the pelvic colon and the rectum, and divides into two branches which pass downwards on the sides of the rectum. Half-way down the rectum each of the two terminal branches of the superior rectal artery divides into two or more branches which pass through the muscular coats into the sub-mucous tissue, where they divide into numerous small branches which pass vertically downwards, anastomosing with one another, with offsets from the middle rectal branches of the internal iliac arteries, the inferior rectal branches of the internal pudendal arteries, and with branches from the median sacral artery.

The superior rectal artery supplies the muscular and the mucous coats of the pelvic colon and upper part of the rectum but the mucous coat only of the lower part of the rectum (see p. 655).

Variations.—The **inferior mesenteric artery** may give hepatic, renal, or middle colic branches; occasionally it is absent, being replaced by branches of the superior mesenteric, and sometimes, as in ruminants and some rodents, its left colic branch does not anastomose with the middle colic artery.

Parietal Branches of Abdominal Aorta

The **phrenic arteries** (Fig. 1096), right and left, are of small size; they arise, either separately or by a common trunk, from the aorta immediately below the diaphragm, to which they are distributed. Diverging from its fellow, each artery runs upwards and laterally on the corresponding crus of the diaphragm—on the right side passing behind the inferior vena cava, on the left side behind the œsophagus—

nd just before reaching the central tendon of the diaphragm each divides into medial nd lateral terminal branches. The *medial branch* runs forwards, to anastomose with ts fellow of the opposite side, forming an arch, convex forwards, along the anterior border of the central tendon of the diaphragm. Offsets from this arch anastomose with the pericardiaco-phrenic and musculo-phrenic arteries. The *lateral branch*

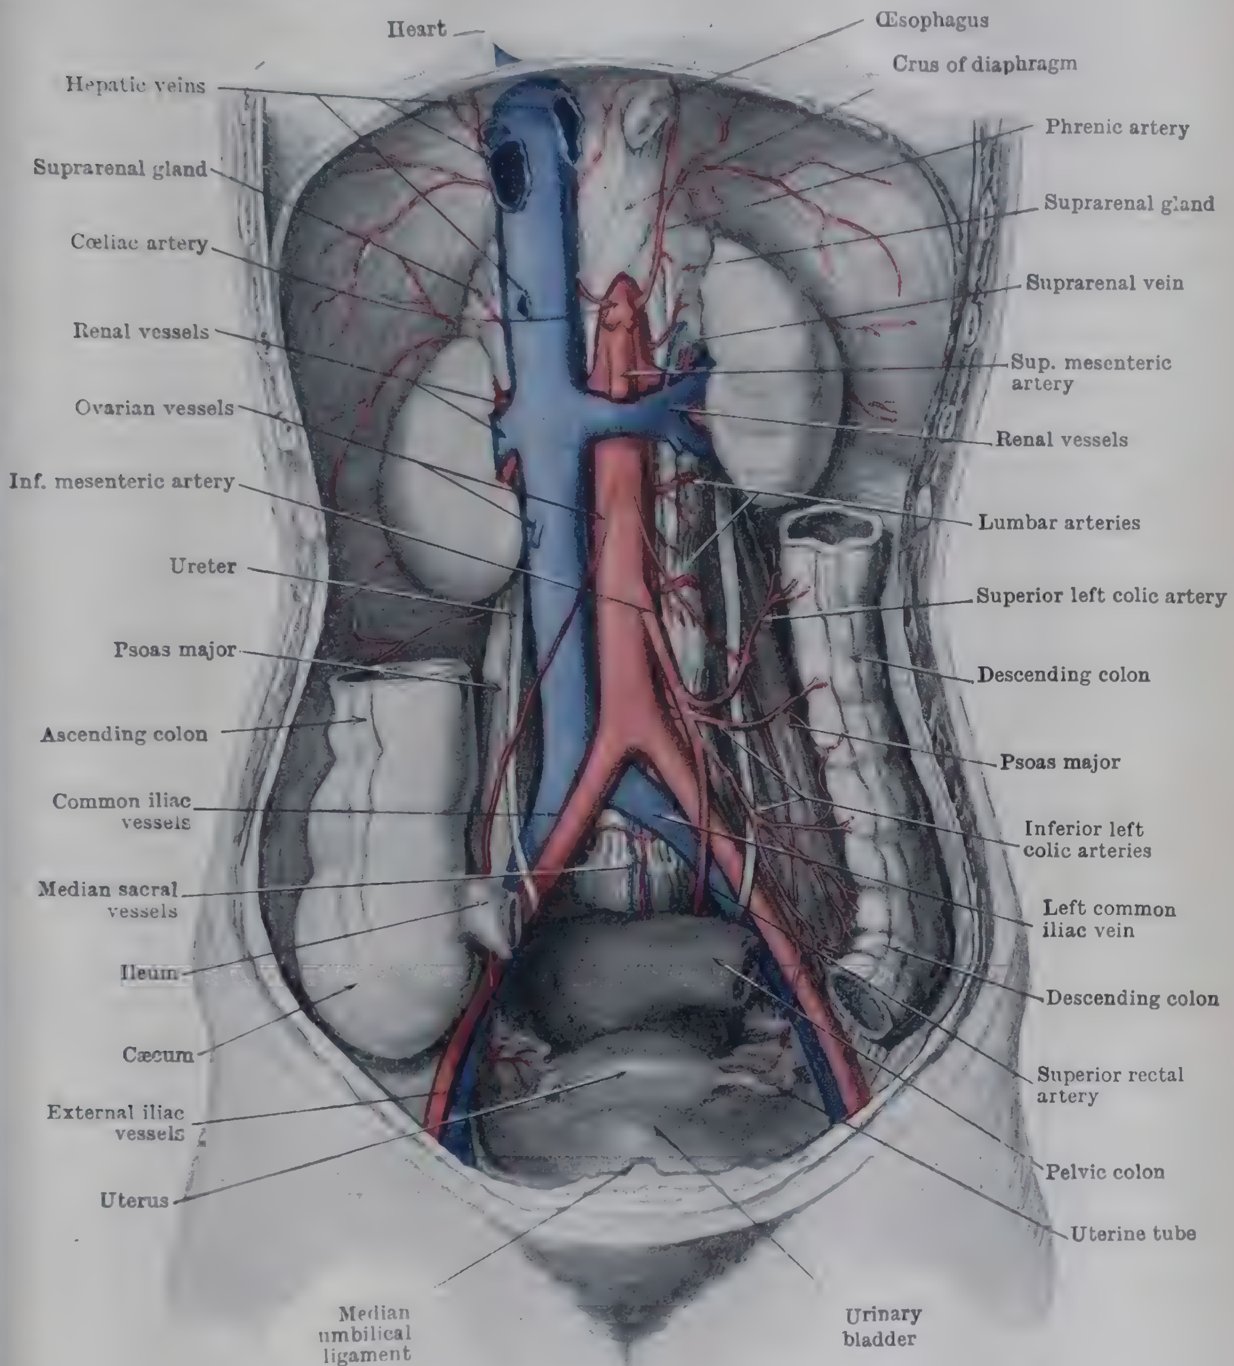

FIG. 1096.—ABDOMINAL AORTA AND ITS BRANCHES.

passes laterally towards the lower ribs, and anastomoses with the musculo-phrenic and lower intercostal arteries.

In addition to supplying the diaphragm, each phrenic artery gives off one or more **superior suprarenal arteries** to the suprarenal gland of its own side. The right artery sends small hepatic branches into the liver through the bare area, and minute branches pass to the inferior vena cava. The left artery gives œsophageal branches which anastomose with œsophageal branches of the aorta and of the left gastric artery.

Variations.—The **phrenic arteries** are very variable; they may arise by a common trunk either from the cœliac artery or from the aorta; they may arise separately either from the aorta or from the cœliac artery; or again, one may spring from the aorta or cœliac artery, and the other from the left gastric, renal, or even from the superior mesenteric artery.

The **lumbar arteries** are in series with the posterior intercostal arteries, and their distribution is very similar. The upper four pairs, like the intercostals, arise either separately or by common trunks, from the back of the aorta; the fifth pair arises from, or in common with, the median sacral artery. From their origins the lumbar arteries pass laterally and backwards, across the front and sides of the bodies of the lumbar vertebræ, to the intervals between the adjacent transverse processes, beyond which they are continued into the lateral part of the abdominal wall.

Each artery, in its backward course, and while still in relation with the vertebral body, is crossed by the sympathetic trunk, and then, after passing medial to, and being protected by, one of the fibrous arches from which the psoas major muscle arises, it runs behind the muscle and the lumbar plexus. The upper two arteries, on each side, pass behind the crus of the diaphragm also. Beyond the interval between the transverse processes of the vertebræ each artery runs laterally behind the quadratus lumborum—the fourth occasionally passing in front of the muscle; each then pierces the aponeurosis of origin of the transversus abdominis, and proceeds forwards in the lateral abdominal wall, between the transversus and internal oblique muscles. On the right side the arteries pass behind the inferior vena cava; but the upper two are separated from the vena cava by the cisterna chyli and the right crus of the diaphragm.

The lumbar arteries anastomose with one another, with the lower posterior intercostal and the subcostal arteries, and with branches of the superior and inferior epigastric and of the deep circumflex iliac and ilio-lumbar arteries. Fine twigs also pass from the lumbar arteries to the extraperitoneal fat; these anastomose with corresponding branches from the phrenic and ilio-lumbar arteries, and with small branches from the hepatic, renal, and colic arteries, to form the *subperitoneal plexus* of Turner (1863).

Branches.—Each lumbar artery gives off, opposite the interval between the vertebral transverse processes, a **posterior branch** of considerable size. It is homologous with and is distributed like the posterior branch of a posterior intercostal artery (p. 1294); a *spinal branch* enters the vertebral canal through the corresponding vertebral foramen. **Muscular branches** are given off both from the main trunk and its posterior branch.

Variations.— Variations of the **lumbar arteries** are very similar to those of the posterior intercostal arteries (p. 1295), and they are due to similar causes. Further, a lumbar artery may have its area of distribution extended into the adjacent segment.

The **median sacral artery** (Fig. 1096) is commonly regarded as a caudal aorta and as the direct continuation of the abdominal aorta. It is, however, of small size, and almost invariably arises from the back of the aorta about half an inch above its bifurcation. It descends in front of the lower two lumbar vertebræ and the sacrum and coccyx, and ends on the pelvic surface of the coccyx by anastomosing with the lateral sacral arteries to form loops from which branches pass to the coccygeal glomus. Opposite the fifth lumbar vertebra it is crossed, anteriorly, by the left common iliac vein, below which it is covered by peritoneum and coils of small intestine as far as the third piece of the sacrum, and in the rest of its extent it is posterior to the rectum. It is accompanied below by venæ comitantes, which, however, unite above to form a single median sacral vein.

In front of the last lumbar vertebra it gives off on each side the **fifth lumbar artery** which is distributed like an ordinary lumbar artery: and as it descends in front of the sacrum it distributes small parietal branches laterally which anastomose with the lateral sacral arteries. The parietal branches usually give off small *spinal* offsets which enter the anterior sacral foramina. Small and irregular visceral branches pass to the rectum and anastomose with the superior and middle rectal arteries.

Variations.—The **median sacral artery** usually springs from the back of the aorta above its bifurcation; it may arise considerably above, or more rarely directly from the bifurcation. Not infrequently it arises from a fourth lumbar artery or from a stem common to the two, and occasionally it arises from a common iliac or internal iliac artery. Sometimes it gives off an accessory renal artery, and occasionally a larger rectal branch arises from it. The vessel is not always present; it may be double, entirely or in part.

COMMON ILIAC ARTERIES

The **common iliac arteries** (Figs. 1096 and 1100) are the terminal branches of the abdominal aorta. They commence opposite the middle of the body of the fourth lumbar vertebra, a little to the left of the median plane. Each artery passes downwards and laterally, across the bodies of the fourth and fifth lumbar vertebræ and the intervening intervertebral disc, and it ends, at the level of the lumbo-sacral disc and anterior to the sacro-iliac joint, by dividing into external and internal iliac branches.

The direction of each common iliac is indicated by a line drawn from the bifurcation of the aorta to a point on the inguinal ligament midway between the pubic symphysis and the anterior superior iliac spine.

The right artery is a little longer than the left, the former being about 2 inches (50 mm.) and the latter $1\frac{3}{4}$ inches (43 mm.) in length.

Relations.—*Anterior.*—Both arteries are covered by peritoneum, and are separated by it from coils of the small intestine. The aortic plexus of sympathetic nerves (Fig. 967, p. 1141) is continued into the hypogastric plexus in front of the upper ends of the arteries and each of them is often crossed, near its termination, by the corresponding ureter.

The left artery is crossed, in addition, by the superior rectal vessels.

Posterior.—Behind the artery, of each side, are the bodies of the fourth and fifth lumbar vertebræ and the intervening intervertebral disc, the sympathetic trunk, and the psoas major muscle. Those relationships, however, are much closer on the left side than on the right. The right common iliac, except at its lower end, where it is in contact with the psoas major, is separated from the structures named by the terminations of the right and left common iliac veins and the commencement of the inferior vena cava. More deeply placed, in the areolar tissue between the psoas major and the lumbar vertebræ, are the obturator nerve, the lumbo-sacral trunk, and the ilio-lumbar artery, which form distant posterior relations to the common iliac artery.

Lateral.—The lateral relations of each artery are coils of small intestine, the ureter, testicular or ovarian vessels, and the genito-femoral nerve.

Medial.—The medial side of each artery is clothed with peritoneum. The left vein is medial to and below its artery, but on a posterior plane. The right vein is at first postero-medial to its artery, but at its upper part it is directly behind the artery and is joined there by the left vein.

Branches.—The external and internal iliac arteries are the only branches.

Variations.—The **common iliac artery** may be longer or shorter than usual, a modification which is determined largely, though not altogether, by the point at which the bifurcation of the aorta takes place. If exceptionally long, it is usually tortuous. In Man the artery is very rarely absent. It occasionally gives off the median sacral or a lateral sacral artery, and ilio-lumbar, testicular, accessory renal or ureteric branches may arise from it.

INTERNAL ILIAC ARTERY

The **internal iliac artery** (Figs. 1097 and 1100) in the fœtus is the direct continuation of the common iliac trunk. It supplies numerous branches to the pelvis, runs upwards on the anterior abdominal wall to the umbilicus as the umbilical artery, and is prolonged through the umbilical cord to the placenta. One of its pelvic branches—the inferior gluteal—is at first the main artery of the lower limb, but subsequently another branch is given off which becomes the chief arterial trunk. That branch is the external iliac artery; it soon equals and ultimately exceeds the internal iliac in size, and the common iliac then appears to bifurcate into those two vessels.

When the placental circulation ceases after the umbilical cord is severed at birth, the part of the internal iliac trunk which extends from the pelvis to the umbilicus atrophies, and is afterwards represented almost entirely by a fibrous cord known as the *lateral umbilical ligament*. The proximal part of the obliterated artery remains pervious to convey blood to its superior vesical branch. The permanent internal iliac artery is a comparatively short vessel. Owing to the arrange-

ment of some of its branches it appears to end in an anterior and a posterior division; the anterior is the original continuation of the vessel, and the posterior is simply a common stem of origin for some of the branches.

With this explanation the artery may be described in the usual manner.

It arises from the common iliac opposite the sacro-iliac joint and at the level of the lumbo-sacral disc, and descends into the true pelvis, to end near the upper border of the greater sciatic notch in two divisions—anterior and posterior—from which the branches of distribution are given off. The artery measures about one and a half inches (35 mm.) in length.

Relations.—*Antero-medial.*—Each internal iliac artery is covered antero-medially by peritoneum, under cover of which the ureter descends along the anterior border of the artery. Some part of the intestine is in contact with the peritoneum covering it, usually the pelvic colon on the left and the terminal part of the ileum on the right. In the female, the ovary and the infundibulum of the uterine tube usually lie close in front of it, but separated from it by the peritoneum and the ureter (Fig. 661, p. 782).

Posterior to it are the internal iliac vein and the commencement of the common iliac vein; behind these are the lumbo-sacral trunk and the sacro-iliac joint.

Lateral.—On its lateral side the external iliac vein separates it from the psoas major muscle, above. At a lower level the obturator nerve, embedded in a mass of fat, intervenes between the artery and the side-wall of the pelvis.

Branches.—The internal iliac artery supplies the greater part of the pelvic wall and contents, and branches are distributed also to the gluteal region and thigh and to the external genital organs.

All the branches may be given off separately from a single undivided parent trunk, but as a rule they arise in two groups that correspond to the two divisions in which the artery, under these circumstances, appears to end. The branches are usually classified as parietal and visceral.

Posterior Division	Anterior Division		
Parietal	**Parietal**	**Visceral**	
Ilio-lumbar Lateral sacral Superior gluteal	Obturator Internal pudendal Inferior gluteal	Umbilical Superior vesical Middle rectal	Inferior vesical (male) Uterine } (female) Vaginal } (female)

Branches of Posterior Division of Internal Iliac Artery

The **ilio-lumbar artery** runs upwards and laterally, out of the true pelvis, to the iliac fossa. It passes anterior to the sacro-iliac joint, between the lumbo-sacral trunk and the obturator nerve, and posterior to the lower part of the common iliac vessels and the psoas major muscle.

In the iliac fossa it divides into an iliac and a lumbar branch. The **iliac branch** ramifies in the iliac fossa and anastomoses with branches of the deep circumflex iliac and obturator arteries; it gives offsets to the iliacus, and supplies a large nutrient branch to the ilium. The **lumbar branch** ascends, behind the psoas major, to the iliac crest. It supplies the psoas and quadratus lumborum, and anastomoses with the lumbar and deep circumflex iliac arteries; it gives off also a *spinal branch*, which enters the intervertebral foramen between the fifth lumbar vertebra and the sacrum, and is distributed like the spinal branches of the lumbar and posterior intercostal arteries.

There are usually two **lateral sacral arteries**—superior and inferior—but they may arise by a common stem.

Both run downwards and medially, on the front of the sacrum. The *inferior* passes anterior to the piriformis and the sacral nerves, and descends, on the lateral side of the sympathetic trunk, to the coccyx, where it ends by anastomosing with the median sacral. The *superior* reaches only as far as the first or the second anterior sacral foramen; then it enters the sacral canal. It anastomoses with the lower lateral sacral and with the median sacral artery. Branches are given off by

the lateral sacral arteries to the piriformis and to the sacral nerves. Spinal offsets pass through the anterior sacral foramina into the sacral canal; they supply the sacral dura mater and the arachnoid, the roots of the sacral nerves and the filum terminale, and anastomose with other spinal arteries. They then pass through the posterior sacral foramina to supply muscles on the back of the sacrum and anastomose with branches of the superior and inferior gluteal arteries.

The **superior gluteal artery** (Figs. 1097 and 1099) is the continuation of the posterior division of the internal iliac artery after it has given off its ilio-lumbar

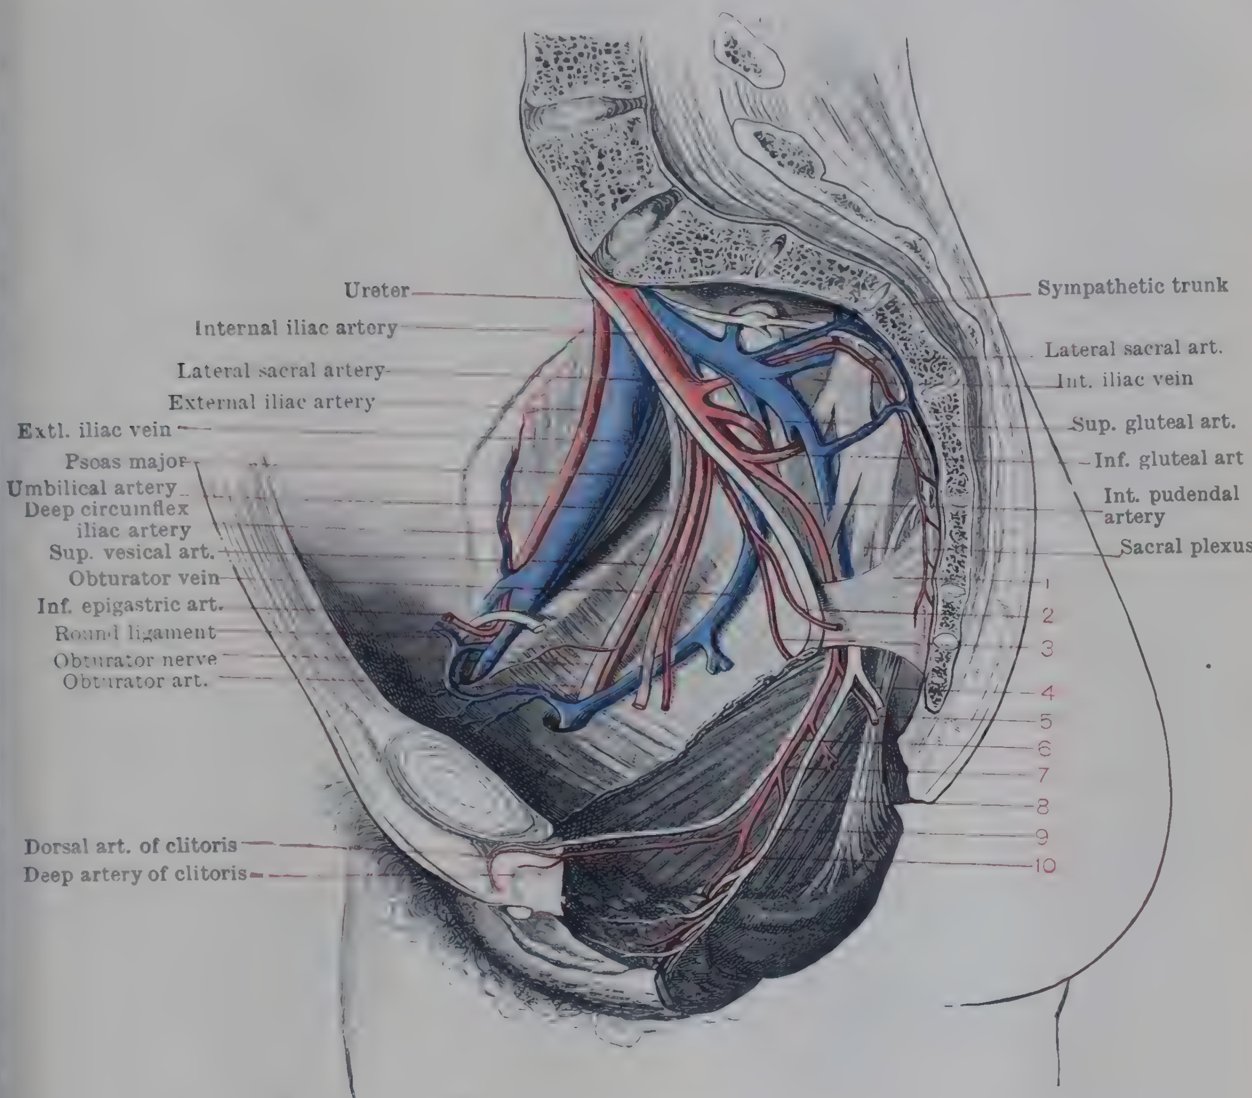

FIG. 1097.—INTERNAL ILIAC ARTERY AND ITS BRANCHES IN THE FEMALE.

9. Labial artery.
10. Artery of bulb of the vestibule.

and lateral sacral branches. It is a large vessel which pierces the pelvic fascia, and passes backwards between the lumbo-sacral trunk and the first sacral nerve. It leaves the pelvis through the upper part of the greater sciatic foramen, above the piriformis muscle, and enters the gluteal region, where it divides, under cover of the gluteus maximus and between the adjacent borders of the piriformis and gluteus medius muscles, into superficial and deep branches.

The **superficial branch** divides at once into numerous secondary branches, some of which supply the gluteus maximus, whilst others pass through it, near its origin, to the overlying skin. The branches freely anastomose with branches of the inferior gluteal, internal pudendal, medial circumflex, deep circumflex iliac, and lateral sacral arteries.

The **deep branch** runs forwards between the gluteus medius and minimus, and, after giving a nutrient branch to the ilium, divides into upper and lower branches. The

upper branch runs forwards along the upper border of the gluteus minimus and passes beyond the anterior margins of the gluteus medius and minimus to anastomose, under cover of the tensor fasciæ latæ, with the ascending branch of the lateral circumflex artery. It anastomoses with the deep circumflex iliac artery also, and it supplies muscular branches to the adjacent muscles. The *lower branch*, accompanied by the superior gluteal nerve and its branch to the tensor fasciæ latæ, passes more directly forwards, across the gluteus minimus, towards the greater trochanter. It supplies the gluteal muscles, and anastomoses with the ascending branch of the lateral circumflex artery.

Before leaving the pelvis the superior gluteal artery gives **muscular branches** to the piriformis and the obturator internus, nutrient branches to the hip-bone, and supplies the roots of the sacral plexus.

Parietal Branches of Anterior Division of Internal Iliac Artery

The **obturator artery** (Figs. 1097 and 1100) runs forwards and downwards along the side-wall of the true pelvis, near its brim, to the obturator foramen, through the upper part of which it passes. It ends immediately on entering the thigh by dividing into anterior and posterior terminal branches, which skirt round the margin of the obturator foramen deep to the obturator externus muscle. It is accompanied, in the whole of its pelvic course, by the obturator nerve and vein, the nerve being above the artery and the vein below it.

To its lateral side is the obturator fascia, which intervenes between it and the upper part of the obturator internus muscle, whilst on its medial side it is covered by peritoneum. The ureter intervenes between the posterior part of the artery and the peritoneum. When the bladder is distended it also comes into close relation with the lower and anterior part of the artery. In the female the ovarian vessels and the broad ligament are medial relations of the obturator artery.

Branches.—All the branches except the terminal are given off before the artery leaves the pelvis. *Muscular* branches supply the adjacent muscles; a *nutrient* branch to the ilium passes deep to the ilio-psoas muscle, supplies the bone, and anastomoses with the ilio-lumbar artery; and a *vesical* branch or branches pass medially to the bladder. A **pubic branch**, given off just before the artery leaves the pelvis, ascends on the pelvic surface of the pubis; it anastomoses with its fellow of the opposite side and with the pubic branch of the inferior epigastric, which, in its downward course, may pass on either the lateral or medial side of the femoral ring. In the latter position the branch of the inferior epigastric is important in relation to femoral hernia; the importance is emphasized when, as sometimes happens, the obturator artery arises as an enlarged pubic branch of the inferior epigastric artery instead of from the internal iliac (p. 1312). The *anterior terminal branch* runs forwards and the *posterior* backwards around the margin of the obturator foramen. They lie on the obturator membrane under cover of the obturator externus, and they anastomose together at the lower margin of the foramen Both give off offsets which anastomose with the medial circumflex artery, and supply the adjacent muscles. The posterior branch gives also an **acetabular branch** to the hip joint, which passes upwards, through the acetabular notch, to supply the head of the femur and its ligament.

The **internal pudendal artery** (Figs. 1097 and 1098) arises in common with the inferior gluteal artery. It runs downwards and backwards, to the lower part of the greater sciatic foramen, lying anterior to the piriformis muscle and the sacral plexus, from both of which it is separated by the pelvic fascia. At the lower border of the piriformis it pierces the pelvic fascia, passes between the piriformis and coccygeus muscles, and leaves the pelvis to enter the gluteal region. It is accompanied by venæ comitantes, the pudendal nerve, and the nerve to the obturator internus; and the inferior gluteal vessels lie at first behind and then lateral to it. In the gluteal region it lies on the ischial spine under cover of the gluteus maximus, and between the pudendal nerve and the nerve to the obturator internus, the former being medial to it. It next passes through the lesser sciatic foramen and enters the perineum, in the anterior part of which it ends by dividing into the deep and dorsal arteries of the penis or of the clitoris.

In the first part of its course *in the perineum* the artery lies in the lateral wall of the ischio-rectal fossa, where it is enclosed in a canal in the obturator fascia—

the pudendal canal. This canal, which is situated about 1½ inches above the lower margin of the ischial tuberosity, contains also the pudendal veins and the terminal parts of the pudendal nerve, *i.e.*, the dorsal nerve of the penis or clitoris, which lies above the artery, and the perineal nerve, which lies below it. From the ischio-rectal fossa the internal pudendal artery is continued forwards in the deep perineal pouch close to the ramus of the pubis. About half an inch below the pubic symphysis it pierces the perineal membrane and immediately divides into its terminal branches—the deep artery and the dorsal artery. The division sometimes takes place while the artery is still within the deep perineal pouch.

Branches.—*In the pelvis.*—Small branches to muscles and to the sacral plexus.

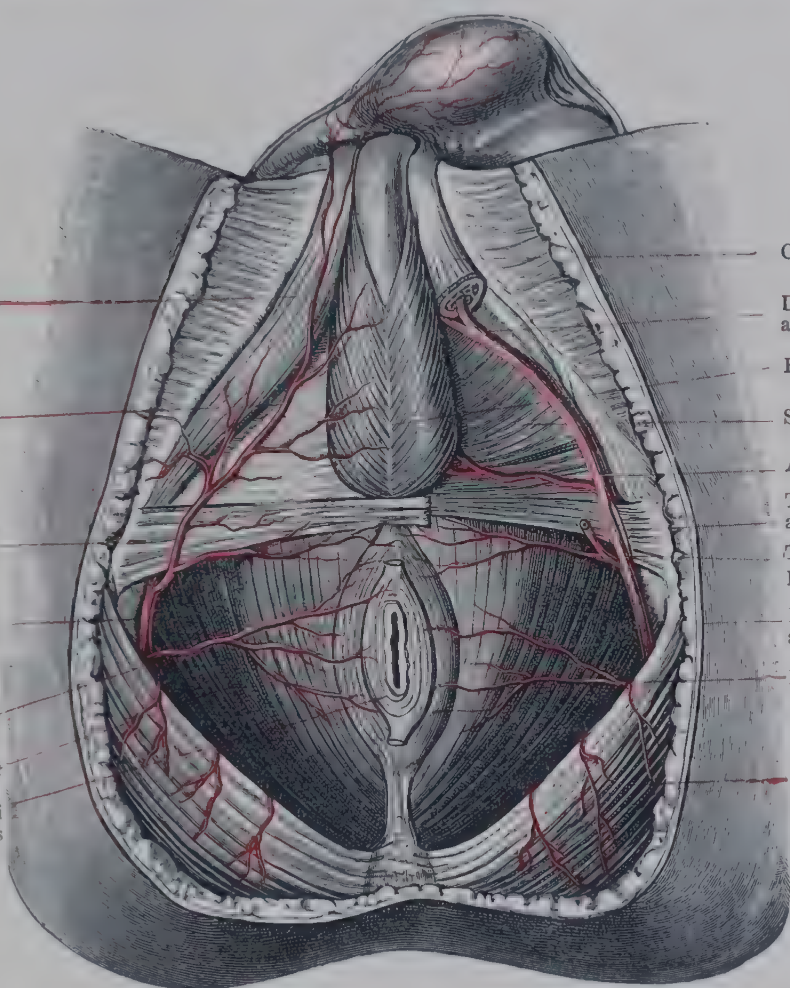

FIG. 1098.—PERINEAL DISTRIBUTION OF INTERNAL PUDENDAL ARTERY IN THE MALE.

In the gluteal region.—*Muscular* branches are distributed to the adjacent muscles and anastomose with branches of the gluteal and medial circumflex arteries.

In the ischio-rectal fossa.—The **inferior rectal artery** pierces the wall of the fascial canal, and runs obliquely forwards and medially. It soon divides into two or three main branches, which may arise separately from the pudendal; they pass across the fossa to the anal canal. The branches of the artery anastomose with the transverse perineal and, in the walls of the anal canal, with their fellows of the opposite side, and with the middle and superior rectal arteries: they supply cutaneous twigs to the region of the anus, and send others round the lower border of the gluteus maximus to supply the lower part of the buttock.

Two **scrotal** or **labial branches** arise in the anterior part of the ischio-rectal fossa, either separately or by common trunk, and pierce the posterior border of the perineal membrane. They are continued forwards, in the urogenital triangle, to the scrotum or the labium majus according to sex, deep to the superficial fascia. They anastomose with their fellows of the opposite side, with the transverse perineal and the external pudendal arteries, and supply the muscles and subcutaneous structures of the urogenital triangle.

The **transverse perineal artery** is a small branch which arises from one of the scrotal or labial branches or from the common trunk; it may arise directly from the internal pudendal. It runs medially along the superficial transversus perinei to the perineal

body, where it anastomoses with its fellow of the opposite side and with the inferior rectal arteries. It supplies adjacent muscles.

In the urogenital triangle.—The **artery of the bulb of the penis**, usually of relatively large size, is given off in the deep perineal pouch. It runs transversely along the posterior border of the sphincter urethræ, and then pierces the perineal membrane a short distance from the side of the urethra to enter the substance of the bulb. It passes onwards in the corpus spongiosum to the glans, where it anastomoses with its fellow and with the dorsal arteries of the penis.

It supplies the sphincter urethræ, the bulbo-urethral gland, the corpus spongiosum penis, and the spongy part of the urethra. *In the female*, the corresponding artery supplies the bulb of the vestibule.

The **deep artery of the penis** (**of the clitoris** in the female) is usually the larger of the two terminal branches. Immediately after its origin it enters the crus, and runs forwards in the corpus cavernosum of the penis (or clitoris), which it supplies.

The **dorsal artery of the penis** (**of the clitoris** in the female) ascends between the crus and the bone, passes forwards between the layers of the suspensory ligament of the penis (or clitoris), and runs along the dorsal surface of the organ, with the dorsal nerve immediately lateral to it, and separated from its fellow of the opposite side by the deep dorsal vein, which lies in the median plane. It supplies the superficial tissues on the dorsal aspect of the penis, sends branches into the corpus cavernosum to anastomose with the deep artery, and its terminal branches enter the glans, where they anastomose with the arteries to the bulb. It anastomoses also with the external pudendal branches of the femoral.

The **inferior gluteal artery** (Figs. 1097 and 1099) arises by a common trunk with the internal pudendal artery. It descends a little postero-lateral to the internal pudendal vessels, pierces the pelvic fascia, runs backwards and laterally between the first and second, or second and third sacral nerves, and leaves the pelvis through the lower part of the greater sciatic foramen to enter the gluteal region just below the piriformis. In the gluteal region it descends along the postero-medial side of the sciatic nerve, deep to the gluteus maximus, and behind the obturator internus, the two gemelli, the quadratus femoris, and upper part of the adductor magnus muscles, to reach the proximal part of the thigh.

Below the lower border of the gluteus maximus the artery is comparatively superficial, and, having given off its largest branches, it descends, as a long slender vessel, with the posterior cutaneous nerve of the thigh.

Branches.—*In the pelvis.*—Small and irregular branches supply the adjacent viscera and muscles and the sacral nerves; they anastomose with branches of the internal pudendal and lateral sacral arteries.

In the buttock.—**Muscular branches** are given off to the muscles of the buttock, and to the proximal parts of the hamstring muscles. They anastomose with the internal pudendal, medial circumflex, and obturator arteries. One or two **coccygeal branches** arise immediately after the artery leaves the pelvis. They run medially, pierce the sacro-tuberous ligament and the gluteus maximus, and end in the soft tissues over the posterior surface of the coccyx and of the lower part of the sacrum. They supply twigs to the gluteus maximus, and anastomose with branches of the gluteal and lateral sacral arteries. An *anastomosing* branch passes laterally, superficial or deep to the sciatic nerve, towards the greater trochanter of the femur. It gives a branch to the back of the hip joint and anastomoses with branches of the gluteal, internal pudendal, medial and lateral circumflex, and the first perforating arteries, taking part in the formation of the so-called "crucial anastomosis" of the thigh. *Cutaneous* branches, accompanying twigs of the posterior cutaneous nerve of the thigh, pass round the lower border of the gluteus maximus muscle to the skin. The **companion artery of the sciatic nerve** is a long slender branch which runs downwards on the surface of the sciatic nerve or in its substance. It supplies the nerve and anastomoses with the perforating arteries.

Visceral Branches of Anterior Division of Internal Iliac Artery

Umbilical Artery.—Atrophy of that portion of the **umbilical artery** which extends from the anterior division of the internal iliac to the umbilicus has already been mentioned. The atrophy is complete between the umbilicus and the origin of the superior vesical artery, but between that origin and the internal

iac it is incomplete, and the lumen of the vessel, though greatly diminished in ze, persists. It is from the incompletely obliterated portion that the superior esical artery arises. The completely obliterated part of the umbilical artery is educed to a fibrous cord which runs along the side of the bladder almost to its pex, and then ascends, on the posterior surface of the anterior abdominal wall, o the umbilicus. In the latter part of its course it is known as the **lateral mbilical ligament**. As it passes along the wall of the true pelvis it is external to he peritoneum, and it is crossed by the vas deferens in the male, and by the round igament of the uterus in the female.

The **superior vesical artery** arises from the pervious part of the umbilical artery, as it lies at the side of the bladder. It passes medially to the upper part of the urinary bladder and divides into numerous branches which anastomose with the other vesical arteries, and it also gives small branches to the median umbilical ligament (urachus), and often to the lower part of the ureter. Not infrequently the *artery of the vas deferens* arises from it.

The **inferior vesical artery** runs medially, upon the upper surface of the levator ani, to the lower part of the bladder. It gives branches also to the seminal vesicle, the vas deferens, the lower part of the ureter and the prostate, and it anastomoses with its fellow of the opposite side, with the other vesical arteries, and with the middle rectal artery.

The **artery of the vas deferens** may arise from either the superior vesical or the inferior vesical artery. It is a long, slender vessel which accompanies the vas deferens to the testis, where it anastomoses with the testicular artery. It anastomoses also with the artery of the cremaster.

The **middle rectal artery** arises either directly from the anterior division of the internal iliac or from the inferior vesical; more rarely it springs from the internal pudendal. It runs medially and is distributed to the rectum; it gives branches also to the prostate, the seminal vesicle, and the vas deferens; and it anastomoses with its fellow of the opposite side, with the inferior vesical, and with the other rectal arteries.

The **vaginal artery** may arise either directly from the anterior division of the internal iliac or from a stem common to it and the uterine artery, and it may be represented by several branches.

It runs downwards and medially, on the floor of the pelvis, to the side of the vagina, and divides into numerous branches which ramify on its anterior and posterior walls. The corresponding branches of opposite sides anastomose and form anterior and posterior longitudinal vessels—the so-called *azygos arteries*. They also anastomose above with the vaginal branches of the uterine arteries, and below with the perineal branches of the internal pudendal. In addition to supplying the vagina, it gives small branches to the bulb of the vestibule, to the base of the bladder, and to the rectum.

The **uterine artery** arises either separately or in common with the vaginal or middle rectal artery. It runs medially and slightly forwards upon the upper surface of the levator ani, to the lower border of the broad ligament, between the two layers of which it passes medially, and arches above the ureter about three-quarters of an inch from the uterus (Figs. 656 (p. 775) and 661). It passes above the lateral fornix of the vagina to the side of the neck of the uterus, and then ascends in a tortuous manner towards the fundus, but at the level of the uterine tube it turns laterally, below the tube and between the layers of the broad ligament, and ends as an *ovarian branch* which anastomoses with the ovarian artery. It supplies the uterus, the ligament of the ovary, and the round ligament of the uterus, and gives off *vaginal* and *tubal branches* to the upper part of the vagina and the medial part of the uterine tube. It anastomoses with its fellow of the opposite side, with the vaginal and ovarian arteries, and, along the round ligament of the uterus, with the inferior epigastric arteries.

Variations.—The **internal iliac artery** varies in length. It is longer and arises at a higher level when the common iliac is short. In rare cases it arises from the aorta without the intervention of a common iliac. Frequently, as in the fœtus, it does not end in anterior and posterior divisions, but forms a single trunk from which the branches are given off.

The visceral branches vary much in number and size, and the **middle rectal** may not b present, its place being taken by branches from the vesical arteries. An accessory renal branch o a ureteric artery sometimes arises from the internal iliac artery.

The **ilio-lumbar branch** often arises from the common iliac instead of the internal iliac the **superior gluteal** and **inferior gluteal** arteries may arise by a common stem. The inferio gluteal artery may, as in the fœtus, constitute the main artery of the lower limb, and run distall to become continuous with the popliteal artery; probably the companion artery of the sciati nerve represents the original continuity of the two vessels (Fig. 1136, p. 1376).

In some instances the **obturator artery** arises from the inferior epigastric artery instead c from the internal iliac. The condition is apparently due to obliteration of the usual origin of th obturator artery and the subsequent enlargement of the anastomosing pubic branches of th obturator and inferior epigastric arteries. The course of the *abnormal obturator artery* is c importance. From its origin it descends into the true pelvis, on the medial side of the externa iliac vein, and usually on the lateral side of the femoral ring; but in three-tenths of examples, an more often in males than in females, it descends on the medial side of the ring. If it passes or the medial side of the ring, the artery may be injured in the operation for the relief of a strangulated femoral hernia.

The obturator artery sometimes gives off an accessory pudendal branch which passes along the side of the prostate, pierces the sphincter urethræ, and ends by dividing into the deep anc dorsal arteries of the penis. When that occurs the internal pudendal artery is small, and i ends as the artery to the bulb. Occasionally the accessory pudendal arises from the interna pudendal artery within the pelvis, or from one of the vesical arteries.

EXTERNAL ILIAC ARTERY

The **external iliac artery** (Figs. 1096, 1100) extends from a point opposite the sacro-iliac joint, at the level of the lumbo-sacral disc, to a point at the inguinal ligament, midway between the anterior superior iliac spine and the pubic symphysis, where it becomes the femoral artery. Its length is three and a hal to four inches (85 to 100 mm.), and in the adult it is usually slightly wider thar the internal iliac artery.

It runs downwards, forwards, and laterally, along the brim of the pelvis resting upon the fascia iliaca, which separates it above from the medial border of the psoas major muscle, and below from its anterior surface; and it is enclosed with its accompanying vein, in a thin fascial sheath.

Relations.—*Anterior.*—It is covered in front by peritoneum, which separates it on the right side from the terminal portion of the ileum, and sometimes from the vermiform appendix, and on the left side, from small intestine, except where the termination of the descending colon crosses it. Several branches of the lower of the two inferior left colic arteries also cross it on the left side. The ureter crosses the artery at its origin and in the female the ovarian vessels cross the artery an inch below its origin. Near its lower end the testicular vessels and the genital branch of the genito-femoral nerve lie on the artery, and they are all crossed by the deep circumflex iliac vein. In the male that part of the artery is crossed also by the vas deferens, and in the female by the round ligament of the uterus. External iliac lymph-glands lie in front and at the sides of the artery, and almost invariably one of these is directly in front of its termination.

Posterior.—The fascia iliaca and psoas major muscle lie behind the artery. Near its upper end the external iliac vein is posterior to the vessel and separates it from the obturator nerve.

Lateral.—On its lateral side is the genito-femoral nerve. *Medial.*—To the medial side is the peritoneum, and at its lower part the external iliac vein.

Branches.—In addition to small branches to the psoas major muscle and to the lymph-glands, two named branches of considerable size spring from the external iliac artery—the inferior epigastric and the deep circumflex iliac.

The **inferior epigastric artery** (Figs. 1097 and 1100) arises, immediately above the inguinal ligament, from the front of the external iliac. It lies in the extraperitoneal fat; it curves forwards from its origin, turns round the lower border of the peritoneal sac, and runs upwards and medially, along the medial side of the deep inguinal ring and onwards towards the rectus abdominis muscle raising a fold of the peritoneum; it then pierces the transversalis fascia, passes over the arcuate line and enters the sheath of the rectus. For a short distance it ascends posterior to the rectus, but it soon penetrates into the substance of the muscle, and breaks up into branches which anastomose with terminal offsets of the

perior epigastric branch of the internal mammary artery and with the lower osterior intercostal arteries. At the deep inguinal ring, the vas deferens in the male,

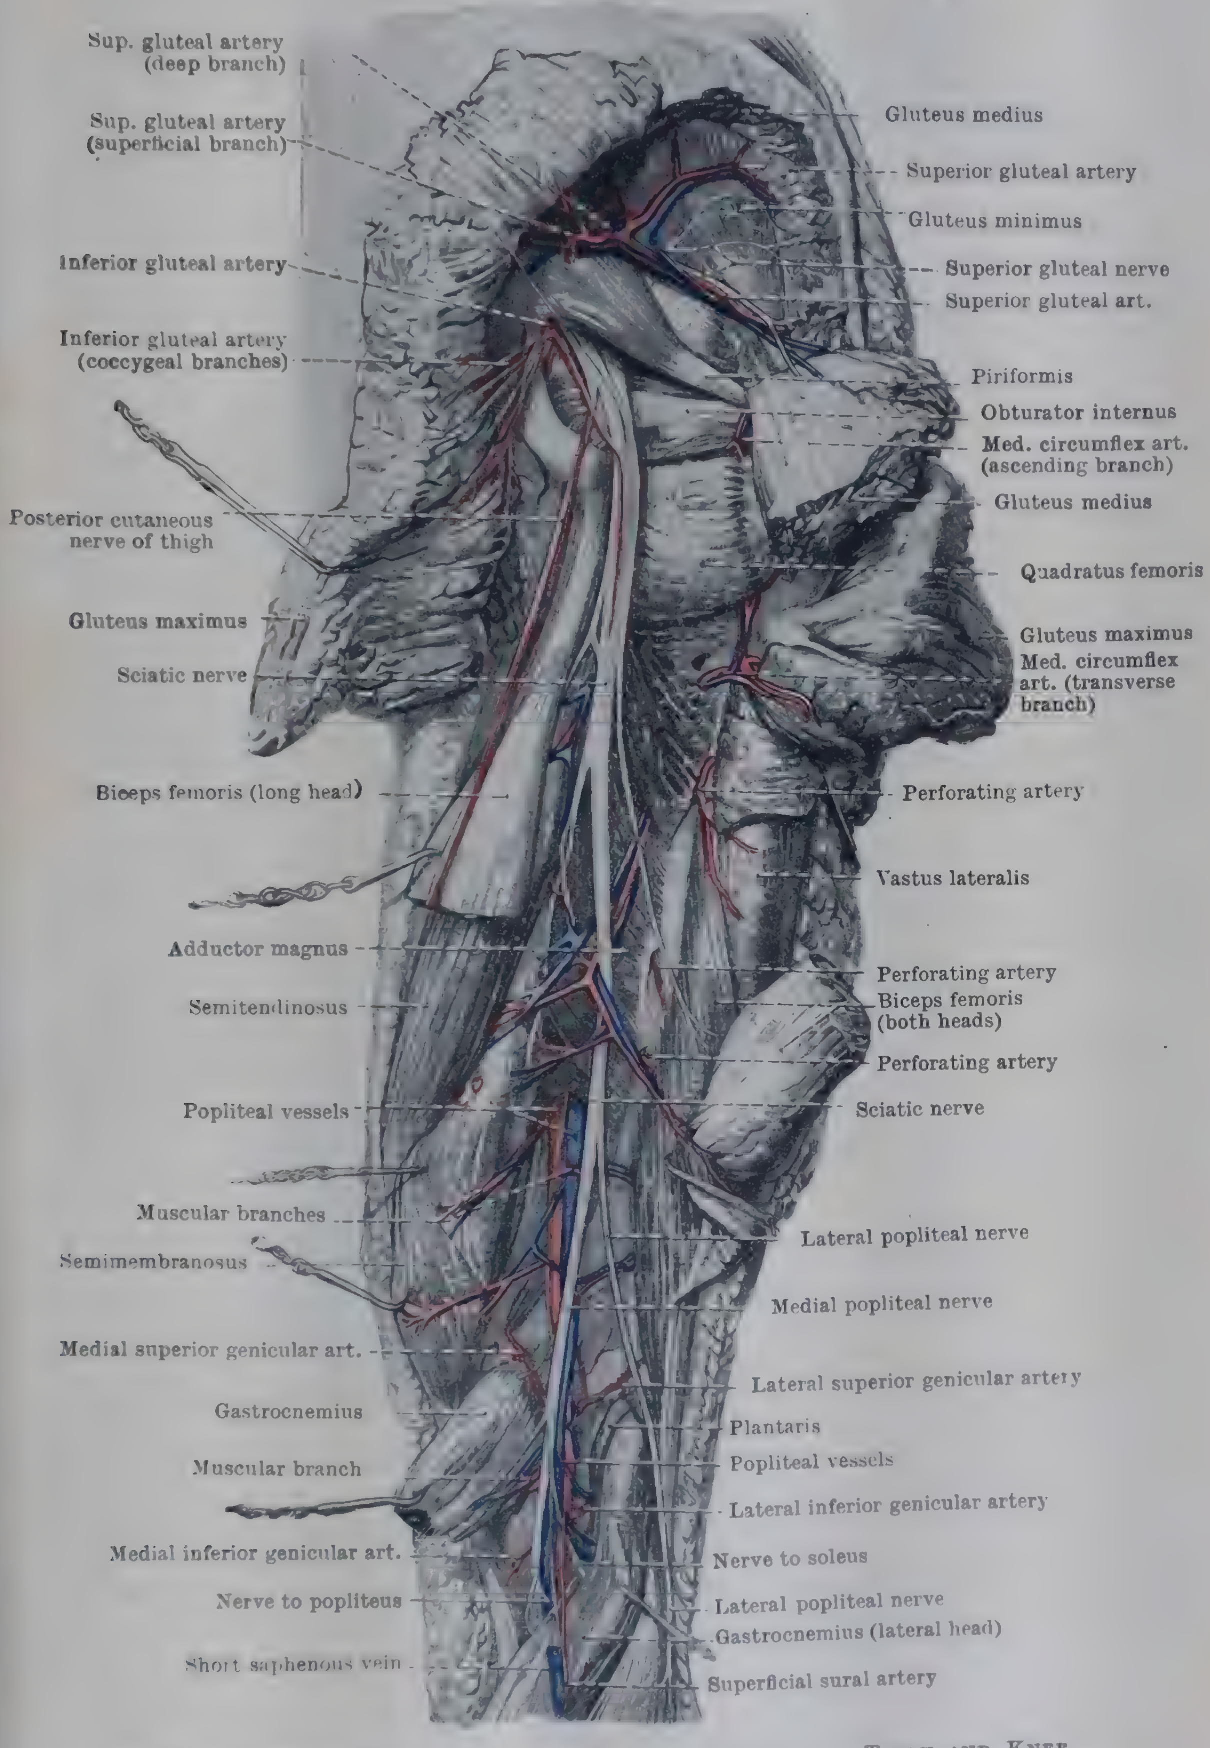

Fig. 1099.—Arteries of Buttock and Posterior Aspect of Thigh and Knee.

Note.—In the specimen there was no anastomotic branch of the inferior gluteal artery, and the transverse terminal branch of the medial circumflex artery pierced the upper part of the adductor magnus.

or the round ligament of the uterus in the female, hooks round the artery and passes medially behind it towards the pelvis.

Branches.—**Muscular branches** supply the muscles of the abdominal wall, ar anastomose with branches of the deep circumflex iliac, the lumbar, and the lower posteri intercostal arteries. **Cutaneous branches** pierce the rectus abdominis and the anterior pa of its sheath, and end in the subcutaneous tissues of the anterior abdominal wa where they anastomose with corresponding branches of the opposite side and wit branches of the superficial epigastric artery. The **artery of the cremaster** in the ma (**artery of the round ligament of the uterus** in the female) is small. It descends throug the inguinal canal and anastomoses with the external pudendal arteries and the scrot or labial branches of the pudendal artery, and in the male with the testicular artery als

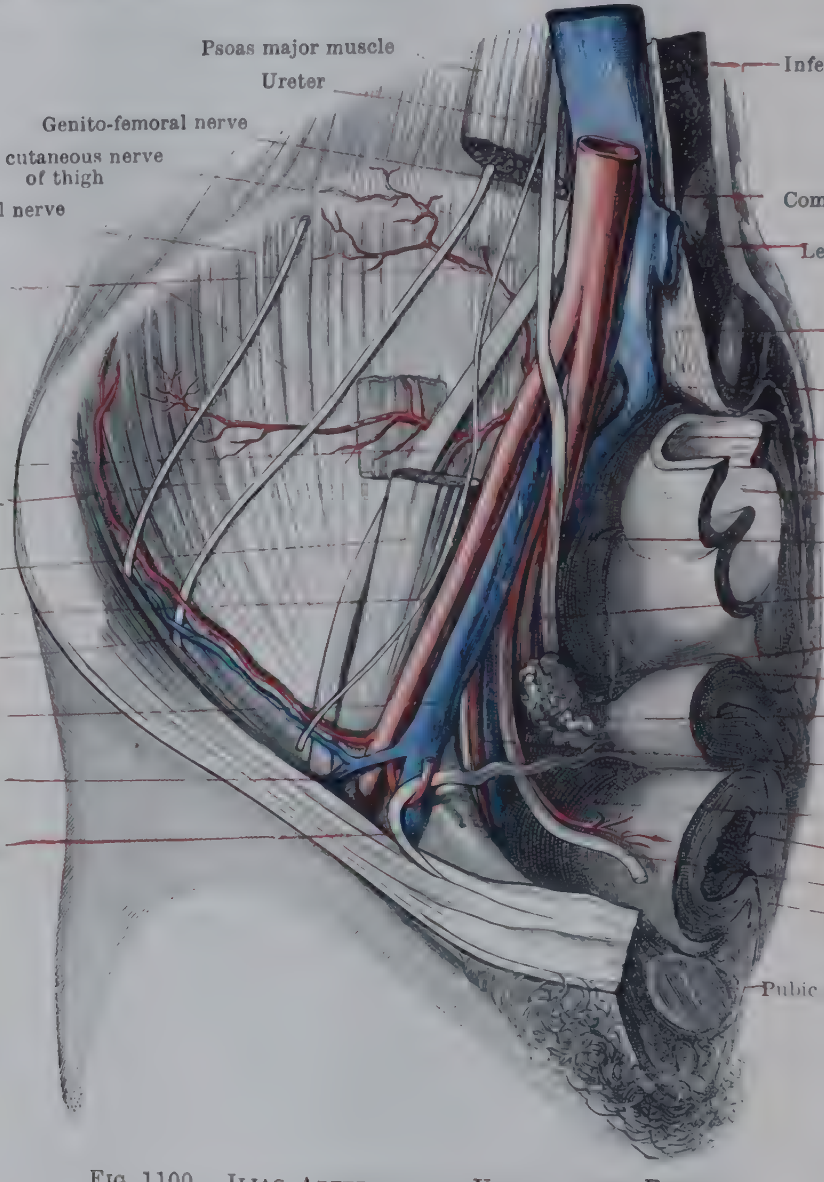

Fig. 1100.—Iliac Arteries and Veins in the Female.

In the male it accompanies the spermatic cord, supplying its coverings, including t cremaster. In the female it runs with the round ligament. The **pubic branch** descen either on the lateral or the medial side of the femoral ring, to anastomose with the pul branch of the obturator artery; it anastomoses also with its fellow of the opposite sid Sometimes, when the obturator branch of the internal iliac artery is absent, the pul branch of the inferior epigastric artery enlarges and becomes the obturator artery, whi descends to the obturator foramen either on the lateral or the medial side of the femor ring (see p. 1312).

The deep circumflex iliac artery (Figs. 1100 and 1101) springs from t lateral side of the external iliac artery, usually a little below the inferior epigastr and immediately above the inguinal ligament. It runs laterally and upwards the anterior superior iliac spine. In that part of its course it lies just above t inguinal ligament, and is enclosed in a fibrous canal formed by the union of t transversalis and iliac fasciæ. A little beyond the anterior superior spine it pierc the transversus abdominis, and is continued between the transversus and t

ternal oblique, to end by anastomosing with branches of the ilio-lumbar tery.

Branches.—**Muscular branches** are given to the adjacent muscles. One of them frequently of considerable size and is known as the **ascending branch**; it pierces the ansversus muscle a short distance in front of the anterior superior spine, and ascends ertically, between the transversus and the internal oblique, anastomosing with the imbar and the epigastric arteries. **Cutaneous branches** pierce the muscles. They id in the skin over the iliac crest, and anastomose with the superior gluteal, the superficial circumflex iliac, and the ilio-lumbar arteries.

Variations.—The **external iliac artery** may be much smaller than usual, especially if ie inferior gluteal artery persists as the main vessel of the lower limb. It may give off two eep circumflex iliac branches, a dorsal artery of the penis, a medial circumflex artery of the iigh, or a vas aberrans (p. 1320), and its deep circumflex iliac and inferior epigastric branches iay arise at higher or lower levels than usual.

ARTERIES OF LOWER LIMB

The main artery of the lower limb is continued from the common iliac rtery. It descends as a single trunk as far as the lower border of the opliteus, and ends there by dividing into the anterior and posterior tibial arteries.)istinctive names are, however, applied to different parts of the artery, corresponding to the several regions through which it passes. Thus in the abdomen it is alled the **external iliac artery**, in the proximal two-thirds of the thigh it receives he name of the **femoral artery**, whilst its distal part, which is situated in the opliteal fossa, is termed the **popliteal artery**.

FEMORAL ARTERY

The **femoral artery** (Figs. 1101 and 1102) is the continuation of the external liac into the thigh. It begins behind the inguinal ligament, passes through the proximal two-thirds of the thigh, and ends at the opening in the adductor magnus.

Course.—Its general direction is indicated by a line drawn from the inguinal ligament, midway between the anterior superior iliac spine and the pubic symphysis, to the adductor tubercle, the thigh being flexed, abducted, and rotated laterally.

In its proximal half the femoral artery lies in the femoral triangle and is comparatively superficial; at the apex of the triangle it passes deep to the sartorius, enters the subsartorial canal (Hunter's canal), and is then more deeply placed.

At their entry into the femoral triangle both the artery and its vein are enclosed, for a distance of $1\frac{1}{4}$ inches (30 mm.), in a funnel-shaped fascial sheath formed of the fascia transversalis in front and the fascia iliaca behind. That sheath is called the **femoral sheath**; it is divided by antero-posterior septa into three compartments. The lateral compartment is occupied by the femoral artery and the femoral branch of the genito-femoral nerve; the intermediate compartment contains the femoral vein; and the medial compartment is the femoral canal.

Relations.—**In Femoral Triangle**—*Anterior.*—The femoral artery is covered superficially by skin and fasciæ, by superficial inguinal lymph-glands and small superficial vessels. The anterior part of the femoral sheath and the cribriform fascia are in front of the proximal part of the artery, and the fascia lata is in front of the distal part. Near the apex of the triangle the artery is crossed by the medial cutaneous nerve, and not infrequently by a tributary of the long saphenous vein. *Posterior.*—It is in relation behind, proximo-distally, with the posterior part of the femoral sheath and the psoas major, the pectineus, and the adductor longus. The nerve to the pectineus passes between the artery and the psoas major; the femoral vein and the profunda artery intervene between it and the pectineus, and the femoral vein separates it from the adductor longus also.

The femoral vein, which lies behind the artery in the lower part of the femoral triangle, passes to its *medial side* above, where it is separated from the artery by the lateral septum of the femoral sheath. On the *lateral side* of the artery are the femoral branch of the genito-femoral nerve, the femoral sheath, and the femoral nerve proximally;

more distally the saphenous nerve and the nerve to the vastus medialis are continued o the lateral side.

In Subsartorial Canal—*Posterior.*—The adductors longus and magnus are behin

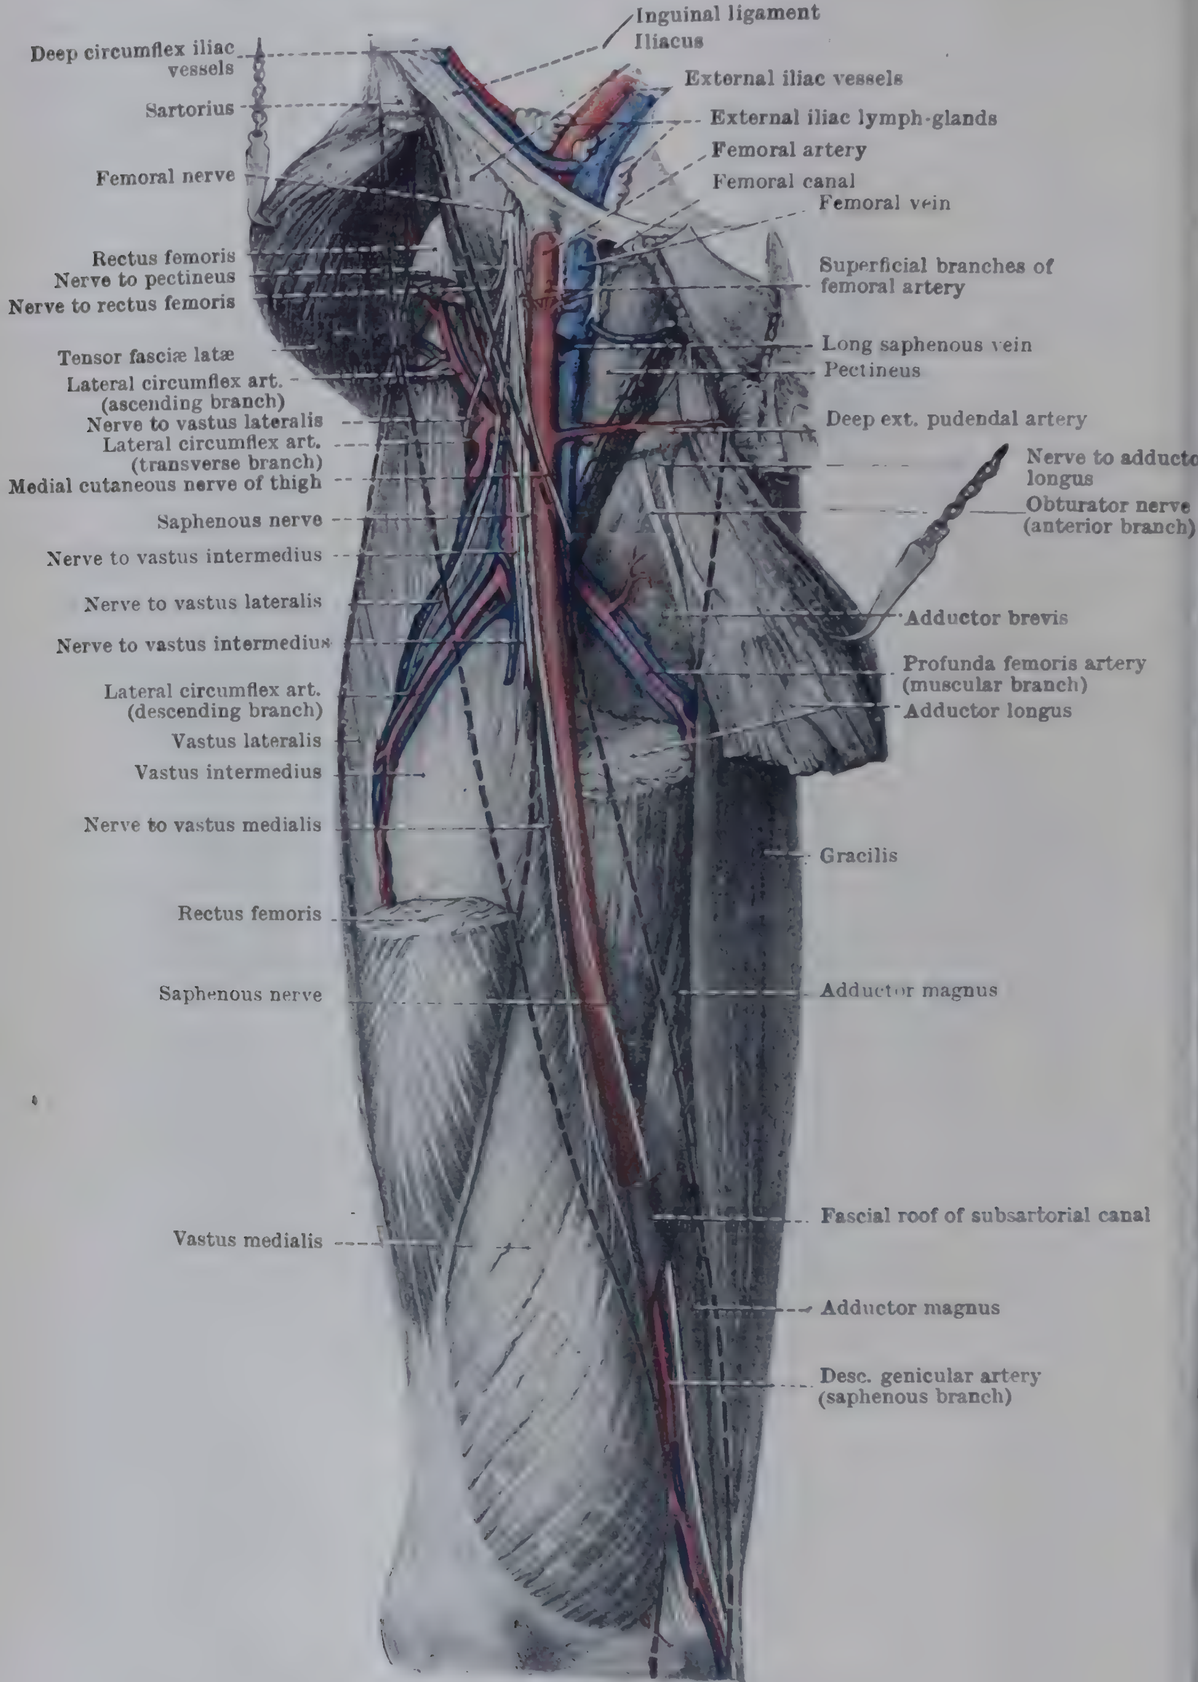

FIG. 1101.—FEMORAL ARTERY AND ITS BRANCHES.
The outlines of the sartorius, the upper part of the rectus femoris, and the adductor longus are indicated by broken black lines.

the artery, but are separated from it by the femoral vein, which is posterior to th artery proximally, and postero-lateral distally. The vastus medialis is *antero-latera* The fascial roof of the canal, the subsartorial plexus of nerves and the sartorius a

tero-medial. The saphenous nerve enters the canal with the artery, and runs first on its lateral side, then anterior, and lastly on its medial side.

Branches.—The femoral artery gives off the following branches :—

(1) Superficial branches.
- (*a*) Superficial circumflex iliac.
- (*b*) Superficial epigastric.
- (*c*) Superficial external pudendal.

(2) Muscular.
(3) Deep external pudendal.
(4) Profunda femoris.
(5) Descending genicular.

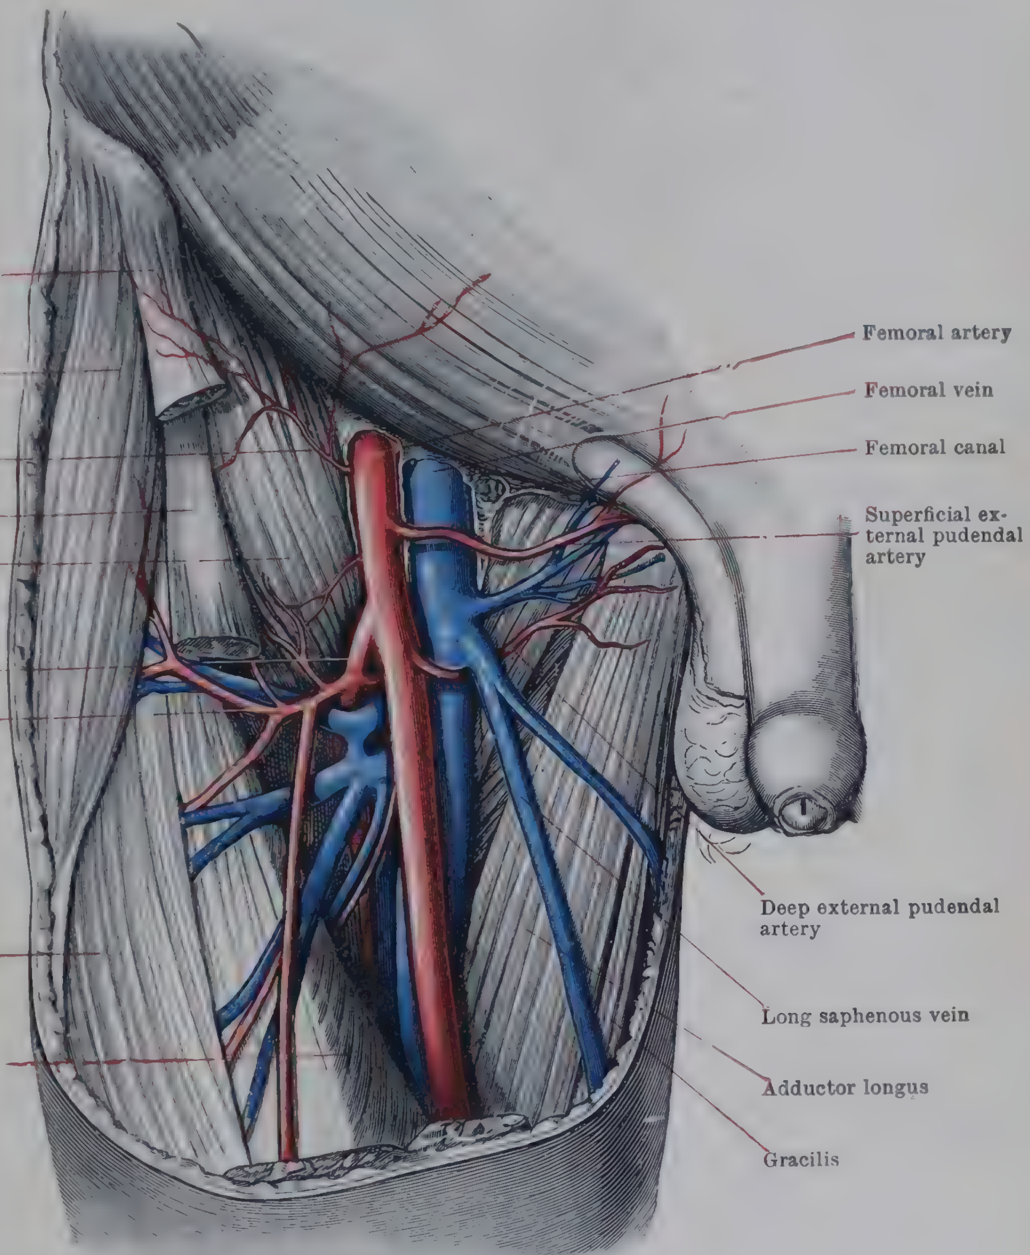

Fig. 1102.—Femoral Vessels in the Femoral Triangle.

The **superficial circumflex iliac artery** springs from the front of the femoral artery just below the inguinal ligament. It pierces the femoral sheath and the fascia lata, lateral to the saphenous opening of the fascia lata, and runs in the superficial fascia as far as the anterior superior iliac spine. It supplies the lateral set of inguinal lymph-glands and the skin of the groin; and it sends branches, through the fascia lata, to anastomose with branches of the deep circumflex iliac artery and to supply the upper parts of the sartorius and tensor fasciæ latæ muscles.

The **superficial epigastric artery** arises near the preceding. It pierces the femoral sheath and the cribriform fascia, and passes upwards and medially towards the umbilicus between the superficial and deep layers of the superficial fascia of the abdominal wall. It supplies the inguinal lymph-glands and the skin; it

anastomoses with its fellow of the opposite side, with the inferior epigastric, and with the superficial circumflex iliac and superficial external pudendal arteries.

The **superficial external pudendal artery** also springs from the front of the femoral artery, and, after piercing the femoral sheath and the cribriform fascia, runs upwards and medially towards the pubic tubercle, where it crosses superficial to the spermatic cord or the round ligament of the uterus and divides into terminal *scrotal* or *labial branches* according to the sex. It supplies the skin of the lower part of the abdominal wall, the root of the dorsum of the penis in the male, and the region of the mons pubis in the female; and it anastomoses with its fellow of the opposite side, with the deep external pudendal, with the dorsal artery of the penis or clitoris, and with the superficial epigastric artery.

The **muscular branches** are distributed to the adjacent muscles.

The **deep external pudendal artery** arises from the medial side of the femoral. It runs medially, anterior to the pectineus, and either anterior or posterior to the adductor longus, to the medial side of the thigh; it then pierces the deep fascia, and ends in the scrotum or the labium majus, where it anastomoses with the scrotal or labial branches of the superficial external and the internal pudendal arteries, and with the artery of the cremaster or of the round ligament.

The **profunda femoris artery** (Fig. 1102) is the largest branch of the femoral artery. It arises from the lateral side of the femoral artery about an inch and a half distal to the inguinal ligament. It curves backwards and medially, passes posterior to the main artery, and runs downwards, close to the medial aspect of the femur, to the distal third of the thigh, where it perforates the adductor magnus and passes to the back of the thigh. Its termination is known as the *fourth perforating artery*. As the profunda artery descends, it lies anterior to the iliacus, the pectineus, the adductor brevis, and the adductor magnus. It is separated from the femoral artery by its own vein, by the femoral vein, and by the adductor longus muscle.

Branches.—**Muscular branches** are given off from the profunda, both in the femoral triangle and between the adductor muscles; many of them end in the adductors, others pass through the adductor magnus, and end in the hamstring muscles, where they anastomose with the transverse branch of the medial circumflex and with the proximal muscular branches of the popliteal artery.

The **lateral circumflex artery** (Figs. 1101 and 1102) springs from the lateral side of the profunda, or occasionally from the femoral artery proximal to the origin of the profunda. It runs laterally, anterior to the iliacus and among the branches of the femoral nerve, to the lateral border of the femoral triangle; then, passing posterior to the sartorius and the rectus femoris, it ends by dividing into three terminal branches—the ascending, the transverse, and the descending. Before its termination it supplies branches to the muscles mentioned and to the proximal part of the vastus intermedius.

The **ascending branch** runs upwards and laterally, posterior to the rectus femoris and the tensor fasciæ latæ, along the trochanteric line, to the adjacent anterior borders of the gluteus medius and gluteus minimus, between which it passes to anastomose with the deep branches of the superior gluteal artery. It supplies twigs to the neighbouring muscles, anastomoses with the gluteal, the deep circumflex iliac, and the transverse branch of the lateral circumflex arteries, and, as it ascends along the trochanteric line, it gives off a branch which passes between the two limbs of the ilio-femoral ligament into the hip joint. The **transverse branch** is small; it runs laterally, between the vastus intermedius and the rectus femoris, passes into the substance of the vastus lateralis, winds round the femur, and anastomoses with the ascending and descending branches, with the perforating branches of the profunda, and with the inferior gluteal and medial circumflex arteries. The **descending branch** runs downwards, posterior to the rectus and along the anterior border of the vastus lateralis, accompanied by the nerve to the latter muscle. It anastomoses with the transverse branch, with twigs of the inferior perforating arteries, with the descending genicular branch of the femoral, and with the lateral superior genicular branch of the popliteal artery.

The **medial circumflex artery** springs from the medial and posterior part of the profunda, at the same level as the lateral circumflex, and runs backwards through the floor of the femoral triangle, passing between the psoas major and the pectineus; then it crosses the upper border of the adductor brevis, and continuing backwards, below the neck of the femur, it passes between the adjacent borders of the obturator externus and

the adductor brevis to the upper border of the adductor magnus, where it divides into two terminal branches—a transverse and an ascending branch.

Branches.—An **acetabular branch** is given off as the artery passes below the neck of the femur. It ascends to the acetabular notch where it anastomoses with twigs from the posterior

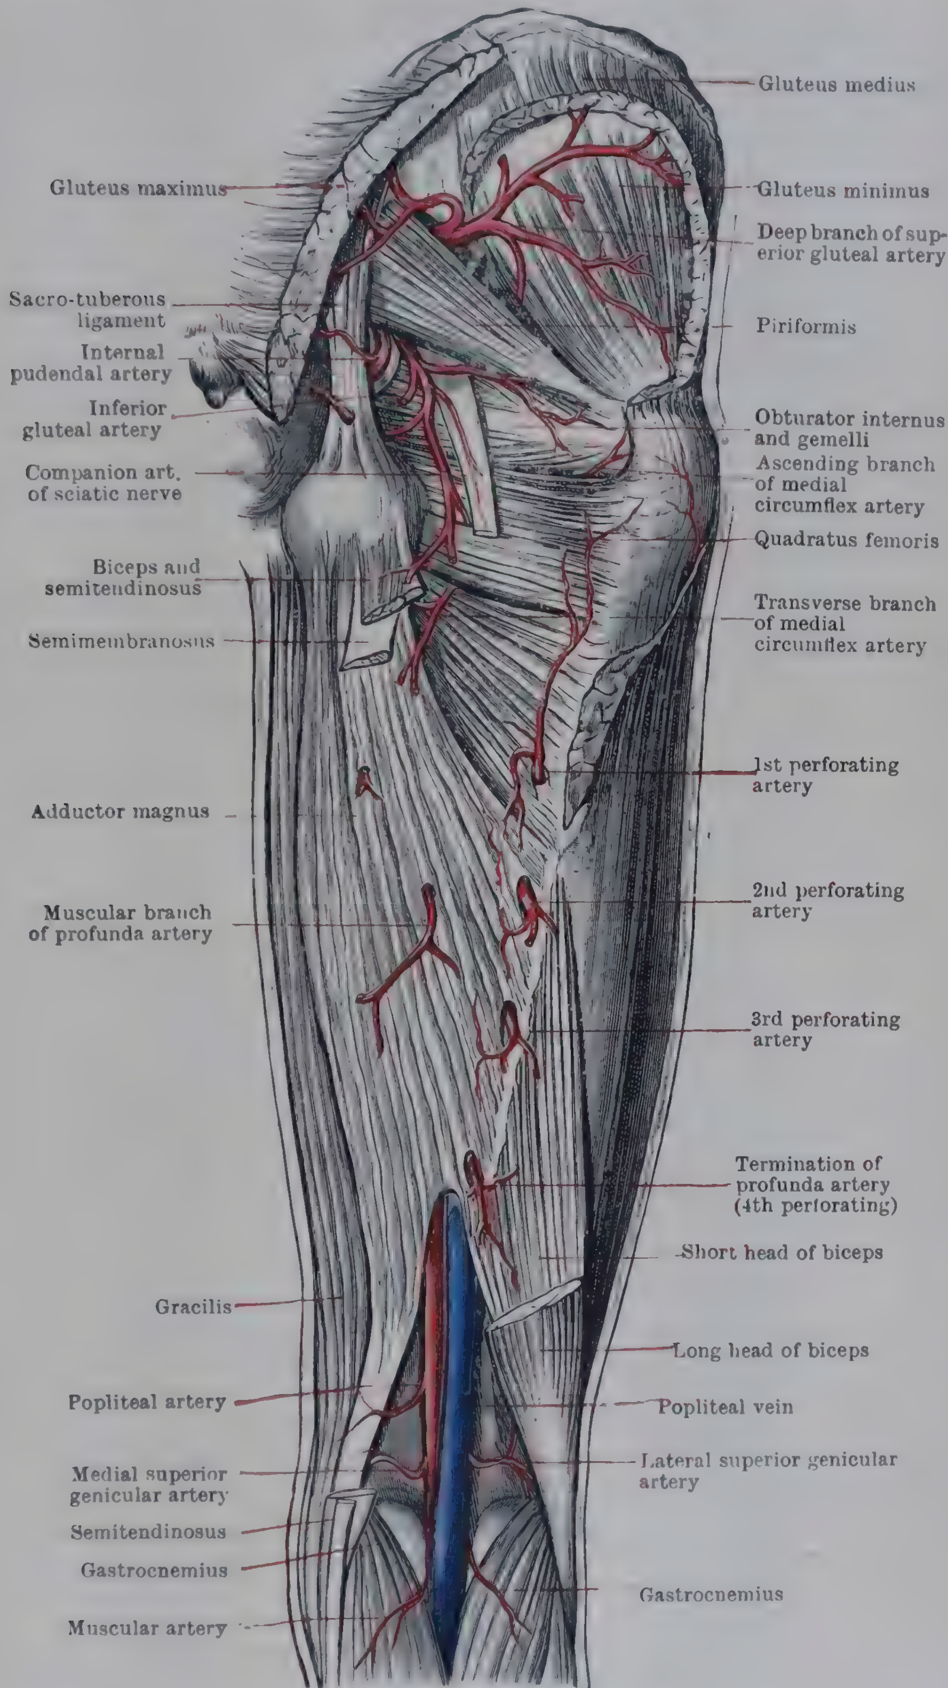

FIG. 1103.—ARTERIES OF GLUTEAL REGION AND BACK OF THIGH AND KNEE.

branch of the obturator artery, and it sends branches into the acetabular fossa and along the ligament of the head of the femur to supply the bone. **Muscular branches** are given off to the neighbouring muscles. The largest of those branches usually arises immediately before the termination of the artery; it runs downwards, on the anterior surface of the adductor magnus, and anastomoses with the muscular branches of the profunda artery. The **ascending branch** passes

upwards and laterally, between the obturator externus and the quadratus femoris to the trochanteric fossa of the femur, where it anastomoses with branches of the superior and inferior gluteal arteries. The **transverse branch** runs backwards to the hamstring muscles—usually between the lower border of the quadratus femoris and the upper border of the adductor magnus, but it may pierce the upper part of the adductor magnus. It anastomoses, in front of the distal part of the gluteus maximus, with the inferior gluteal and first perforating arteries and with the transverse branch of the lateral circumflex, and, in the substance of the hamstrings, with the muscular branches of the profunda.

The **perforating arteries** (Fig. 1103), including the terminal branch of the profunda, are usually described as four in number; but they are often irregular. They curve backwards and laterally, around the back of the femur, lying close to the bone and anterior to the well-marked tendinous arches which interrupt the continuity of muscular attachments; their terminal branches enter the vastus lateralis and anastomose in its substance with one another, with the descending branch of the lateral circumflex, with the descending genicular artery, and with the lateral superior genicular branch of the popliteal.

The **first perforating artery** pierces the insertions of the adductors brevis and magnus. Its branches anastomose, anterior to the gluteus maximus, with the inferior gluteal, and with the transverse branches of the medial and lateral circumflex arteries, forming what is known as the *crucial anastomosis of the thigh.*

The **second perforating artery** pierces the adductors brevis and magnus, and then passes between the gluteus maximus and the short head of the biceps femoris into the vastus lateralis. It anastomoses with its proximal and distal fellows, and with the medial circumflex and the proximal muscular branches of the popliteal artery.

The **third** and **fourth perforating arteries** pass through the adductor magnus and the short head of the biceps femoris into the vastus lateralis. Their anastomoses are similar to those of the second perforating.

A nutrient branch to the femur is given off from either the second or third perforating artery, usually the former; an additional nutrient branch may be supplied also by the first or fourth perforating arteries.

The **descending genicular artery** arises in the distal part of the subsartorial canal, near the termination of the femoral artery, and divides almost immediately into a superficial (saphenous) and a deep (musculo-articular) branch; indeed, very frequently the two branches arise separately from the femoral trunk.

The **saphenous branch** passes through the distal end of the subsartorial canal with the saphenous nerve, and appears superficially, on the medial side of the knee, between the gracilis and the sartorius. It gives twigs to the skin of the proximal and medial part of the leg, and it anastomoses with the medial inferior genicular artery. The **musculo-articular branch** runs towards the knee, in the substance of the vastus medialis, along the anterior aspect of the tendon of the adductor magnus. It anastomoses with the medial superior genicular artery; and it sends branches laterally, one on the surface of the femur and another along the proximal border of the patella, to anastomose with the descending branch of the lateral circumflex, the fourth perforating artery, the lateral superior genicular, and the anterior tibial recurrent (Pl. LXXXIV, p.1313).

Variations.—The **femoral artery** is small and ends in the profunda and circumflex branches, when the inferior gluteal artery forms the principal vessel of the lower limb. The **profunda** branch, which arises usually from the lateral side of the femoral trunk, about 1½ in. (35 mm.) distal to the inguinal ligament, may begin at a more proximal or a more distal level, and from the back or the medial side of the femoral trunk. In rare cases when the profunda arises at a more proximal level than usual it may cross anterior to the femoral vein, above the entrance of the long saphenous vein, after which it passes downwards and laterally behind the femoral vessels (Johnston, 1912). Absence of the profunda has been noted, and in those cases the branches usually given off by it spring directly from the femoral artery.

The femoral artery may be double for a portion of its extent, or it may be joined by a vas aberrans given off from the external iliac artery. In addition to its ordinary branches, it may furnish one or both of the circumflex arteries of the thigh, and sometimes it gives off, near the origin of the profunda, a *long saphenous artery*, such as exists normally in many mammals. This vessel runs downwards through the femoral triangle and the subsartorial canal, and accompanies the saphenous nerve to the medial side of the foot.

The deep circumflex iliac, the obturator, and the inferior epigastric arteries are occasionally given off from the femoral.

POPLITEAL ARTERY

The **popliteal artery** is the direct continuation of the femoral. It begins at the medial and proximal side of the popliteal fossa, under cover of the semimem-

branosus, and ends at the distal border of the popliteus muscle, and on a level with the distal part of the tubercle of the tibia, by dividing into the anterior and the posterior tibial arteries. The artery passes with a slight lateral obliquity from its origin to the interspace between the condyles of the femur, and then descends vertically between them (Pl. LXXXIII, p. 1312).

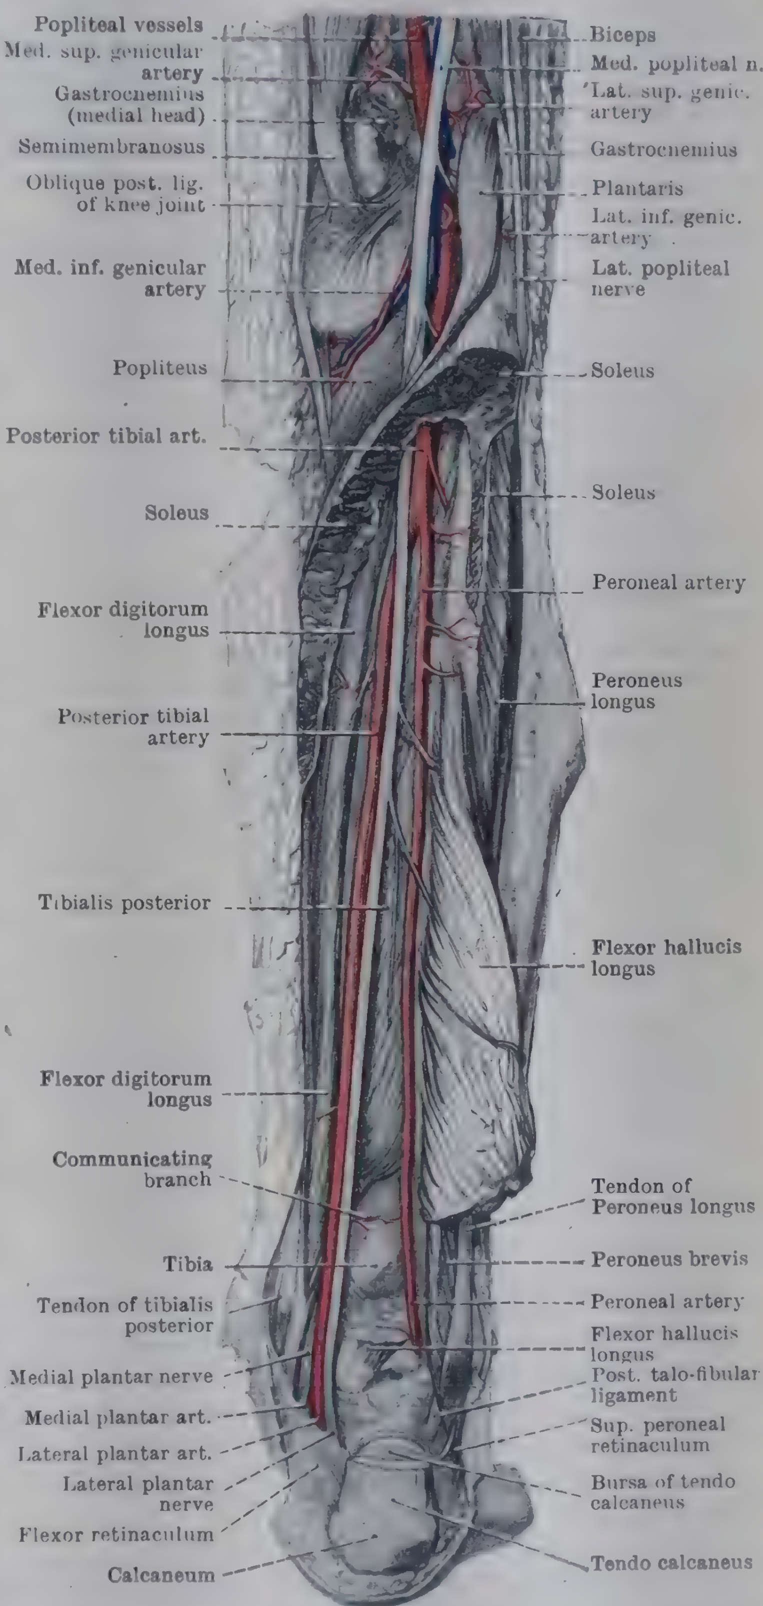

Fig. 1104.—Popliteal and Posterior Tibial Arteries and their Branches.

Relations. — *Anterior.* — It is closely related, from above downwards, to the popliteal surface of the femur, the posterior part of the capsule of the knee joint, and the fascia covering the popliteus.

Posterior. — The artery is overlapped behind, in the proximal part of its extent, by the lateral border of the semimembranosus; it is crossed, about its middle, by the popliteal vein and the medial popliteal nerve, the vein intervening between the artery and the nerve; whilst, in the distal part of its extent, it is overlapped by the adjacent borders of the two heads of the gastrocnemius, and is crossed by the nerves to the soleus and popliteus and by the plantaris muscle.

Lateral.—On its lateral side it is in relation, proximally, with the medial popliteal nerve and the popliteal vein, then with the lateral condyle of the femur and the plantaris, and, distally, with the lateral head of the gastrocnemius.

Medial.—On the medial side it is in relation, proximally, with the semimembranosus, then with the medial condyle of the femur, and distally with the medial popliteal nerve, the popliteal vein, and the medial head of the gastrocnemius. Popliteal lymph-glands are arranged irregularly around the artery.

Branches.—Muscular branches are given off in two sets, proximal and distal.

The *proximal muscular branches* are distributed to the distal parts of the hamstring muscles, in which they anastomose with branches of the profunda artery.

The distal muscular or *sural arteries* enter the proximal parts of the muscles of the calf, and they have little or no anastomoses with other arteries. Each head of the gastrocnemius receives a single large branch which enters at a definite neuro-vascular hilum: these branches are virtually end-arteries (Pl. LXXXIV, p. 1313) and damage to one of them may result in necrosis of the entire head it supplies.

There are five **genicular arteries**—namely, lateral superior and inferior, medial superior and inferior, and a middle.

The **lateral superior genicular artery** passes laterally, proximal to the lateral condyle, in front of the biceps tendon, into the vastus lateralis, where it anastomoses with the descending genicular artery, the descending branch of the lateral circumflex, and the fourth perforating artery; it also sends branches distally to anastomose with the lateral inferior genicular and with the anterior recurrent branch of the anterior tibial.

The **medial superior genicular artery** passes medially, proximal to the medial condyle, anterior to the tendon of the adductor magnus, into the vastus medialis. It anastomoses with branches of the descending genicular artery and of the lateral superior genicular artery.

The **lateral inferior genicular artery** runs laterally, across the popliteus muscle and anterior to the plantaris and the lateral head of the gastrocnemius; then, turning forwards, it is joined by an articular branch of the lateral popliteal nerve, and passes deep to the lateral ligament of the knee. It ends by anastomosing with its fellow of the opposite side, with the lateral superior genicular and the anterior recurrent branch of the anterior tibial artery.

The **medial inferior genicular artery** passes medially, distal to the medial condyle of the tibia, along the proximal border of the popliteus and in front of the medial head of the gastrocnemius, to the medial side of the knee, where it turns forwards, between the bone and the medial ligament of the knee, and ends anteriorly by anastomosing with its fellow of the opposite side, with the anterior recurrent branch of the anterior tibial artery, and with the medial superior genicular artery.

The **middle genicular artery** passes directly forwards from the front of the popliteal artery, pierces the central part of the posterior surface of the capsule of the knee joint, and enters the intercondylar notch. It supplies branches to the cruciate ligaments and to the synovial membrane, and is accompanied by an articular branch of the medial popliteal nerve, and sometimes by the articular branch of the obturator nerve.

Cutaneous branches are distributed to the skin over the popliteal fossa. One of these—the *superficial sural artery*—runs along the middle of the back of the calf with the short saphenous vein (Pl. LXXXIV, p. 1313).

Variations.—The **popliteal artery** may exceptionally form the direct continuation of the inferior gluteal artery. It sometimes divides at a more proximal or more distal level than usual, and the division may be into either two or three branches; if three terminal branches are present, they are the anterior and posterior tibial and the peroneal arteries, and if only two, either the anterior and posterior tibial, or the anterior tibial and the peroneal arteries.

Occasionally the artery is double for a short portion of its course, and it has been found to cross, first posterior to the medial head of the gastrocnemius to the medial side of the knee, and then anterior to the medial head of the gastrocnemius to regain the popliteal fossa. The number of its branches may be reduced, or they may be increased by the addition of a vas aberrans which connects it with the posterior tibial artery. Its superficial sural branch may enlarge to form a well-marked *short saphenous artery*.

Posterior Tibial Artery

The **posterior tibial artery**, the larger of the two terminal branches of the popliteal, begins at the distal border of the popliteus and ends midway between the tip of the medial malleolus and the most prominent part of the heel, at the distal border of the flexor retinaculum. It ends by dividing into the medial and the lateral plantar arteries, which pass onwards to the sole of the foot (Fig. 1105, Pl. LXXXVI, p. 1383).

The posterior tibial artery runs downwards and medially, in the posterior part of the leg, between the superficial and deep layers of muscles and covered, posteriorly, by the intermuscular fascia which intervenes between them.

Relations.—*Anterior.*—It is in contact, proximo-distally, with the tibialis posterior, the flexor digitorum longus, the posterior surface of the tibia, and the posterior ligament of the ankle joint.

Posterior.—The artery is crossed by the posterior tibial nerve about an inch distal to its origin. Elsewhere it is in contact with the intermuscular fascia which binds down the deep layer of muscles. More superficially the proximal half of the artery is covered by the fleshy parts of the soleus and gastrocnemius muscles; the distal half of the artery is much nearer the surface, and is covered only by skin and fasciæ. At its termination it lies deep to the flexor retinaculum.

Lateral and Medial.—The posterior tibial nerve lies at first on the medial side of the vessel, then crosses posterior to it, and is continued downwards on its lateral side. In the most distal part of its course the artery is separated from the medial malleolus by the tendons of the tibialis posterior and the flexor digitorum longus, whilst the tendon of the flexor hallucis longus lies lateral to it. It is accompanied by two venæ comitantes.

Branches.—The posterior tibial gives off numerous branches, the largest of which—the peroneal—is one of the chief arteries of the leg. The branches include :—

Large **muscular branches** to the adjacent muscles, including the soleus which is supplied also by a branch from the popliteal artery

Cutaneous branches are distributed to the skin of the medial and posterior part of the leg.

A **circumflex fibular branch** passes laterally round the neck of the fibula through the fibres of the soleus, and anastomoses with the lateral inferior genicular artery. Occasionally it springs from the lower end of the popliteal artery, or from the anterior tibial.

The **nutrient artery to the tibia**, the largest of the nutrient group of arteries to long bones, springs from the proximal part of the posterior tibial, pierces the tibialis posterior and enters the nutrient foramen on the posterior surface of the bone. Before it enters the tibia the nutrient artery gives small muscular branches.

The **communicating branch** unites the posterior tibial to the peroneal artery about an inch above the inferior tibio-fibular joint. It passes between the shaft of the tibia and the flexor hallucis longus.

Calcanean branches arise from the artery just before it divides. They pierce the flexor retinaculum, supply the medial side of the heel, and anastomose with the peroneal and the malleolar arteries.

A **malleolar branch** is distributed to the medial surface of the medial malleolus, anastomosing with malleolar branches of the anterior tibial and peroneal arteries.

The **peroneal artery** (Fig. 1104) is the largest branch of the posterior tibial (Pl. LXXXIV, p. 1313). Arising about 1 inch (25 mm.) below the distal border of the popliteus, it curves laterally across the proximal part of the tibialis posterior to the medial crest of the fibula, along which it passes to the distal part of the interosseous space. About 1 inch proximal to the ankle joint it gives off a perforating branch and then passes, behind the inferior tibio-fibular joint and lateral malleolus, to the lateral side of the heel and the foot. It supplies the ankle, the inferior tibio-fibular and talo-calcanean joints, and anastomoses with a calcanean branch of the lateral plantar artery, and with the tarsal and arcuate branches of the dorsalis pedis.

As the peroneal artery passes laterally from its origin it lies behind the tibialis posterior, and is covered posteriorly by the deep intermuscular fascia and by the soleus. As it descends along the medial crest of the fibula it lies in a fibrous canal between the tibialis posterior in front and the flexor hallucis longus behind. It is accompanied by two venæ comitantes which anastomose around it.

Branches.—**Muscular branches** are distributed to the adjacent muscles. Some pass through the interosseous membrane and help to supply the anterior muscles of the leg.

The **nutrient artery to the fibula** enters the nutrient foramen of that bone.

The **communicating branch** passes across the back of the tibia, about an inch above the inferior tibio-fibular joint, to anastomose with the posterior tibial artery.

The **perforating branch** passes forwards at the junction of the distal border of the interosseous membrane and the interosseous tibio-fibular ligament, and runs, in front of the ankle joint, to the dorsum of the foot, where it anastomoses with the lateral malleolar branch of the anterior tibial artery and with the tarsal branch of the dorsalis pedis ; it also supplies branches to the inferior tibio-fibular joint, to the ankle joint, and to the peroneus tertius.

A **malleolar branch** and **calcanean branches** take part in the anastomosis on the lateral side of the ankle and heel.

Variations.—The **posterior tibial artery** may be small or altogether absent, its place being taken by branches of the peroneal artery ; again, it may be longer or shorter than usual, in conformity with the more proximal or more distal division of the popliteal trunk. The peroneal artery is large, if either the anterior or the posterior tibial artery is small. The perforating branch of the peroneal is almost invariably large when the anterior tibial artery is small ; in some cases it replaces the whole of the dorsalis pedis continuation of the latter vessel ; in others, however, only the tarsal and arcuate branches are so replaced. The peroneal sometimes arises from a stem common to it and the anterior tibial artery.

Plantar Arteries

The **medial and lateral plantar arteries** are the terminal branches of the posterior tibial artery. They arise, under cover of the flexor retinaculum, midway between

the tip of the medial malleolus and the most prominent part of the medial side of the heel (Figs. 1104, 1105, Pl. LXXXVI, p. 1383.)

The **medial plantar artery** is the smaller of the two. It passes forwards, on the medial side of the medial plantar nerve, along the medial side of the foot in the interval between the abductor hallucis and the flexor digitorum brevis, to the head of the first metatarsal bone, where it ends by uniting with the digital branch of the first plantar metatarsal artery which is distributed to the medial side of the big toe. In its course forwards it gives off a branch which ramifies on the superficial surface of the abductor hallucis, branches to the adjacent muscles and articulations, and branches to the skin; it also gives three *digital branches* which anastomose, at the roots of the medial three interdigital clefts, with the medial plantar metatarsal arteries. Some of the cutaneous branches of the medial plantar artery anastomose, round the medial border of the foot, with cutaneous branches of the dorsalis pedis artery.

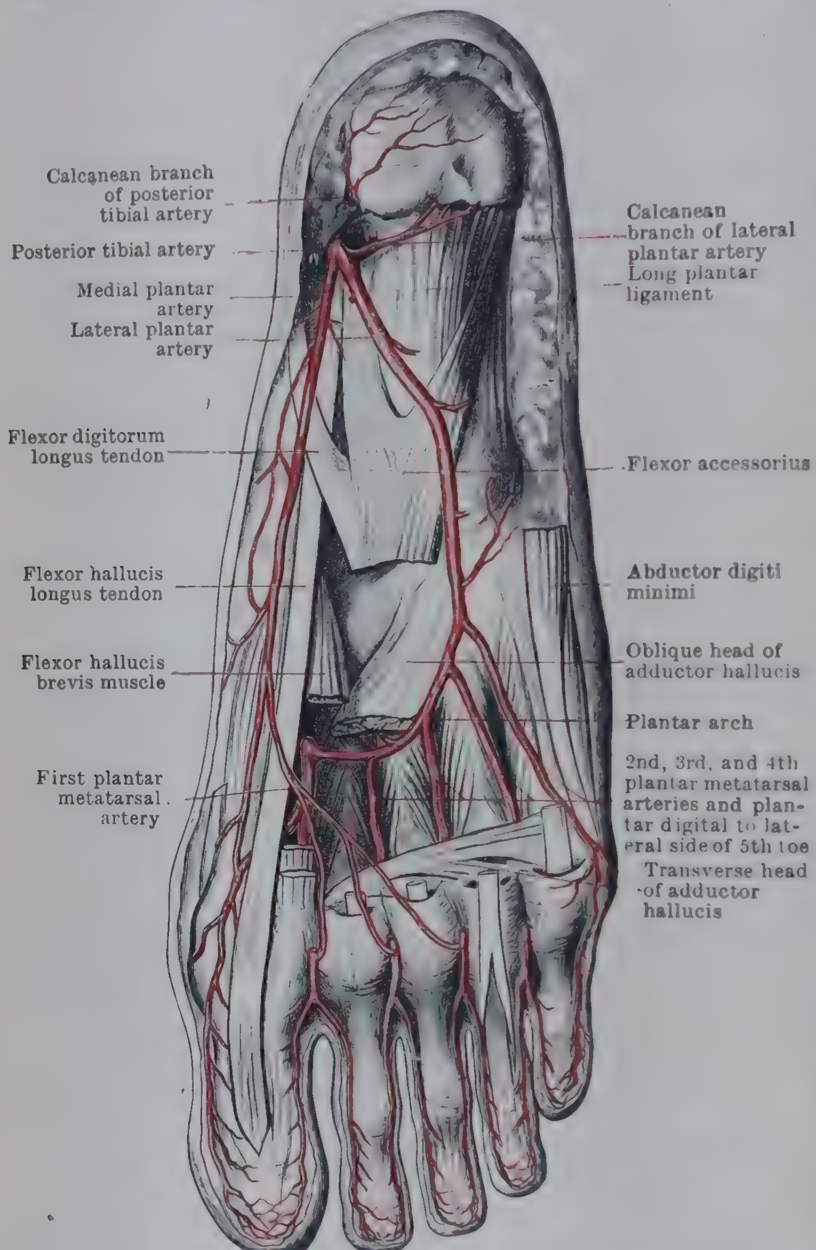

Fig. 1105.—Plantar Arteries and their Branches.

The **lateral plantar artery** is the larger of the two terminal branches of the posterior tibial artery. It runs obliquely forwards across the sole on the lateral side of the lateral plantar nerve, first between the flexor digitorum brevis superficially and the flexor accessorius deeply, and then, in the interval between the flexor digitorum brevis and the abductor digiti minimi, to the medial side of the base of the fifth metatarsal bone. There it turns abruptly medially and, gaining a deeper plane, passes across the metatarsal bones, near their bases, and the origins of the interossei, and above the oblique head of the adductor hallucis, to the lateral side of the first metatarsal bone, where it ends by anastomosing with the dorsalis pedis artery. The last part of the artery is convex forwards and forms the *plantar arch*, which is completed by its junction with the dorsalis pedis.

Branches.—Between its origin and the base of the fifth metatarsal the lateral plantar artery gives off: A **calcanean branch**, which is distributed to the skin and the subcutaneous tissue of the heel; **muscular branches** to the adjacent muscles; and **cutaneous branches** to the skin of the lateral side of the foot.

Between the base of the fifth metatarsal bone and the first interosseous space it forms the **plantar arch**, and gives off: Four **plantar metatarsal arteries**; three **perforating**

branches to the dorsal metatarsal arteries; and twigs to the tarsal joints and the muscles in the vicinity.

The **first plantar metatarsal artery** is a branch of the dorsalis pedis, arising from that artery as it joins the lateral plantar to complete the plantar arch (see p. 1328). The **second, third**, and **fourth plantar metatarsal branches** run forwards on the plantar surfaces of the interossei, the medial two lying dorsal to the oblique head of the adductor hallucis, and all three passing dorsal to the transverse head. At the bases of the interdigital clefts the second, third, and fourth plantar metatarsal arteries divide into **plantar digital arteries** which run along the plantar aspects of adjacent toes, and supply skin, joints, and the flexor tendons and sheaths. Opposite the distal phalanx of each toe the digital arteries of opposite sides of the toe anastomose together. The plantar digital artery *to the lateral border of the little toe* has an independent origin from the lateral plantar artery where it becomes the plantar arch. It crosses the plantar surface of the flexor digiti minimi brevis to reach the lateral border of the toe along which it runs.

The **perforating branches** are three in number; they pass through the lateral three intermetatarsal spaces, between the heads of the dorsal interosseous muscles, and join the corresponding dorsal metatarsal arteries. *Anterior perforating branches*, which also join the dorsal metatarsal arteries, are given off from two or three of the plantar metatarsal arteries just before they divide.

Variations.—The **medial plantar artery** is sometimes very small. It may be absent and its place is then taken by branches of the dorsalis pedis or lateral plantar arteries. The **lateral plantar artery also may** be small; or it may be absent, the plantar arch being then formed entirely by the dorsalis pedis.

Anterior Tibial Artery

The **anterior tibial artery**, the smaller of the two terminal divisions of the popliteal, begins opposite the distal border of the popliteus muscle, and ends in front of the ankle, where it is continued as the dorsal artery of the foot.

Course and Relations.—From its origin, at the back of the leg, the artery passes forwards, between the two slips of the proximal part of the tibialis posterior and through an aperture in the upper end of the interosseous membrane. It then runs downwards, resting, in the proximal two-thirds of its course, against the anterior surface of the interosseous membrane and, subsequently, on the distal part of the tibia and the anterior ligament of the ankle joint. In the proximal third of the anterior compartment of the leg it lies between the extensor digitorum longus laterally and the tibialis anterior medially; in the middle third it is between the extensor hallucis longus and the tibialis anterior; in the distal third the extensor hallucis longus crosses in front of the artery and reaches its medial side, and the most distal part of the vessel lies between the tendon of the extensor hallucis longus on the medial side and the most medial tendon of the extensor digitorum longus on the lateral side. Two venæ comitantes, with numerous intercommunications, lie along the sides of the artery.

The anterior tibial nerve is at first well to the lateral side of the artery, but it approaches the vessel and lies in front of its middle third; more distally the nerve is usually found on the lateral side again, and at the ankle it intervenes between the artery and the most medial tendon of the extensor digitorum longus.

The proximal part of the anterior tibial artery is deeply placed and the adjacent muscles overlap it. In the distal two-thirds of its extent it is easily accessible from the surface; and beyond being covered by the nerve and crossed by the tendon, as already described, is covered, in addition, only by skin, fascia, and the superior extensor retinaculum.

Branches.—Close to its origin the artery gives off a posterior recurrent and sometimes a circumflex fibular branch; after it reaches the front of the leg it gives off anterior recurrent, muscular, cutaneous, and medial and lateral anterior malleolar branches.

The **circumflex fibular branch** is a small vessel that may arise from the posterior tibial or the popliteal artery (see p. 1323).

The **posterior recurrent branch**, also small, and not always present, runs upwards, anterior to the popliteus muscle, to the back of the knee joint. It anastomoses with the

inferior genicular branches of the popliteal, and gives branches to the popliteus muscle and the superior tibio-fibular joint.

The **anterior recurrent branch** arises from the anterior tibial artery in front of the interosseous membrane. It runs upwards and medially, between the proximal part of the tibialis anterior and the lateral condyle of the tibia, accompanied by the recurrent articular branch of the lateral popliteal nerve, and, after supplying the tibialis anterior and the superior tibio-fibular joint, it pierces the deep fascia of the leg; it is connected with the anastomosis round the knee joint, formed by the genicular branches of the popliteal artery, the descending branch of the lateral circumflex artery, and the descending genicular artery.

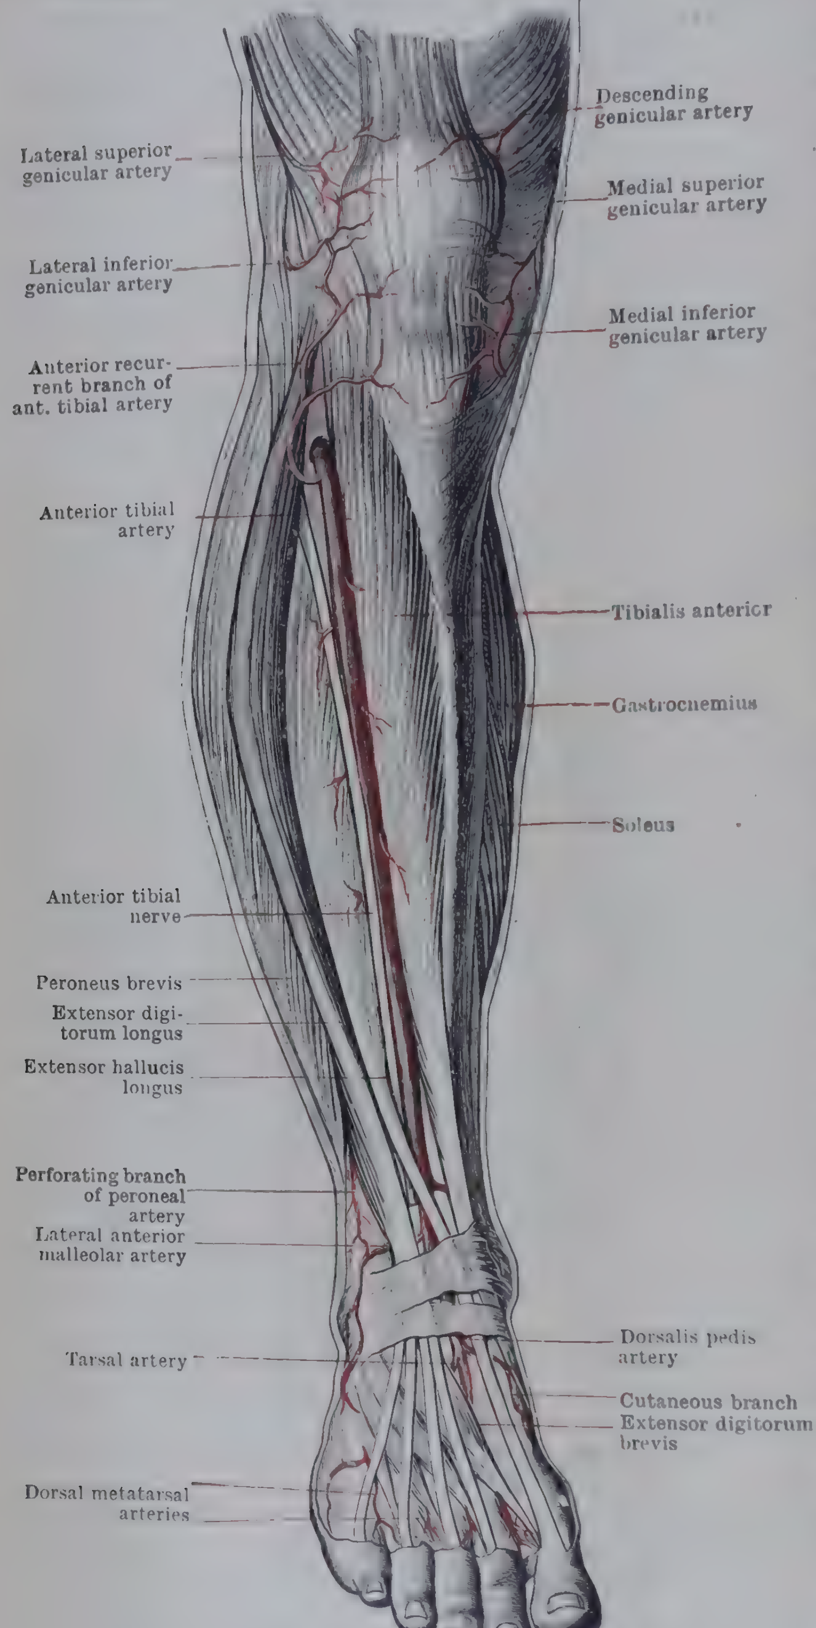

Fig. 1106.—Anterior Tibial Artery and its Branches.

The **muscular branches** are distributed to the adjacent muscles of the front and back of the leg.

The **cutaneous branches** supply the skin of the front of the leg.

The **medial anterior malleolar artery** arises from the lower part of the anterior tibial artery, and is smaller than its companion on the lateral side. It runs medially, posterior to the tibialis anterior tendon, ramifies over the medial malleolus, anastomosing with branches of the posterior tibial artery, and is distributed to the skin and to the ankle joint.

The **lateral anterior malleolar artery**, more constant and larger than the medial, passes laterally, posterior to the extensor digitorum longus and peroneus tertius, towards the lateral malleolus. It anastomoses with the perforating branch of the peroneal artery and with the tarsal artery, and supplies the ankle joint and the adjacent joints.

Dorsalis Pedis Artery.—The dorsal artery of the foot is the direct continuation of the anterior tibial; it begins on the front of the ankle joint and runs to the posterior end of the first interosseous space, where it gives off the first dorsal metatarsal artery and then passes into the sole of the foot between the two heads

of the first dorsal interosseous muscle to unite with the lateral plantar artery in the formation of the plantar arch (Pls. LXXXV, LXXXVI, p. 1382).

It is covered superficially by skin and fasciæ, including the inferior extensor retinaculum, and it is crossed, just before it reaches the first interosseous space, by the tendon of the extensor hallucis brevis. It rests upon the anterior ligament of the ankle, the head of the talus, the talo-navicular ligament, the navicular bone, the dorsal cuneo-navicular ligament and the intercuneiform ligament between the medial and intermediate cuneiform bones. On its lateral side is the medial terminal branch of the anterior tibial nerve, which intervenes between it and the extensor digitorum brevis and the most medial tendon of the extensor digitorum longus. On its medial side it is in relation with the tendon of the extensor hallucis longus. Two venæ comitantes, one on each side, accompany the artery.

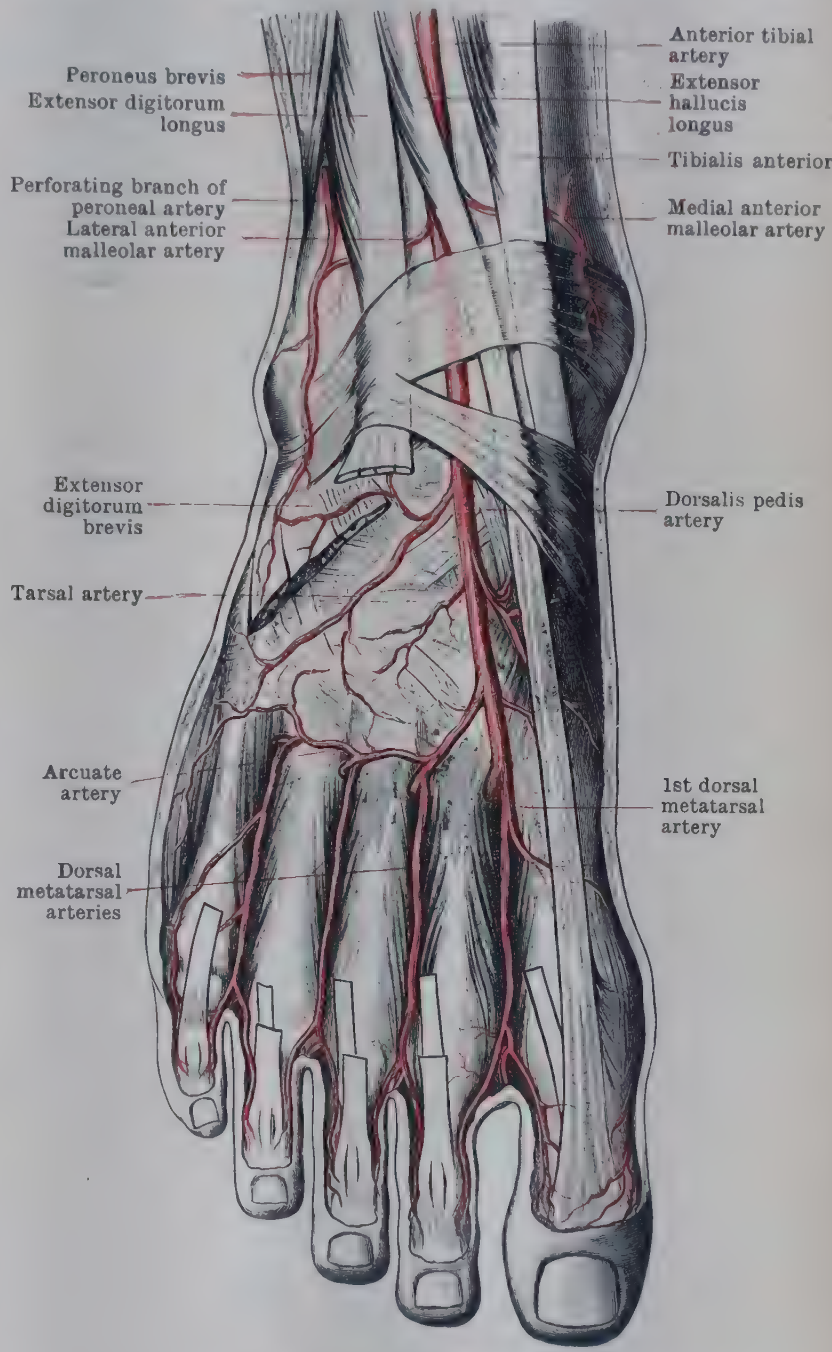

FIG. 1107.—DORSALIS PEDIS ARTERY AND ITS BRANCHES.

Branches.—Cutaneous branches are distributed to the skin on the dorsum and medial side of the foot; they anastomose with branches of the medial plantar artery.

The **tarsal artery** arises opposite the head of the talus; it runs laterally, deep to the extensor digitorum brevis, supplying that muscle and the tarsal joints, and it anastomoses with the perforating branch of the peroneal, the arcuate, and lateral plantar arteries, and with the lateral anterior malleolar artery. Other smaller tarsal branches are given off on both lateral and medial sides of the artery.

The **arcuate artery** arises opposite the medial cuneiform bone. It runs laterally, on the bases of the metatarsal bones, deep to the long and short extensor tendons, supplies the extensor digitorum brevis, and anastomoses with branches of the tarsal and lateral plantar arteries. It gives off three **dorsal metatarsal arteries**, second, third, and fourth, which run forwards on the interosseous muscles in the lateral three interosseous spaces to the clefts of the toes, where each divides into two *dorsal digital arteries* for the adjacent sides of the toes bounding the cleft to which it goes. The lateral side of the little toe receives a branch from the most lateral dorsal metatarsal artery. Each dorsal metatarsal artery gives off a *posterior perforating branch*, which passes through the posterior part of the intermetatarsal space, between the heads of the dorsal interosseous muscle, to anastomose with the plantar arch, and an *anterior perforating branch*, which passes through the anterior part of the space to anastomose with the corresponding plantar metatarsal artery.

The **first dorsal metatarsal artery** is continued forwards from the dorsalis pedis and runs on the dorsal surface of the first dorsal interosseous muscle. It ends by dividing into dorsal digital branches for the adjacent sides of the first and second toes. Before it divides it usually gives off a *dorsal digital branch* which passes, deep to the tendon of the extensor hallucis, to the medial side of the big toe.

As the dorsalis pedis unites with the lateral plantar artery to complete the plantar arch it gives off the **first plantar metatarsal artery,** which passes forwards, along the first intermetatarsal space, to the base of the first interdigital cleft, where it divides into *plantar digital arteries* for the adjacent sides of the first and second toes; before it divides it gives off a *plantar digital artery* to the medial side of the big toe.

Variations.—The **anterior tibial artery** may be absent, its place being taken by branches of the posterior tibial and peroneal arteries. It is longer than normal when the popliteal artery divides at a higher level than usual, and in those cases it may pass either posterior or anterior to the popliteus muscle. Occasionally the anterior tibial artery and its dorsalis pedis continuation are larger than normal, and the terminal part of the dorsalis pedis takes the place, more or less completely, of the lateral plantar artery.

VEINS

Veins commence in the networks of capillaries. They converge towards the heart, and unite with one another to form larger and still larger vessels, until, finally, seven large trunks are formed which open into the atria of the heart. Three of the trunks—the **superior vena cava**, the **inferior vena cava**, and the **coronary sinus**—belong to the *systemic circulation*; they contain venous blood, and open into the right atrium. The remaining four—the **pulmonary veins**—belong to the *pulmonary circulation*; they return oxygenated blood from the lungs, and open into the left atrium. They are described on p. 1243.

In addition to the systemic and pulmonary veins, there is also a third group of veins, constituting the **portal system**, in which blood from the abdominal part of the alimentary canal, and from the spleen and pancreas, is conveyed to the liver. The portal system is peculiar in that it both begins and ends in capillaries; and its communications with systemic veins are of clinical importance (p. 1367). From the sinusoidal capillaries in the liver the *hepatic veins* arise, and as those open into the inferior vena cava the blood of the portal system is finally poured into the general systemic circulation. The hepatic veins receive also the blood supplied to the liver by the hepatic arteries.

For a general survey of the anatomy and physiology of the venous system with full bibliography, consult the monograph by Franklin (1937).

SYSTEMIC VEINS

The **systemic veins** return blood to the right atrium of the heart through the superior vena cava, the inferior vena cava, and the coronary sinus. The two venæ cavæ receive blood from the head and neck, the body-wall, the limbs, and from the abdominal and pelvic viscera. The coronary sinus receives blood from the veins of the walls of the heart alone.

The veins in general are much more numerous than the arteries and of greater capacity; also they anastomose more freely and in many parts of the body they form *venous plexuses* composed of networks of thin-walled, intercommunicating vessels, *e.g.*, the pterygoid plexus (p. 1340), the pampiniform plexuses of the testis and ovary (p. 1356) and the venous plexuses of the pelvic organs (p. 1358). The presence of *valves* in the veins is of importance in the maintenance of the circulation; their structure has been described on p. 1223.

General Arrangement.—The veins of the head and neck, the body-wall and limbs, form two groups: (1) the superficial veins; (2) the deep veins.

The **superficial veins** lie in the superficial fascia; they begin in the capillaries of the skin and subcutaneous tissues, and are very numerous. They freely anastomose with one another, and they also communicate with the deep veins, in which they end after piercing the deep fascia. They may or may not accompany superficial arteries.

The **deep veins** accompany arteries, and are known as *venæ comitantes.* The large arteries have only one accompanying vein, but with the medium-sized and small arteries there are usually two venæ comitantes, which anastomose freely with each other by short transverse channels of communication.

Visceral veins usually accompany the arteries which supply viscera in the head, neck, thorax, and abdomen. As a rule there is only one vein with each visceral artery, and, with the exception of those which enter into the formation of the portal system, they end in the deep systemic veins.

The **venous sinuses** which are found inside the cranium (p. 1344) differ from ordinary veins in that they are formed by channels, between the two layers of the dura mater, lined by endothelium only and have no muscular coat.

CORONARY SINUS AND VEINS OF HEART

The **coronary sinus** (Fig. 1057) is a short, but relatively wide, venous trunk which receives the majority of the veins of the heart. It lies in the lower part of the atrio-ventricular groove, between the left atrium and the left ventricle, and it is covered superficially by some of the muscular fibres of the atrium.

It terminates in the lower and posterior part of the right atrium, between the orifice of the inferior vena cava on the right, and the right atrio-ventricular orifice in front; an imperfect valve, consisting of one cusp, called the **valve of the coronary sinus**, is situated at the right margin of the opening of the sinus into the atrium (Fig. 1060).

The apertures of the tributaries of the coronary sinus are not provided with valves, except those of the great and small cardiac veins, and their valves are often incompetent.

Tributaries.—The **great cardiac vein** (Fig. 1058) begins at the apex of the heart. It ascends in the anterior interventricular groove to the atrio-ventricular groove; it then turns to the left, passes round the left surface of the heart into the lower part of the atrio-ventricular sulcus, and ends in the left extremity of the coronary sinus. It receives tributaries from the walls of both ventricles and from the wall of the left atrium. It receives also the *left marginal vein* which ascends from the apex of the heart along its left border.

The **small cardiac vein** is very variable; as a rule it begins at the lower border of the heart near the apex and passes to the right to the atrio-ventricular groove, in which it turns to the left, and ends in the right extremity of the coronary sinus. It receives tributaries from the walls of the right atrium and the right ventricle.

The **middle cardiac vein** begins at the apex of the heart, and passes backwards in the inferior interventricular groove to end in the coronary sinus near its right extremity. It receives tributaries from the walls of both ventricles; some of those from the left ventricle, of which one may be large, end independently in the coronary sinus.

The **oblique vein of the left atrium** (Fig. 1057) is a small venous channel which descends obliquely on the posterior wall of the left atrium, and ends in the coronary sinus. It is of special interest inasmuch as it represents the left superior vena cava of some other mammals, and is developed from the left duct of Cuvier. It is continuous above with the *ligament of the left vena cava* (see Pericardium, p. 1242).

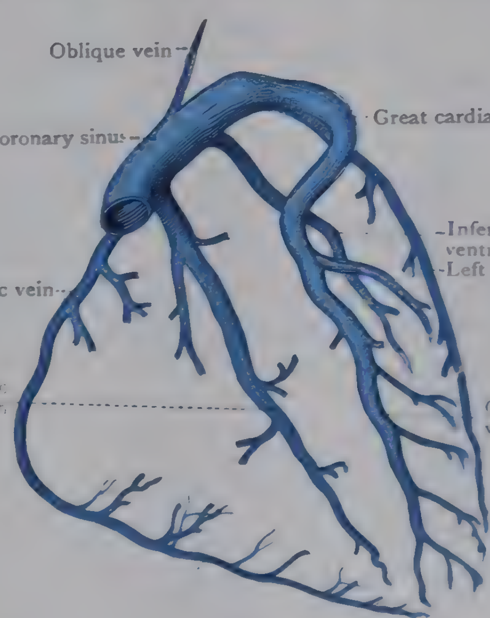

FIG. 1108.—DIAGRAM OF VEINS ON SURFACE OF HEART.

Veins of Heart which do not end in Coronary Sinus.—The **anterior cardiac veins** are two or three small vessels which ascend on the anterior wall of the right ventricle to the atrio-ventricular groove, across which they pass to end directly in

the right atrium. The **venæ cordis minimæ** are a number of small veins which begin in the substance of the walls of the heart and end directly in its cavities, principally in the atria.

SUPERIOR VENA CAVA

The **superior vena cava** (Figs. 1071 and 1109) returns the blood from the head and neck, the upper limbs, the thoracic wall, and a portion of the upper part of the wall of the abdomen. It is formed, at the lower border of the first right costal

cartilage, by the union of the two innominate veins, and it descends to the level of the third right costal cartilage, where it opens into the upper and posterior part of the right atrium. It is about 3 inches (75 mm.) long; in the lower half of its extent it is enclosed within the fibrous layer of the pericardium, and it is covered in front and on each side by the serous layer.

Relations.—It is overlapped *anteriorly* by the margins of the right lung and pleura and by the ascending aorta. The lung and pleura intervene between it and the second and third costal cartilages, the internal intercostal muscles in the first and second intercostal spaces, and the internal mammary vessels. It is in relation *posteriorly* with the right margin of the trachea, the vena azygos, which opens into it at right angles, the right bronchus, the right pulmonary artery, and the upper right pulmonary vein. On its *left side* are the ascending aorta and the origin of the innominate artery, whilst on the *right side* it is in close relation with the right pleura—the phrenic nerve and the pericardiaco-phrenic vessels intervening.

Tributaries.—In addition to the two innominate veins, by the union of which it is formed, the superior vena cava receives only one large tributary—the vena azygos; but several small pericardial and mediastinal veins open into it.

Abnormalities.—The **superior vena cava** may develop on the left side instead of on the right. That peculiarity is due to the persistence of the left common cardinal vein (duct of Cuvier) (p. 1381) instead of the right, and it is associated with absence of the coronary sinus, which is replaced by the lower part of the left superior vena cava. In one exceptional case the opening of the coronary sinus into the heart was obliterated, and the cardiac veins terminated in a trunk which passed upwards to the left innominate vein. That trunk was obviously formed by enlargement of the left duct of Cuvier and the lower part of the left anterior cardinal vein. Not very uncommonly, as the result of the persistence of both ducts of Cuvier, there are two superior venæ cavæ, the transverse anastomosis which usually forms the left innominate vein being small or absent. In such cases the left innominate vein descends in the left part of the superior mediastinum, crosses the aortic arch, is joined by the left superior intercostal vein, and becomes the left superior vena cava, which descends anterior to the root of the left lung and ends in the lower and back part of the right atrium. It receives the great cardiac vein and replaces the coronary sinus. This arrangement is normal in many mammals. Occasionally in Man the left superior vena cava terminates in the left atrium, and the coronary sinus, which represents a part of the sinus venosus, has been seen to have a similar ending; both these abnormal endings are the result of malposition of the atrial septum.

Vena Azygos and its Tributaries

The **vena azygos** is variable in its origin. It usually springs from the back of the inferior vena cava at the level of the renal veins (see *right lumbar azygos vein*, p. 1332), and enters the thorax through the aortic opening of the diaphragm, but may begin, between the diaphragm and the body of the twelfth thoracic vertebra, as the continuation of the right subcostal vein, or from the junction of that vein and the right ascending lumbar vein. It ascends through the posterior mediastinum to the upper part of the fifth thoracic vertebra. There it enters the superior mediastinum, arches forwards above the root of the right lung, and ends, opposite the second costal cartilage, by entering the back of the superior vena cava just before the vena cava pierces the pericardium. It frequently possesses imperfect valves.

Relations.—In Posterior Mediastinum.—*Posteriorly*, it rests upon the lower eight thoracic vertebræ, the intervertebral discs, and the anterior longitudinal ligament; and it crosses the posterior intercostal arteries of the right side. *Medial* to it are the thoracic duct and the descending aorta. *Lateral* to it there are the diaphragm, the greater splanchnic nerve, and the right pleura and lung. *Anteriorly*, it is related, in succession, to the diaphragm, the overlapping right pleura and lung, and the œsophagus. **In Superior Mediastinum.**—The root of the lung is *below*. The trachea and the right vagus are *medial*. The right pleura and lung are *lateral*. The vein grooves the lung deeply above its hilum, and therefore the pleura and lung are also *above*.

Tributaries.—(1) Right bronchial veins. (2) Œsophageal, pericardial and phrenic veins. (3) Mediastinal veins. (4) Right ascending lumbar vein. (5) Right subcostal vein. (6) Right posterior intercostal veins of the lower eight spaces. (7) Right superior intercostal vein formed

by the union of the posterior intercostal veins of the second and third spaces. (8) Inferior vena hemiazygos and superior vena hemiazygos, which convey much of the blood of the left side of the thoracic and abdominal walls to the vena azygos.

The **superior vena hemiazygos** begins, at the vertebral end of the fourth intercostal space of the left side, as the continuation of the fourth posterior intercostal vein. It runs downwards and forwards on the body of the fourth thoracic vertebra to reach the aorta, and descends close along the left side of the descending aorta as far as the eighth thoracic vertebra. There, it bends abruptly to the right and crosses behind the aorta and the thoracic duct to end in the vena azygos. Till it bends to the right it is under cover of the pleura, and crosses superficial to the upper left posterior intercostal arteries. Its **tributaries** are: (1) the left bronchial veins; (2) some mediastinal veins; and (3) the

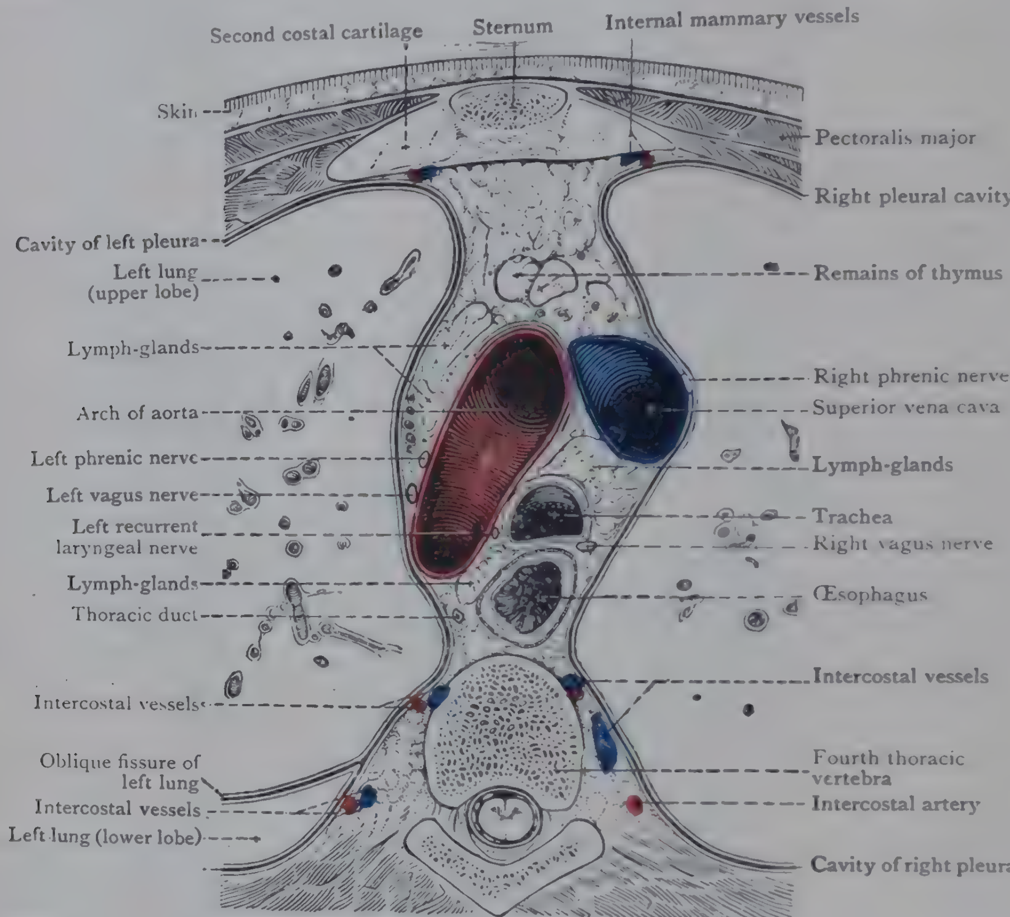

FIG. 1110.—TRANSVERSE SECTION OF THORAX OF YOUNG MAN THROUGH ARCH OF AORTA. The section is in the Plane B-B, FIG. 1109.

left posterior intercostal veins of the fourth, fifth, sixth, and seventh spaces, and, sometimes, the eighth. Its upper part is often connected with the left superior intercostal vein.

The **inferior vena hemiazygos** usually springs from the back of the left renal vein (see *left lumbar azygos vein*) and enters the thorax by piercing the left crus of the diaphragm; but it may begin, between the diaphragm and the left side of the body of the twelfth thoracic vertebra, as the continuation of the left subcostal vein or from the junction of that vein and the left ascending lumbar vein. It runs upwards on the vertebral bodies to the ninth vertebra, where it turns abruptly to the right, and crosses behind the aorta and the thoracic duct to end in the vena azygos. In its upward course it is under cover of first the diaphragm and then the left pleura, and it crosses superficial to the lower left posterior intercostal arteries; the greater splanchnic nerve descends close along its lateral side; and the descending aorta is on its medial side and overlaps it anteriorly. Its **tributaries** are: (1) some mediastinal veins; (2) the left ascending lumbar vein; (3) the left subcostal vein; (4) the left posterior intercostal veins of the eleventh, tenth, and ninth spaces, and, sometimes, the eighth.

The azygos and inferior hemiazygos veins are the continuations of the "lumbar azygos veins" (see p. 1383). These veins, when present, may receive the upper two (or more) of the lumbar veins, but in the adult they are often reduced to mere fibrous threads or

may not be found. The *right lumbar azygos vein* is the usual origin of the vena azygos and springs from the back of the inferior vena cava at the level of the renal veins. It passes upwards between the crura of the diaphragm (or pierces the right crus), and enters the thorax through the aortic opening (or to the right of that opening). The *left lumbar azygos vein* is the usual origin of the inferior vena hemiazygos; it arises from the back of the left renal vein, and pierces the left crus.

The **bronchial veins** do not quite correspond to the bronchial arteries, and they are not found on the walls of the smallest bronchi. On each side the tributaries run in front of or behind the bronchial tubes to reach the root of the lung, where they unite, as a rule, into two small trunks; those of the right side open into the vena azygos, and those of the left into the superior vena hemiazygos, or into the left superior intercostal vein. On both sides they receive tracheal and mediastinal veins. Some small bronchial veins, including most of those from the smaller tubes, open into the pulmonary veins.

The **œsophageal**, **pericardial**, and **phrenic veins** are small, irregular vessels that drain blood from the œsophagus, the back of the pericardium, and the posterior part of the diaphragm; and they end in the vena azygos.

The **mediastinal veins** are small, irregular vessels that drain blood from the fat and the lymph-glands of the posterior mediastinum. They end in the azygos vein, in the two hemiazygos veins, and in the bronchial veins.

The **ascending lumbar vein** (p. 1357) is a longitudinal, anastomosing channel that connects the lateral sacral, ilio-lumbar and lumbar veins. The upper two lumbar veins may end in it or may be merely connected by it. It ends in the vena azygos on the right side and the inferior vena hemiazygos on the left side.

The **intercostal veins** are in two sets—an anterior and a posterior. The **anterior intercostal veins** are described on p. 1334.

The **posterior intercostal veins** are eleven on each side. Each vein accompanies a posterior intercostal artery in an intercostal space, and where they lie in the costal groove the vein is above the artery. It is provided with valves, both near its termination and along its course, which prevent the blood from flowing towards the anterior wall of the chest. It receives small unnamed tributaries from the adjacent muscles and bones, and at the vertebral end of the intercostal space it receives a *posterior tributary*, which passes forwards between transverse processes from the back. That tributary is formed by the union of small veins from the muscles of the back, from the plexuses on the fronts and backs of the vertebræ, and from the plexuses inside the vertebral canal. It also receives a *lateral cutaneous tributary* corresponding to the branch of the artery.

The **first posterior intercostal vein** ascends across the front of the neck of the first rib usually on the lateral side of the superior intercostal artery, and arches forwards over the summit of the pleura to end in either the innominate or the vertebral vein. The second and third (and sometimes the fourth) unite to form the **superior intercostal vein.** The **right** superior intercostal vein inclines downwards and forwards to join the vena azygos where that vein begins to arch forwards. The **left** vein runs downwards and forwards to the aorta, and then forwards and upwards on the left side of the aortic arch, superficial to the left vagus and deep to the left phrenic nerve, and joins the lower border of the left innominate vein. The remaining posterior intercostal veins curve forwards over the bodies of the vertebræ; those of the right side end in the vena azygos; those of the left side end in the superior and inferior hemiazygos veins.

Variations.—The **vena azygos** may be formed on the left side; it then arches over the root of the left lung, and ends in the coronary sinus. This is the normal arrangement in some mammals, and it is due to the persistence of the cephalic end of the left posterior cardinal vein, the thoracic part of the left supracardinal vein, and the left duct of Cuvier.

Occasionally the azygos vein is the only vessel by which blood is returned to the heart from the lower limbs and the lower parts of the body walls. In such cases that portion of the inferior vena cava which usually extends from the right renal vein to the liver is absent and the azygos vein is the direct continuation of the inferior vena cava (see p. 1354).

The vena azygos is occasionally enclosed in a fold of pleura and sunk deeply into the right lung, cutting off an accessory lobe—the *lobe of the vena azygos* (p. 715 and Fig. 2, Pl. LXVIII, p. 721).

The **superior and inferior hemiazygos veins** may be absent. In such cases each left intercostal vein opens separately into the vena azygos. On the other hand, the hemiazygos veins may form a continuous trunk which may open by a transverse anastomosis into the azygos vein, or it may join the left innominate vein. When the hemiazygos veins form a single trunk, which receives the left posterior intercostal veins and opens into the left innominate vein, the condition is due to the persistence of the whole of the thoracic part of the azygos venous line, the upper part of the left posterior cardinal vein, and the lower part of the left anterior cardinal vein.

Innominate Veins

The **innominate veins** (Figs. 1069 and 1071) are two in number, right and left. They return blood from the head and neck, the upper limbs, the upper part of the posterior wall of the thorax, the anterior wall of the thorax, and the upper part of the anterior wall of the abdomen. Each innominate vein commences behind the medial end of the clavicle, and is formed by the union of the internal jugular and subclavian veins; the two innominate veins terminate by uniting together, at the lower border of the first costal cartilage of the right side, to form the superior vena cava. To reach that point the left vein has to pass from left to right behind the manubrium sterni, and it is therefore about three times as long as the right vein. The innominate veins do not possess valves.

The **right innominate vein** is a little more than 1 inch (25 mm.) in length. It descends almost vertically to the lower border of the first costal cartilage.

Relations.—In Root of Neck.—The innominate artery is *medial.* The clavicle and the sterno-hyoid and sterno-thyroid muscles are *anterior.* The cervical pleura is *posterior and lateral*; and the internal mammary artery and the phrenic nerve are between it and the pleura. **In Thorax.**—The innominate artery is *medial.* The trachea and the vagus nerve are *postero-medial.* The lung and pleura are *lateral*, but overlap it in front and behind; the phrenic nerve and pericardiaco-phrenic vessels, descending along its right side, are between it and the pleura.

Tributaries.—In addition to the veins by the union of which it is formed, the right innominate vein receives the right vertebral and internal mammary veins, the first right posterior intercostal vein, and sometimes the right inferior thyroid vein or a common trunk of the two veins. The *right lymphatic duct* (or separate lymph-trunks) also opens into it.

The **left innominate vein** passes from left to right, with a slight obliquity downwards, behind the upper half of the manubrium sterni, to the lower border of the first right costal cartilage. It is about 3 inches (60 to 75 mm.) long.

Relations.—In Root of Neck.—*Posteriorly*, it rests first upon the cervical pleura and the internal mammary artery, and next upon the fat surrounding the phrenic and vagus nerves, the cervical cardiac branches of the vagus and sympathetic, and the ascending part of the subclavian artery. *Anteriorly*, the sterno-thyroid and sterno-hyoid muscles separate it from the clavicle and the sterno-clavicular joint. **In Thorax.**—The left common carotid artery and the innominate artery are *posterior* to it, and separate it from the trachea. *Anterior* to it there are the manubrium, the origins of the sterno-hyoid and sterno-thyroid, the remains of the thymus, and, at its termination, the overlapping margin of the right pleura and lung. Its *lower* border is in relation with the arch of the aorta, and on its *upper* border it receives the inferior thyroid vein of one or both sides, or a common trunk.

Tributaries.—It receives the *thoracic duct*, which opens into it at the angle of junction of the internal jugular and subclavian veins and is its most important tributary. It also receives the vertebral, internal mammary, inferior thyroid, and superior intercostal veins of its own side, the first left posterior intercostal vein, and some pericardial, thymic, and mediastinal veins. Sometimes the right inferior thyroid vein joins it, but not uncommonly that vessel ends in the right innominate vein or in the commencement of the superior vena cava.

Internal Mammary Veins.—Each internal mammary artery is accompanied by venæ comitantes; they begin by the union of the venæ comitantes of the superior epigastric and musculo-phrenic arteries, between the sixth costal cartilage and the sterno-costalis; and about the level of the third costal cartilage they fuse into a single vessel which runs on the medial side of the artery and ends in the innominate vein of the same side.

The tributaries of the internal mammary veins are—(*a*) The **venæ comitantes** of the **superior epigastric** and **musculo-phrenic arteries**, which in their turn receive the veins that accompany the branches of those arteries. (*b*) Six **anterior perforating veins**, which accompany the corresponding arteries, one in each of the upper six intercostal spaces. (*c*) Twelve **anterior intercostal veins** from the upper six intercostal spaces, two veins lying in each space with the corresponding branches of the internal mammary artery. (*d*) Small and irregular **pleural, muscular, mediastinal, pericardial**, and **thymic veins**. (*e*) The **pericardiaco-phrenic veins.**

The internal mammary veins are provided with numerous valves which prevent the blood from flowing downwards.

Superior Epigastric Veins.—The venæ comitantes of the superior epigastric artery receive tributaries from the substance of the rectus abdominis, the sheath of the muscle, and the *subcutaneous veins* of the upper part of the abdominal wall; they pass, with the artery, between the sternal and costal origins of the diaphragm, and end in the internal mammary veins.

Musculo-Phrenic Veins.—The venæ comitantes of the musculo-phrenic artery begin in the abdomen, pass through the diaphragm with the musculo-phrenic artery, and end in the internal mammary veins. They receive as tributaries the **anterior intercostal veins** of the seventh, eighth, and ninth intercostal spaces, and venules from the substance of the diaphragm and walls of the abdomen.

The **vertebral veins** correspond only to the extra-cranial parts of the vertebral arteries. Each begins between the skull and the atlas by the union of offsets from the internal vertebral venous plexuses, as they issue from the vertebral canal. It passes across the posterior arch of the atlas, with the vertebral artery, to the foramen in the transverse process of the atlas. In the foramina in the cervical transverse processes, a plexus of venous channels surrounds the artery. At the lower part of the neck efferents from the plexus unite to form a single trunk which issues from the foramen in the transverse process of the sixth cervical vertebra, and descends, between the longus cervicis and scalenus anterior muscles, to end in the back of the upper part of the innominate vein: near its termination there is a unicuspid or bicuspid valve.

Relations.—In the first part of its course the vein lies in the suboccipital triangle. The second, plexiform portion surrounds the artery as it passes through the foramina in the transverse processes of the cervical vertebræ, anterior to the trunks of the cervical spinal nerves. The third part, in the root of the neck, is in front of the first part of the vertebral artery, and behind the internal jugular vein.

Tributaries.—In addition to the offsets from the internal vertebral plexuses by the union of which it is formed, each vertebral vein receives the following tributaries. Small veins join it from the muscles, ligaments, and bones of the deeper parts of the neck, and the lower and posterior part of the head. Tributaries from the internal vertebral plexuses pass out of the vertebral canal by the intervertebral foramina. The **anterior vertebral vein** is formed by the union of tributaries which issue from a venous plexus on the front of the bodies of the cervical vertebræ and the roots of their transverse processes; it lies alongside the ascending cervical artery, and ends in the vertebral vein immediately below the foramen in the sixth cervical transverse process. The **deep cervical vein** begins in the suboccipital triangle from a venous plexus with which the vertebral and occipital veins communicate. It descends behind the cervical transverse processes, in company with the deep cervical artery, turns forwards at the root of the neck, between the transverse processes of the sixth and seventh cervical vertebræ or between the latter and the neck of the first rib, and opens into the vertebral vein. It receives blood from the muscles, ligaments, and bones of the back of the neck. The **first posterior intercostal vein** sometimes opens into the vertebral vein.

Occasionally the venous plexus around the vertebral artery ends below in two terminal trunks—anterior and posterior—instead of one. In those cases the second terminal vessel lies behind the lower part of the vertebral artery, passes through the foramen in the transverse process of the seventh cervical vertebra (which otherwise transmits a small tributary), and turns forwards on the lateral side of the artery to join the anterior trunk, thus forming a common terminal vein which ends in the usual manner.

The **inferior thyroid veins** are formed by the union of tributaries which issue from the isthmus and the lobes of the thyroid gland. The two veins descend, along the front of the trachea, into the superior mediastinum, where the right inferior thyroid vein ends either in the right innominate vein or in the junction of the two innominate veins, and the left in the left innominate vein; or the two veins unite to form a single trunk, which ends usually in the left innominate vein but occasionally in the right, or in the angle between them. As they descend in the neck the inferior thyroid veins are connected by anastomosing channels, and sometimes the anastomoses are so numerous that a venous plexus is formed in front of the lower cervical portion of the trachea.

VEINS OF HEAD AND NECK

Internal Jugular Vein (Figs. 1069, 1071, 1076, 1087, and 1114).—Each internal jugular vein begins in the posterior compartment of the jugular foramen as the direct continuation of the sigmoid sinus, and it ends behind the medial part of the clavicle by uniting with the subclavian vein to form the innominate vein.

Its commencement is dilated and forms the *upper bulb* of the jugular vein. In the upper part of the neck it lies postero-lateral to the internal carotid artery and the last four cranial nerves. As it descends it accompanies first the internal and then the common carotid artery. It inclines forwards as it descends, and gradually passes from its original position, behind and to the lateral side of the internal carotid artery, until it lies more completely to the lateral side of the internal and common carotid arteries, and it overlaps the latter in front. That is more especially the case on the left side, for both internal jugular veins trend slightly towards the right as they descend; consequently, at the root of the neck, the right vein is separated from the common carotid artery by a small interval filled with areolar tissue in which the vagus nerve lies, whilst the left vein is more directly in front of the common carotid artery.

A dilatation, called the *lower bulb*, is present at the lower end of the vein; it is bounded, either above or below, by a valve of two or three semilunar cusps. Sometimes this bulb is bounded by valves both above and below.

Relations.—The vein lies anterior to the transverse processes of the cervical vertebræ, the rectus capitis lateralis, longus capitis, and scalenus anterior muscles, the ascending cervical artery, and the phrenic nerve; the suprascapular and the transverse cervical arteries intervene between it and the scalenus anterior. At the root of the neck the vein lies in front of the first part of the subclavian artery and the origins of the vertebral artery and the thyro-cervical trunk, and on the left side it is anterior to the terminal part of the thoracic duct.

On the antero-medial side of the internal jugular vein, immediately below the skull, are the internal carotid artery and the last four cranial nerves; in the rest of its extent it is in relation, medially, first with the internal and then with the common carotid artery, whilst to its medial side and behind, between it and the large arteries, lies the vagus nerve.

Each internal jugular vein is covered superficially, in the whole of its length, by the sterno-mastoid muscle; near its upper end it is crossed by the styloid process, the stylopharyngeus and stylo-hyoid muscles, and the posterior belly of the digastric, whilst in its lower half, the omo-hyoid, the sterno-hyoid, and the sterno-thyroid muscles are superficial to it, under cover of the sterno-mastoid. Just below the transverse process of the atlas, and under cover of the sterno-mastoid, the vein is crossed, on its lateral side, by the accessory nerve and by the occipital artery; about the middle of its course it is crossed by the descendens cervicalis nerve, and near its lower end by the anterior jugular vein; the latter vessel, however, is separated from it by the sterno-hyoid and sterno-thyroid muscles. Superficial to the vein are numerous deep cervical lymph-glands.

Variations.—The **internal jugular vein** may be either smaller or larger than usual. In either case, compensatory changes in size occur in the transverse and sigmoid sinuses and internal jugular vein of the opposite side, or in the external and anterior jugular veins of the same side.

Tributaries.—The **inferior petrosal sinus** joins it near its commencement, and the **vein of the cochlear canaliculus** is also a direct tributary if it does not join that sinus. Two or three **pharyngeal veins** drain the *pharyngeal venous plexus* on the wall of the pharynx. The common terminal trunk of the **lingual veins** returns part of the blood from the tongue, and may be joined by the **vena comitans n. hypoglossi** which accompanies the hypoglossal nerve and usually ends in the common facial vein. The **superior thyroid vein** accompanies the corresponding artery and its sterno-mastoid branch and receives the **superior laryngeal vein**. The **middle thyroid vein** passes backwards from the lobe of the thyroid gland and crosses the common carotid artery. The **occipital vein** occasionally terminates in the internal jugular vein, but most frequently it ends in the *suboccipital* plexus, which is drained by the vertebral and deep cervical veins (see p. 1335).

The **common facial vein** is formed by the union of the **anterior** and **posterior facial veins**. It crosses the external and internal carotid arteries, and ends in the internal

jugular vein. Just before it disappears beneath the sterno-mastoid, the common facial vein frequently gives off a large branch which descends along the anterior border of the sterno-mastoid to the suprasternal fossa, where it joins the anterior jugular vein.

The **anterior facial vein** (Fig. 1111) begins at the medial angle of the eye by the union of the supra-orbital and supratrochlear veins. It passes downwards and backwards in the face to the lower and anterior part of the masseter muscle, which it crosses, lying in the same plane as the facial artery, but following a much straighter course. After crossing the lower border of the mandible it passes across the submandibular triangle, superficial to the submandibular gland, and separate from the facial

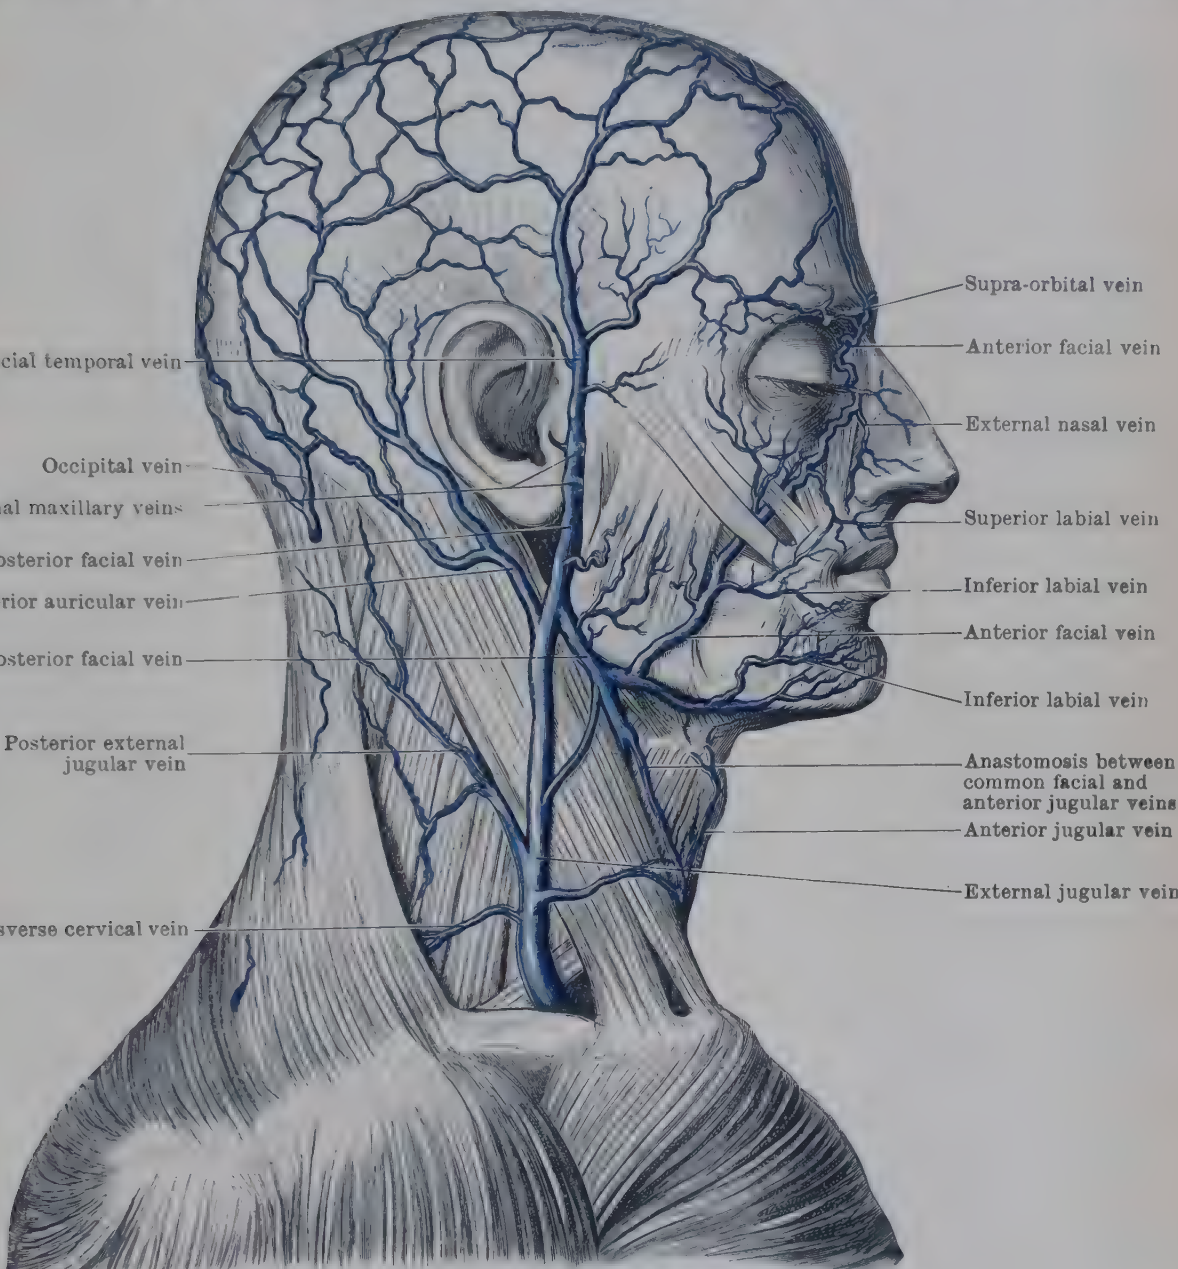

FIG. 1111.—SUPERFICIAL VEINS OF HEAD AND NECK.

artery, which there lies in a deeper plane. It ends, a short distance below the angle of the mandible, by uniting with the posterior facial vein to form the common facial vein.

The anterior facial vein receives tributaries corresponding with all the branches of the facial artery, except the ascending palatine and the tonsillar, which have no accompanying veins, the blood from the region which they supply being returned for the most part through the pharyngeal plexus. The anterior facial vein communicates with the cavernous sinus (p. 1347) through the superior ophthalmic vein, and also with the pterygoid plexus around the lateral pterygoid muscle by means of an anastomosing channel, called the **deep facial vein**, which passes backwards, between the masseter and buccinator muscles, into the infratemporal fossa.

The **posterior facial vein** is described on p. 1340.

Subclavian Vein.—The subclavian vein, of each side, is the direct continuation of the main vein of the upper limb, *i.e.*, the axillary vein; but through its

tributary, the external jugular vein, it receives blood both from the head and from the superficial parts of the neck.

From its commencement, at the outer border of the first rib, it runs medially, below and anterior to the corresponding artery, from which it is separated by the lower part of the scalenus anterior muscle, and it ends behind the medial end of the clavicle by joining the internal jugular vein to form the innominate vein. As it passes medially it forms a slight curve the convexity of which is directed upwards.

Each subclavian vein possesses a single bicuspid valve which is situated immediately to the lateral side of the opening of the external jugular vein.

Relations.—The subclavian vein is in relation *anteriorly* with the posterior layer of the clavi-pectoral fascia, which separates it from the subclavius muscle, and the nerve to the subclavius, and with the back of the medial part of the clavicle.

It is closely attached to the posterior surface of the clavi-pectoral fascia; consequently, it is expanded when the clavicle is moved forwards, an arrangement which constitutes a distinct danger when operations are being performed in the neighbourhood of the vein; for, in the event of the vessel being wounded, forward movement of the clavicle may cause air to be sucked into the vein, with fatal results.

Posterior to the vein, and on a higher plane, is the third part of the subclavian artery, but it is separated from the second part by the scalenus anterior. As soon as it reaches the medial border of the muscle it unites with the internal jugular vein.

The upper surface of the first rib is *below* the vein.

Tributaries.—Whilst the subclavian vein is the direct continuation of the axillary vein, and receives, therefore, the blood from the upper limb, it has, as a general rule, only one named tributary—the external jugular vein.

The **external jugular vein** (Fig. 1111) is formed on the superficial surface of the sterno-mastoid muscle, a little below and behind the angle of the mandible, by the union of the posterior auricular vein with a branch from the posterior facial vein. In many cases the branch from the posterior facial vein is so preponderantly large that it is more correct to describe the external jugular vein as its continuation. After its formation the external jugular vein descends across the sterno-mastoid to the supraclavicular part of the posterior triangle of the neck, where it pierces the deep fascia, crosses in front of the third part of the subclavian artery, and ends in the subclavian vein.

As it passes across the sterno-mastoid muscle it is covered by the superficial fascia and platysma muscle, and it lies in front of and parallel with the great auricular nerve; after crossing the anterior cutaneous nerve of the neck it reaches the posterior border of the sterno-mastoid, where it receives a tributary called the **posterior external jugular vein**, which drains the superficial tissues of the upper and back part of the neck, and runs downwards and forwards, across the roof of the upper part of the posterior triangle.

As the external jugular vein pierces the deep cervical fascia above the clavicle, its wall is closely attached to the margin of the opening through which it passes; and in the lowest part of the neck it is joined by the suprascapular, transverse cervical, and anterior jugular veins.

There are usually two valves in the lower part of the vein—one, which is generally incompetent, at or near its termination, and a second at a higher level.

Tributaries.—The **posterior auricular vein** (Fig. 1111) receives tributaries from the posterior parts of the parietal and temporal regions and from the medial surface of the auricle. It is considerably larger than the posterior auricular artery, which it accompanies only in the scalp. At the base of the scalp it leaves the artery and descends in the superficial fascia, over the upper part of the sterno-mastoid, to join the external jugular vein.

The **transverse cervical** and **suprascapular veins** accompany the corresponding arteries; not infrequently they open directly into the subclavian vein.

The **anterior jugular vein** begins in the submental region, and is formed by the union of small veins from the lower lip and chin. It descends, in the superficial fascia, at a variable distance from the median plane, perforates the outer layer of the deep fascia a short distance above the sternum, and enters the suprasternal space between

the first and second layers of the deep fascia. In the space it sometimes receives a communication from the common facial vein, and it is connected with its fellow of the opposite side by a transverse channel which lies in front of the trachea and is called the **jugular arch**. It then turns laterally, between the sterno-mastoid superficially and the sterno-hyoid, sterno-thyroid, and scalenus anterior muscles deeply, and ends in the external jugular vein at the posterior border of the sterno-mastoid.

The external jugular vein sometimes receives the occipital vein or a communication from it. Occasionally the cephalic vein also opens into it.

Variations.—The **subclavian vein** may pass behind the scalenus anterior instead of in front of it; and it has been seen passing between the clavicle and the subclavius muscle.

The **external jugular vein** is sometimes absent, or it may be smaller than usual; in both cases either the anterior or the internal jugular vein is enlarged. When the external jugular vein is small it sometimes receives no communication from the posterior facial vein, but is merely the continuation of the posterior auricular vein. On the other hand, it may be enlarged, and receive the whole of the posterior facial vein.

The **anterior jugular vein** may be absent, or it may be unusually large, especially in the lower part of its extent, and after it has received the occasional tributary from the common facial vein.

Veins of Scalp

The veins which drain the blood from the superficial parts of the scalp are the supratrochlear, the supra-orbital, the superficial temporal, the posterior auricular, and the occipital. The blood from the deeper part of the scalp, in the region of the temporal fossa, on each side, passes into the deep temporal veins, which are tributaries of the pterygoid plexus.

The **supratrochlear** and **supra-orbital veins** receive blood from the anterior part of the scalp. They unite together, near the medial angle of the eye, to form the *anterior facial vein*; before the union is effected the supra-orbital vein sends a branch backwards, through the supra-orbital notch, into the orbit, where it ends in the ophthalmic vein, and as that branch passes through the notch it receives the frontal diploic vein (p. 1341).

The **superficial temporal vein** (Figs. 1076, 1111) is formed by tributaries which accompany the anterior and posterior terminal branches of the superficial temporal artery. They drain the lateral frontal region, the superficial part of the temporal region, and the anterior part of the parietal region of the scalp, and unite to form a single trunk which descends to the upper border of the zygomatic arch, immediately anterior to the auricle, where it ends in the posterior facial vein (see p. 1340).

The **posterior auricular vein** has been described already (see p. 1338).

The **occipital vein** (Figs. 1076, 1111) receives tributaries from the parietal and occipital regions. As a rule it pierces the occipital origin of the trapezius, and passes into the suboccipital triangle to end in a plexus of veins which is drained by the vertebral and deep cervical veins. It sometimes communicates with the external jugular vein, and occasionally an offset from it accompanies the corresponding artery and ends in the internal jugular vein.

It usually receives the mastoid emissary vein; one of its tributaries receives the parietal emissary vein, and occasionally an emissary vein from the *confluence of the sinuses* opens into it.

Veins of Orbit, Nose, and Infratemporal Region

The veins of those three regions are closely associated together; for although the orbital blood is returned, for the most part, to the cavernous sinus by the ophthalmic veins, these veins are closely connected with the pterygoid plexus, which lies in the infratemporal region.

Veins of Orbit.—The veins of the orbit correspond with the branches of the ophthalmic artery, except the supra-orbital and supratrochlear, and they gradually converge, as they pass backwards in the orbit, until they form two main trunks—a **superior ophthalmic vein** and an **inferior ophthalmic vein**. The two trunks terminate separately, or by a single stem, in the anterior end of the cavernous sinus, to which they pass between the two heads of the lateral rectus muscle

through the superior orbital fissure. The *central vein of the retina* joins the superior ophthalmic or runs direct to the cavernous sinus.

The superior ophthalmic vein communicates, at the supero-medial angle of the orbit, with the anterior facial vein through its supra-orbital tributary. The inferior ophthalmic vein communicates through the inferior orbital fissure with the pterygoid plexus.

Veins of Nose.—The veins of the walls of the nasal cavity end partly in the ethmoidal tributaries of the superior ophthalmic vein, partly in the septal tributaries of the superior labial and in the *external nasal veins*, all of which pass to the anterior facial vein; but the majority of the *internal nasal veins*, both from the septal and lateral walls, join together to form a **spheno-palatine vein**, which passes through the spheno-palatine foramen and the pterygo-palatine fossa to the pterygoid plexus.

Pterygoid Plexus and **Maxillary Vein**.—The **pterygoid plexus** of veins lies in the infratemporal fossa. It covers the lateral surface of the medial pterygoid muscle and surrounds the lateral pterygoid. It receives tributaries which correspond with and accompany the branches of the maxillary artery—namely, spheno-palatine, pharyngeal, veins of pterygoid canal, infra-orbital, posterior superior dental, greater palatine, buccal, two or three deep temporal, pterygoid, masseteric, and inferior dental veins, and the middle meningeal vein. It communicates above with the cavernous sinus by emissary veins through the foramen ovale and the emissary sphenoidal foramen when present; in front with the inferior ophthalmic vein through the inferior orbital fissure; and between the masseter and the buccinator with the anterior facial vein by the deep facial branch. It also communicates behind and medially, on the medial side of the medial pterygoid, with the pharyngeal plexus, and it drains behind into the maxillary vein.

The **maxillary vein** is a short vessel which accompanies the first part of the maxillary artery between the spheno-mandibular ligament and the neck of the mandible. Between the neck of the mandible and the antero-medial surface of the parotid gland it joins the upper part of the posterior facial vein. Occasionally the maxillary vein is double, and sometimes it is represented by several channels.

The **posterior facial vein** is formed, immediately above the zygomatic arch, by the union of the superficial temporal vein with the middle temporal vein, which accompanies the middle temporal artery (p. 1262). It crosses the zygomatic arch, dips deep to the upper part of the parotid gland, and, between the antero-medial surface of the gland and the posterior border of the mandible, receives the maxillary vein or veins. Then it descends, through the substance of the parotid and divides into two parts—anterior and posterior—which emerge from its lower end.

The **anterior division** passes forwards and downwards and unites with the anterior facial vein to form the common facial vein. The **posterior division** forms one of the two tributaries of origin of the **external** jugular vein.

Variations.—The **posterior facial vein** may end entirely in the common facial vein, or in the external or the internal jugular vein. It may be very small or absent.

VENOUS SINUSES AND VEINS OF CRANIUM AND CONTENTS

The venous channels met with in the cranial walls and cranial cavity are:—

(1) The diploic veins, which lie in the spongy tissue of the cranial bones.

(2) The meningeal veins, which accompany the meningeal arteries in the outer layer of the dura mater.

(3) The veins of the brain, which lie in the folds of pia mater and in the subarachnoid space.

(4) The cranial venous sinuses, which are channels situated between the outer and inner layers of the dura mater; they receive blood chiefly from the brain but also from the membranes and bones, and cerebro-spinal fluid is transmitted into them from the arachnoid villi and granulations.

Diploic and Meningeal Veins

Diploic veins are anastomosing spaces, lined with endothelium, in the diploë of the flat bones of the skull. The number of efferent vessels which emerge from the diploic spaces is not constant, but usually there are at least four on each side—a frontal, two parietal (anterior and posterior), and an occipital (Jefferson & Stewart, 1928).

The **frontal diploic vein** is one of the most constant; it arises in the anterior part of the frontal bone, passes through a small aperture in the upper margin of the supra-orbital notch, and ends in the supra-orbital vein.

The **anterior parietal diploic vein** drains the posterior part of the frontal bone

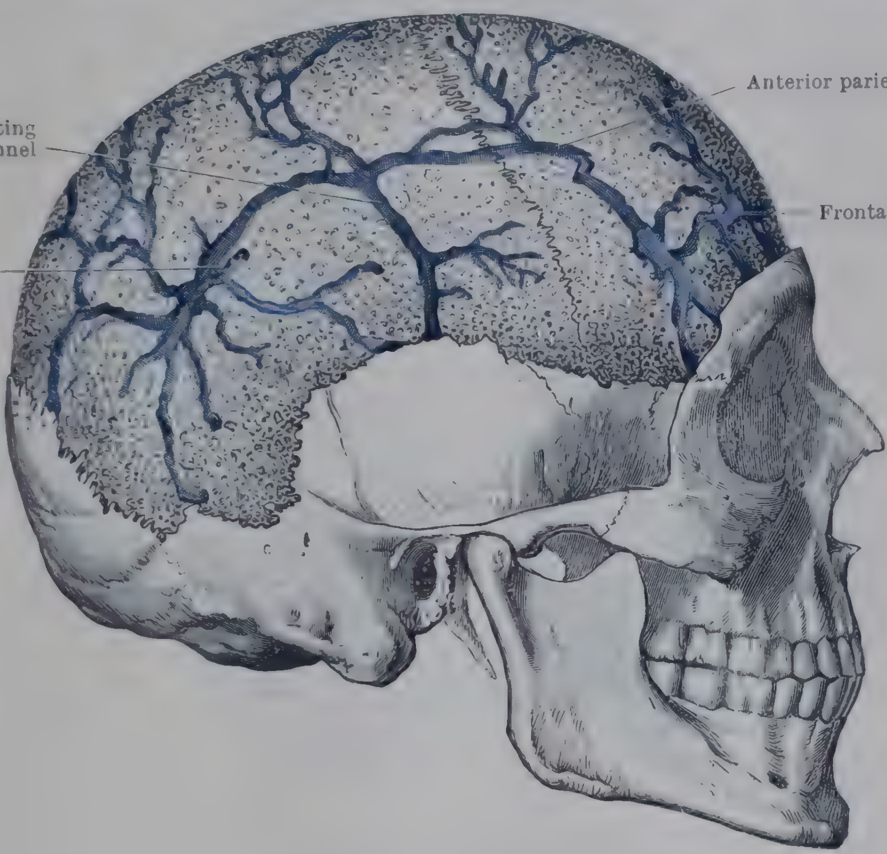

Fig. 1112.—Veins of the Diploë.

and the anterior part of the parietal bone; it emerges from the great wing of the sphenoid, and ends either in the spheno-parietal sinus or in the anterior deep temporal vein.

The **posterior parietal diploic vein** drains the posterior part of the parietal bone; it runs downwards through the posterior inferior angle of the parietal bone and ends either in the transverse sinus, or, more commonly, in the mastoid emissary vein.

The **occipital diploic vein** is usually the largest of the series; it drains the occipital bone, and ends either in the occipital emissary vein or internally in the transverse sinus.

The **meningeal veins** commence in two capillary plexuses—a deep and a superficial. The deep plexus is a wide-meshed network in the inner layer of the dura mater. Its efferent vessels pass to the superficial plexus. The superficial plexus lies in the outer layer of the dura mater. It consists of numerous vessels of uniform calibre which anastomose freely together and terminate in two sets of efferents; of those, one set ends in the cranial venous sinuses, and the other accompanies the meningeal arteries. The efferent meningeal veins are peculiar inasmuch as they do not alter much in size as they approach their terminations. They lie external to the arteries in the grooves in the bones, and are very liable to be torn when the bones are fractured (Wood Jones, 1912).

Veins of Brain

The veins of the brain include the veins of the cerebrum, mid-brain, cerebellum, pons, and medulla oblongata. They do not possess valves.

Veins of Cerebrum.—The **cerebral veins** are arranged in two groups—deep and superficial.

The deep veins issue from the interior of the brain. The superficial veins lie upon its surface in the pia mater and the subarachnoid space. The terminal trunks of both sets pierce the arachnoid membrane and the inner layer of the dura mater, and they open into the cranial venous sinuses.

The **deep cerebral veins** are the choroid veins, the thalamo-striate veins, the internal cerebral veins, the great cerebral vein, and the striate veins.

Each **choroid vein** is formed by the union of tributaries which issue from the choroid plexus in the central part and inferior horn of a lateral ventricle. It passes along the lateral border of the tela chorioidea of the third ventricle

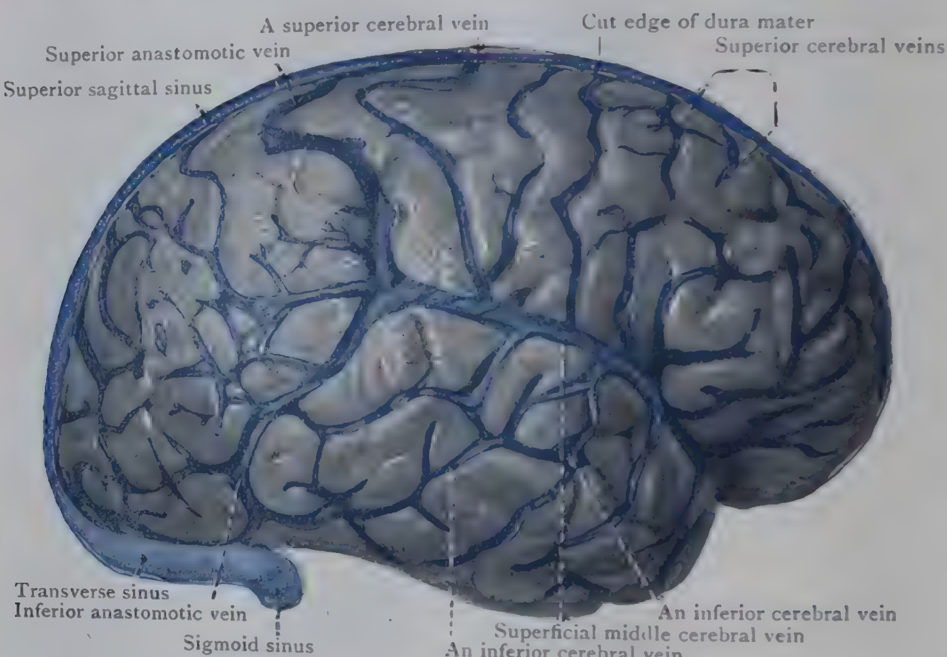

Fig. 1113.—Veins of Supero-Lateral Surface of Right Cerebral Hemisphere, seen through Arachnoid Mater.

to the interventricular foramen, where it receives efferents from the choroid plexus of the third ventricle, and unites with the thalamo-striate vein to form the internal cerebral vein.

The **thalamo-striate vein**, on each side, is formed by the union of tributaries which issue from the corpus striatum and from the thalamus. It runs forwards between the thalamus and the caudate nucleus, in a groove in the floor of the central part of the lateral ventricle, and, after receiving tributaries from the walls of the anterior horn of the ventricle and the septum lucidum, it ends at the apex of the tela chorioidea, where it joins the choroid vein to form the internal cerebral vein.

Each **internal cerebral vein** begins at the apex of the tela chorioidea, near the interventricular foramen, by the union of the thalamo-striate with the choroid vein. The two veins run backwards between the layers of the tela, receiving tributaries from the choroid plexuses of the third ventricle and from the fornix and corpus callosum, and they end beneath the splenium of the corpus callosum, by uniting to form the great cerebral vein.

The **great cerebral vein** (Galen) passes backwards and slightly upwards from its origin round the splenium of the corpus callosum. It ends in the anterior extremity of the straight sinus. In addition to the two internal cerebral veins, by the union of which it is formed, it receives tributaries from the posterior part of the gyrus cinguli of each side, from the pineal and quadrigeminal bodies, from the medial and inferior surfaces of the occipital lobes of the cerebral hemispheres,

and from the upper surface of the cerebellum. It receives also the basal vein of each side (see below).

One or two **striate veins** descend from the substance of the corpus striatum, through the anterior perforated substance, and end in the basal vein.

The **superficial cerebral veins** are more numerous and of larger calibre than the cerebral arteries. They lie upon the surface of the cerebrum, drain blood from the cerebral cortex, and they are divisible into two sets—the superior and the inferior.

The **superior cerebral veins**, six to twelve in number on each side, lie in the pia mater and subarachnoid space on the upper and lateral aspect of the cerebral hemispheres. They run upwards and medially to the margin of the longitudinal fissure where they receive tributaries from the medial surface of the hemisphere. They end in the superior sagittal sinus, and those that encounter the *lacunæ laterales* pass beneath them to reach the sinus (Sargent, 1911). The anterior veins of that set are small and run transversely, but the posterior are large and run obliquely forwards and medially; they are embedded for some distance in the wall of the sinus, and their orifices are directed forwards against the blood-stream.

The **inferior cerebral veins** lie on the lower and lateral aspects of the cerebral hemispheres; they end in sinuses which lie at the base of the skull—the cavernous, the superior petrosal, and the transverse sinuses. One of these veins, the **superficial middle cerebral vein**, runs along the posterior ramus and the stem of the lateral sulcus to the cavernous sinus; occasionally it is united by an anastomotic loop, known as the **superior anastomotic vein**, with the superior sagittal sinus, and sometimes by an **inferior anastomotic vein** with the transverse sinus. These anastomotic veins are persisting members of a series of channels which, in the fœtus, radiate from the superficial cerebral vein to the superior sagittal and transverse sinuses; they may be multiple, three superior and two inferior (O'Connell, 1934).

Each **anterior cerebral vein** lies in the longitudinal fissure, and accompanies the corresponding anterior cerebral artery; it receives tributaries from the corpus callosum and the gyrus cinguli. Turning downwards, round the genu of the corpus callosum, it reaches the base of the brain, and ends in the basal vein.

The **deep middle cerebral vein** lies deeply in the lateral sulcus; it anastomoses freely with the superficial middle vein, receives tributaries from the insula and the opercula, and ends in the basal vein.

The **basal vein** begins at the anterior perforated substance; it is formed by the union of the anterior cerebral vein with the deep middle cerebral vein and receives the striate vein or veins. It passes backwards around the cerebral peduncle and ends in the great cerebral vein. Its tributaries are derived from the tuber cinereum, the mamillary body, the posterior perforated substance, the uncus, the inferior horn of the lateral ventricle, and the cerebral peduncle.

Veins of Mid-Brain.—The veins of the mid-brain end for the most part either in the great cerebral vein or in the basal veins.

Cerebellar Veins.—Those veins also are divisible into two groups, the superficial and the deep. The former are quite independent of and much more numerous than the arteries. They form two sets, the superior and the inferior.

The **superior cerebellar veins** end in a median efferent vessel which is sometimes double, and in several lateral efferents. The median efferent vein runs forwards on the superior vermis and ends in the great cerebral vein. The lateral efferents end in the transverse sinuses and in the superior petrosal sinuses.

The **inferior cerebellar veins** also form a small median efferent and numerous lateral efferents: the former runs backwards on the inferior vermis and joins either the straight sinus or one of the transverse sinuses, and the latter end in the inferior petrosal and occipital sinuses.

The **deep cerebellar veins** issue from the substance of the cerebellum and join the superficial veins.

Veins of Pons.—The deep veins from the substance of the pons pass forwards to its anterior surface, where they become superficial and anastomose to form a

plexus which is drained by superior and inferior efferent veins. The superior efferent veins join the basal vein; the inferior efferent veins either unite with the cerebellar veins, or they open into the superior petrosal sinus.

Veins of Medulla Oblongata.—Deep veins of the medulla oblongata issue from its substance and end in a superficial plexus. This plexus is drained by an anterior and a posterior median vein and by radicular veins.

The *anterior median vein* is continuous below with the corresponding vein of the spinal cord; it communicates above with the plexus on the surface of the pons.

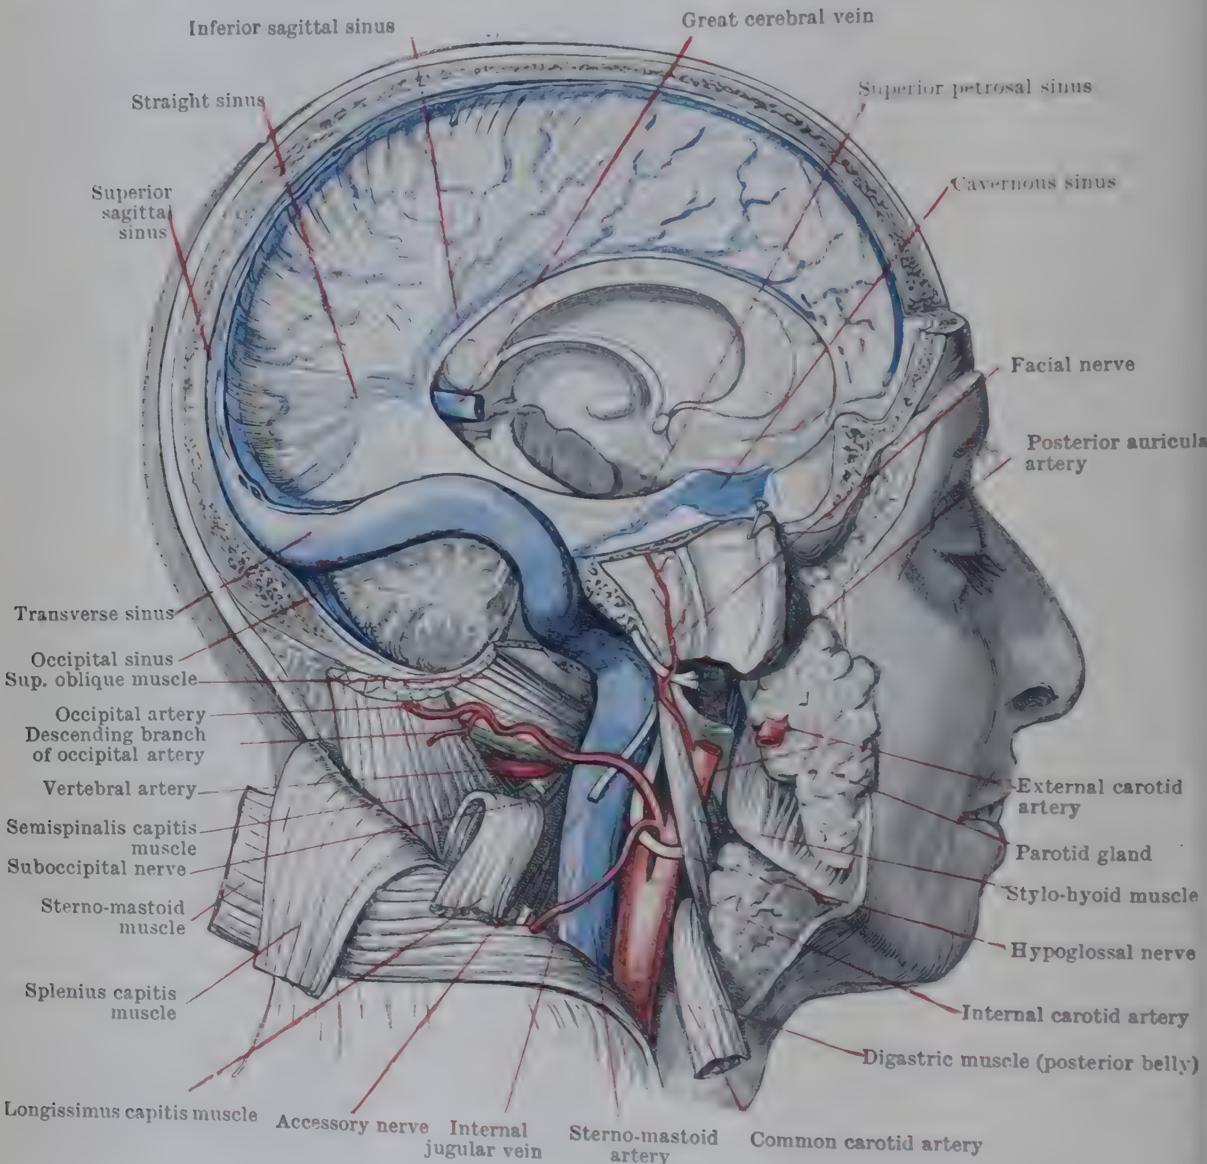

FIG. 1114.—DISSECTION OF HEAD AND NECK, SHOWING VENOUS SINUSES OF DURA MATER AND UPPER PART OF INTERNAL JUGULAR VEIN.

The *posterior median vein* is continuous below with the posterior median vein of the spinal cord, from which it ascends to the lower end of the fourth ventricle, where it divides into two branches which join the inferior petrosal sinuses or the network of basilar sinuses.

The *radicular veins* issue from the lateral parts of the plexus and run with the roots of the last four cranial nerves; they end in the inferior petrosal and occipital sinuses or in the upper part of the internal jugular vein.

VENOUS SINUSES OF DURA MATER

The **venous sinuses** of the cranium are spaces between the layers of the dura mater and they are lined with an endothelium which is continuous with the endothelium of the veins. They receive the veins of the brain, communicate frequently with the

meningeal veins and with veins external to the cranium, and end directly or indirectly in the internal jugular vein. Some of the sinuses are unpaired, others are paired.

Unpaired Sinuses.—These are the superior sagittal, the inferior sagittal, the straight, the intercavernous, and the basilar sinuses.

The **superior sagittal sinus** begins at the crista galli, where it communicates, through the foramen cæcum, frequently with the veins of the frontal sinus, sometimes with the veins of the nasal cavity, and more rarely with the anterior facial vein. It passes backwards in the convex margin of the falx cerebri, grooving the cranial vault. As it descends along the occipital bone it usually deviates slightly to the right, and it ends at the internal occipital protuberance by becoming the right transverse sinus. Instead of passing to the right it occasionally turns to the left and ends in the left transverse sinus, and sometimes it bifurcates and ends in both transverse sinuses. When it ends wholly in the right or the left transverse sinus its termination is associated with a well-marked dilatation, called the *confluence of the sinuses*, which is lodged in a depression at one side of the internal occipital protuberance. The confluence is connected, across the protuberance, by an anastomosing channel, with a similar dilatation which marks the junction of the straight sinus with the transverse sinus of the opposite side. Opening into the superior sagittal sinus are the superior cerebral veins; and it communicates on each side by slit-like openings with a series of spaces in the dura mater, called the **lacunæ laterales**, into which the arachnoid granulations project (see p. 1003 and Fig. 879). It communicates also, by emissary veins which pass through the parietal foramina, with the veins on the exterior of the cranium. Its cavity, which is triangular in transverse section, is crossed by several fibrous strands.

The **inferior sagittal sinus** runs in the posterior two-thirds of the free part of the lower margin of the falx cerebri. It ends behind by joining with the great cerebral vein to form the straight sinus. It receives tributaries from the falx cerebri and from the medial surface of the middle third of each cerebral hemisphere.

Around the hypophysis cerebri in the region of the sella turcica, there are intercommunicating channels which connect the two cavernous sinuses together. Two of these **intercavernous sinuses** lie in the anterior and posterior margins of the diaphragma sellæ; others pass across the floor of the hypophysial fossa (Fig. 707, p. 822).

The **network of basilar sinuses** is situated in the dura mater on the clivus of the skull. It connects the cavernous and the inferior petrosal sinuses together, and communicates below with the anterior longitudinal vertebral sinuses.

The **straight sinus** is formed by the union of the inferior sagittal sinus with the great cerebral vein. It runs downwards and backwards along the line of union between the falx cerebri and the tentorium cerebelli, and receives some of the superior cerebellar veins and a few tributaries from the occipital lobes and the falx cerebri. As a general rule it turns to the left at the internal occipital protuberance, dilates slightly, and becomes continuous with the left transverse sinus, its dilatation being united with the corresponding dilatation on the lower end of the superior sagittal sinus (the "confluence of the sinuses") by a transverse anastomosing channel. Occasionally the straight sinus ends in the right transverse sinus; in that case the superior sagittal sinus ends in the left transverse sinus; and sometimes it bifurcates to join both transverse sinuses.

Paired Sinuses.—There are six pairs of sinuses, viz., the transverse, the occipital, the cavernous, the superior petrosal, the inferior petrosal, and the spheno-parietal.

Each **transverse sinus** begins at the internal occipital protuberance, the right usually as the continuation of the superior sagittal, and the left as the continuation of the straight sinus. Each passes laterally in the postero-lateral part of the attached border of the tentorium cerebelli and in a groove on the occipital bone. From the lateral angle of the occipital bone it passes to the posterior inferior angle of the parietal bone, which it grooves; it then leaves the tentorium and turns

downwards on the cerebral surface of the mastoid portion of the temporal bone; from the latter it passes to the upper surface of the jugular process of the occipital bone; there it turns forwards and then downwards into the jugular foramen, where it becomes continuous with the internal jugular vein. The part which descends

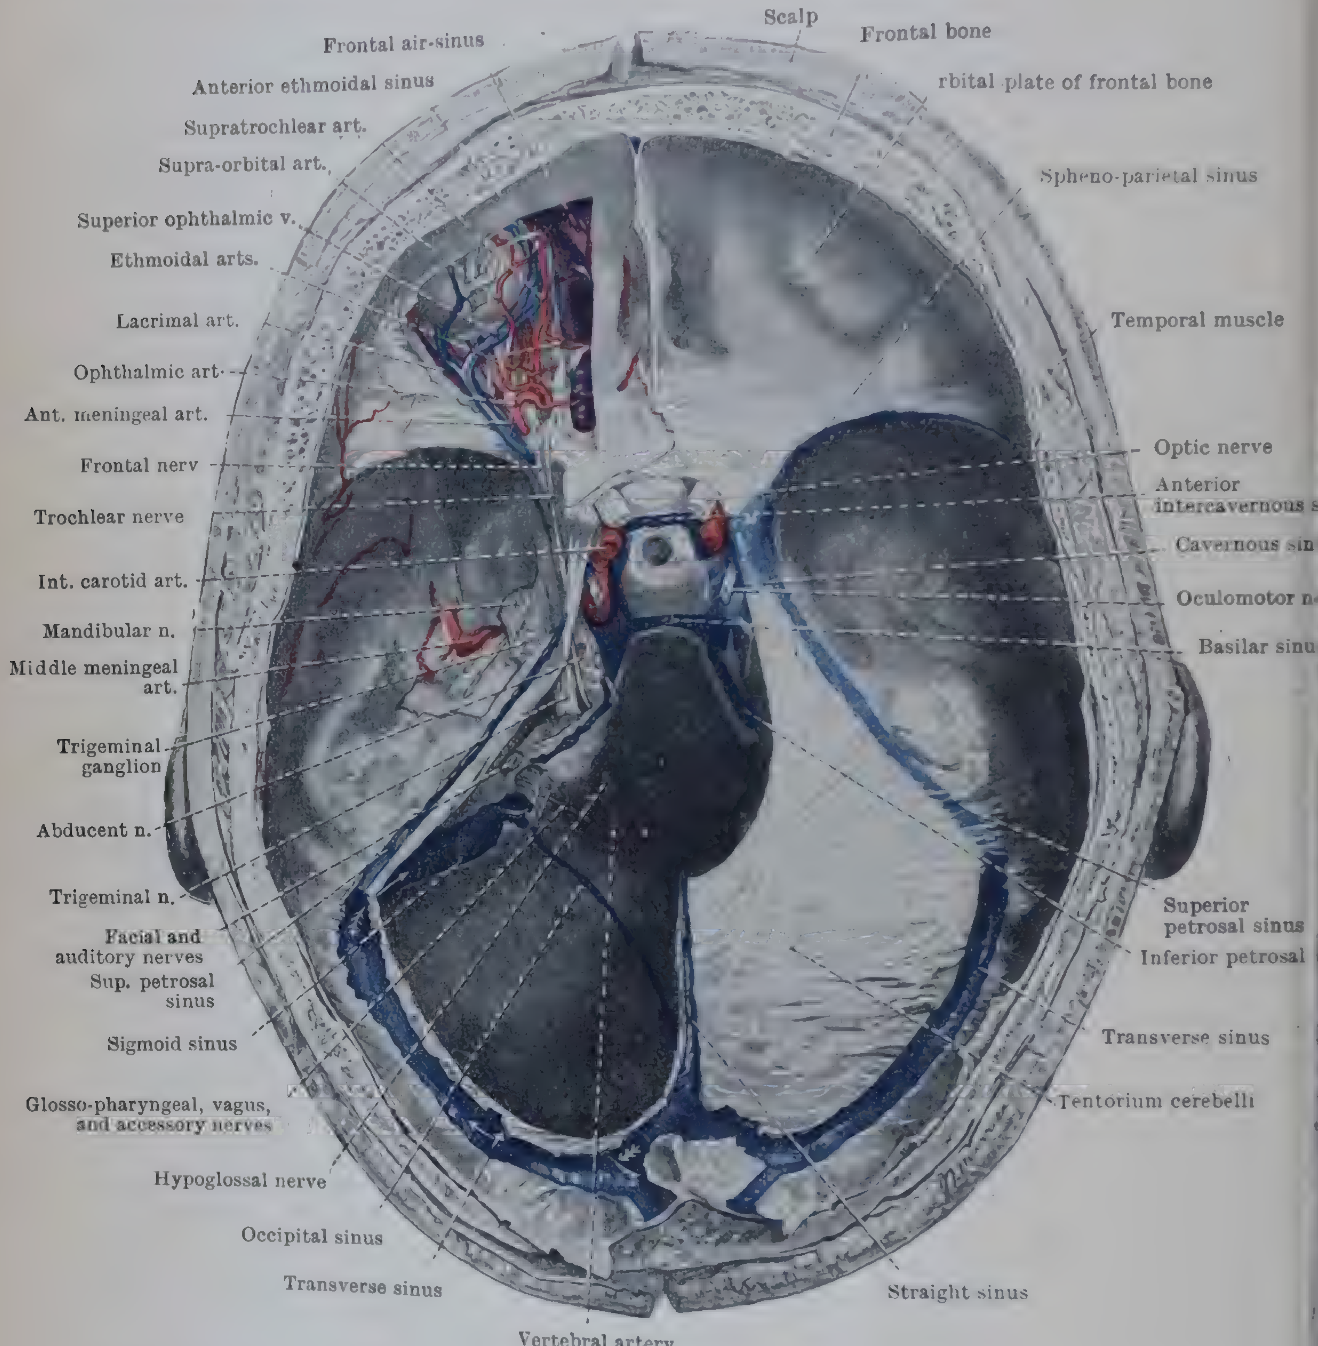

FIG. 1115.—LOWER VENOUS SINUSES OF DURA MATER.

In the specimen represented the superior sagittal sinus opened into both transverse sinuses and chiefly into the left. The straight sinus also opened into both transverse sinuses. The medial part of the left transverse sinus was divided by a horizontal septum into upper and lower parts. The arrow in the figure passes below the septum.

on the temporal bone and turns forwards on the jugular process of the occipital is called the **sigmoid sinus** (Fig. 1115).

Its tributaries are some of the inferior cerebral and superior and inferior cerebellar veins, a posterior parietal diploic vein, and the superior petrosal sinus. It is connected with the veins outside the cranium by emissary veins which pass through the mastoid foramen and the posterior condylar canal.

The **occipital sinuses** lie in the attached border of the falx cerebelli and in the dura mater along the postero-lateral boundaries of the foramen magnum; frequently they unite above and open by a single channel into the commencement of either

the right or the left transverse sinus, but their upper extremities may remain separate, and then each communicates with the transverse sinus of its own side. On the other hand, either the right or the left sinus may be absent. Each opens below into the corresponding sigmoid sinus, and both communicate with the posterior longitudinal vertebral sinuses. Each occipital sinus is an anastomosing channel between the transverse and sigmoid sinuses of the same side, and each receives a few inferior cerebellar veins.

The **cavernous sinuses** lie at the sides of the body of the sphenoid bone. Each sinus begins in front at the medial end of the superior orbital fissure, where it receives the corresponding ophthalmic veins, and it ends at the apex of the petrous portion of the temporal bone by dividing into the superior and inferior petrosal sinuses. Its cavity, which is irregular in size and shape, is so divided by numerous fibrous strands that it assumes the sponge-like appearance of cavernous tissue; and in its lateral wall are embedded the internal carotid artery with its sympathetic plexus, the oculomotor, the trochlear, the ophthalmic and the abducent nerves. Its tributaries are the ophthalmic vein, the spheno-parietal sinus, and inferior cerebral veins, including the superficial middle cerebral vein. It communicates with the opposite cavernous sinus through the intercavernous sinuses; with the pterygoid plexus by an emissary vein which passes either through the foramen ovale or through the sphenoidal emissary foramen; with the internal jugular vein by small venous channels which accompany the internal carotid artery through the carotid canal, and by the inferior petrosal sinus; with the transverse sinus by the superior petrosal sinus; and through the superior ophthalmic vein with the supra-orbital and anterior facial veins.

The **spheno-parietal sinuses** are lodged in the dura mater on the under surfaces of the lesser wings of the sphenoid bone close to their posterior borders. Each sinus communicates with the middle meningeal veins, receives veins from the dura mater, and ends in the anterior part of the cavernous sinus.

Each **superior petrosal sinus** begins at the apex of the petrous portion of the temporal bone in the posterior end of the cavernous sinus, and it runs backwards and laterally in the attached margin of the tentorium cerebelli above the trigeminal nerve. It grooves the superior margin of the petrous portion of the temporal bone, at the lateral end of which it ends in the transverse sinus at the point where it is turning down to become the sigmoid sinus. It receives inferior cerebral, superior cerebellar, and small tympanic veins.

An **inferior petrosal sinus** begins at the posterior end of each cavernous sinus; it runs backwards, laterally, and downwards, in a groove between the petrous part of the temporal bone and the basilar part of the occipital bone, to the anterior compartment of the jugular foramen, through which it passes. It crosses the glosso-pharyngeal, vagus, and accessory nerves either on their lateral or on their medial side, and it ends in the internal jugular vein. Its tributaries include inferior cerebellar veins and veins from the internal ear; the **internal auditory vein** reaches it through the internal auditory meatus, and small venules emerge from the cochlear canaliculus and the aqueduct of the vestibule to join it or the internal jugular vein.

Variations.—Variations of the venous sinuses are not numerous. One transverse sinus may be absent or very small, when, as a rule, that of the opposite side is enlarged. The inferior sagittal, the occipital, or the spheno-parietal sinuses may be absent, and there may be an additional petro-squamous tributary to the transverse sinus. The *petro-squamous sinus*, when present, runs in a groove (the posterior part of which may be a canal) along the line of the petro-sqaumous suture (p. 223) and opens behind into the transverse sinus. It is the remains of a fœtal channel which joined the primary head-vein (p. 1379); and in the human adult, in rare cases, it pierces the skull just above the posterior root of the zygoma (squamosal foramen) or through the root (post-glenoid foramen) above the lateral end of the squamo-tympanic fissure and ends in the external jugular *via* the posterior facial vein. That is the normal arrangement in some mammals.

Emissary Veins

The **emissary veins** are veins which connect the venous sinuses with the veins that lie outside the walls of the cranium, so that blood may pass in either direction. They may be single veins, or plexiform channels surrounding other structures which are passing through the

walls of the cranium ; individual emissary veins vary greatly in size and are not always present. They may communicate with the diploic veins.

In the child, and sometimes in the adult, a **frontal emissary vein** passes from the anterior end of the superior sagittal sinus through the foramen cæcum. Its lower end divides into two channels which either end in the veins of the frontal sinus or those of the roof of the nasal cavities, or they perforate the nasal bones and join the anterior facial veins.

The **parietal emissary veins**, one on each side, pass through the parietal foramina from the superior sagittal sinus to tributaries of the occipital vein.

An **occipital emissary vein** is only occasionally present. It passes from the confluence of the sinuses through the occipital protuberance to one of the tributaries of an occipital vein, and, when present, it receives the occipital diploic vein.

A **mastoid emissary vein** connects the sigmoid sinus, through the mastoid foramen, with the occipital or the posterior auricular vein.

A **posterior condylar emissary vein** passes through the posterior condylar canal when present, and connects the lower end of the sigmoid sinus with the plexus of veins in the sub-occipital triangle.

Emissary veins of the foramen ovale surround the mandibular nerve as it passes through the foramen ovale, and they connect the cavernous sinus with the pterygoid plexus. If the *sphenoidal emissary foramen* (*Vesalii*) is present, the plexus of the foramen ovale is replaced or supplemented by an emissary vein which passes through that foramen.

Emissary veins of the carotid canal accompany the internal carotid artery and connect the cavernous sinus either with the pharyngeal plexus or with the upper part of the internal jugular vein. A few small emissary veins also pass through the foramen lacerum to the pharyngeal veins and the pterygoid plexus.

As the hypoglossal nerve passes through the anterior condylar canal it is accompanied either by a venous plexus or by a large **anterior condylar emissary vein** which connects the veins of the medulla oblongata and the lower part of the occipital sinus with the upper end of the internal jugular vein, or with the extra-cranial part of the inferior petrosal sinus.

Not uncommonly there is a venous connexion between the cavernous sinus and the veins in the facial canal of the temporal bone.

Veins of Vertebral Column

The veins of the vertebral column are arranged in rich venous plexuses which extend along the whole length of the column both inside and outside the vertebral canal. All the plexuses anastomose freely with one another ; they are united by longitudinal channels ; and they are drained by the series of intervertebral veins.

Internal Vertebral Plexuses.—The veins in the interior of the vertebral canal form a continuous venous network which lies between the dura mater and the walls of the vertebral canal. The network communicates laterally with the intervertebral veins, behind with the posterior external venous plexuses, whilst in front it receives the basi-vertebral veins. It receives veins from the spinal cord also.

The **basi-vertebral veins** are venous channels, enclosed by endothelial walls, which lie in the substance of the bodies of the vertebræ. They communicate with the plexuses of veins on the anterior surfaces of the bodies of the vertebræ, and they converge towards the posterior surfaces of the bodies of the vertebræ, where they open into transverse anastomoses between the anterior longitudinal vertebral sinuses.

In the anterior part of the internal plexus, on the posterior surfaces of the bodies of the vertebræ and the intervertebral discs, at the sides of the posterior longitudinal ligament, there are two wide longitudinal channels, called the *anterior longitudinal vertebral sinuses*. They extend the whole length of the vertebral canal, are united together by transverse channels under cover of the posterior longitudinal ligament, and communicate above with the network of basilar sinuses, the terminal parts of the sigmoid sinuses, with the plexus of veins which accompanies each hypoglossal nerve through the anterior condylar canal and, through a plexus which surrounds the foramen magnum, with the occipital sinuses and the vertebral veins. Two less obvious longitudinal channels, called the *posterior longitudinal vertebral sinuses*, can sometimes be distinguished on the internal surfaces of the vertebral arches and the ligamenta flava.

External Vertebral Plexuses.—The **anterior external vertebral plexuses** are formed by anastomosing venous channels which lie on the anterior surfaces of the bodies of the vertebræ. They communicate with the basi-vertebral veins and with the intervertebral veins.

The **posterior external vertebral plexuses** lie on the postero-lateral surfaces

of the vertebræ, in the vertebral grooves, around the spines, the articular and the transverse processes of the vertebræ. They communicate with the internal plexuses and with the intervertebral veins, and they open into the vertebral, intercostal, and lumbar veins.

Intervertebral Veins.—The internal vertebral plexuses are drained not only above into the cranial venous sinuses by the longitudinal vertebral sinuses, but also by a series of **intervertebral veins** which pass through the intervertebral foramina. In the cervical region the intervertebral veins open externally into the vertebral veins, in the thoracic region into the intercostal veins, in the lumbar region into the lumbar veins, and in the sacral region into the lateral sacral veins. The intervertebral veins convey blood both from the internal and the external vertebral plexuses.

Veins of Spinal Cord

The **veins of the spinal cord** issue from its substance and end in a plexus in the pia mater. In that plexus there are six longitudinal channels—one *antero-median*, along the anterior fissure; two *antero-lateral*, immediately behind the anterior nerve-roots; two *postero-lateral*, immediately behind the posterior nerve-roots; and one *postero-median*, behind the posterior septum. Radicular efferent vessels issue from the plexus and pass along the nerve-roots to communicate with the internal vertebral venous network. The veins of the spinal cord vary very much in size, but they are largest on the lower part of the cord and on its posterior surface.

The postero-median and antero-median veins are continued above into the corresponding veins of the medulla oblongata.

The antero-lateral and postero-lateral veins pour their blood partly into the median veins and partly into the radicular veins; the greater part of the blood from the spinal cord is returned by the radicular veins.

VEINS OF UPPER LIMB

The veins of the upper limb are divisible into two sets — **superficial** and **deep**. Both sets open eventually into a common terminal trunk which is known as the **axillary vein**. That vein is continued as the subclavian vein to the innominate vein, through which its blood, together with that from the corresponding side of the head and neck, reaches the superior vena cava.

Deep Veins of Upper Limb

The deep veins of the upper limb, with the exception of the axillary vein, are arranged in pairs (**venæ comitantes**) which accompany the various arteries and are similarly named. So far as those veins are concerned, it is sufficient to state that they are provided with valves, that they are situated one on each side of the artery with which they are associated, and that they are usually united together by numerous transverse anastomoses which cross the artery. The axillary vein, however, requires more detailed consideration.

The **axillary vein** (Figs. 1087 and 1171) begins, as the direct continuation of the basilic vein, opposite the lower border of the teres major muscle. It passes upwards and medially, through the axilla, along the medial side of the axillary artery, and ends at the outer border of the first rib by becoming the subclavian vein. It possesses one or more bicuspid valves, of which one is usually situated opposite the lower border of the subscapularis muscle.

Relations.—Its *anterior* relations are similar to those of the axillary artery, but, in addition, the vein is crossed in front, under cover of the clavicular part of the pectoralis major, by the pectoral branches of the acromio-thoracic artery, and by branches of the medial pectoral nerve, and it receives anteriorly the cephalic vein.

Posterior to it are the muscles which form the posterior wall of the axilla, the axillary artery and the first serration of the serratus anterior. The nerve to the serratus anterior

intervenes between it and that muscle, and the subscapular nerves, the nerve to the latissimus dorsi, and the subscapular artery pass between it and the subscapularis.

It is separated from the third part of the axillary artery by the ulnar nerve and the medial cutaneous nerve of the forearm; from the second part of the axillary artery by the medial cord of the brachial plexus; and in the proximal part of the axilla, behind the clavi-pectoral fascia, it is separated from the first part of the artery by the medial

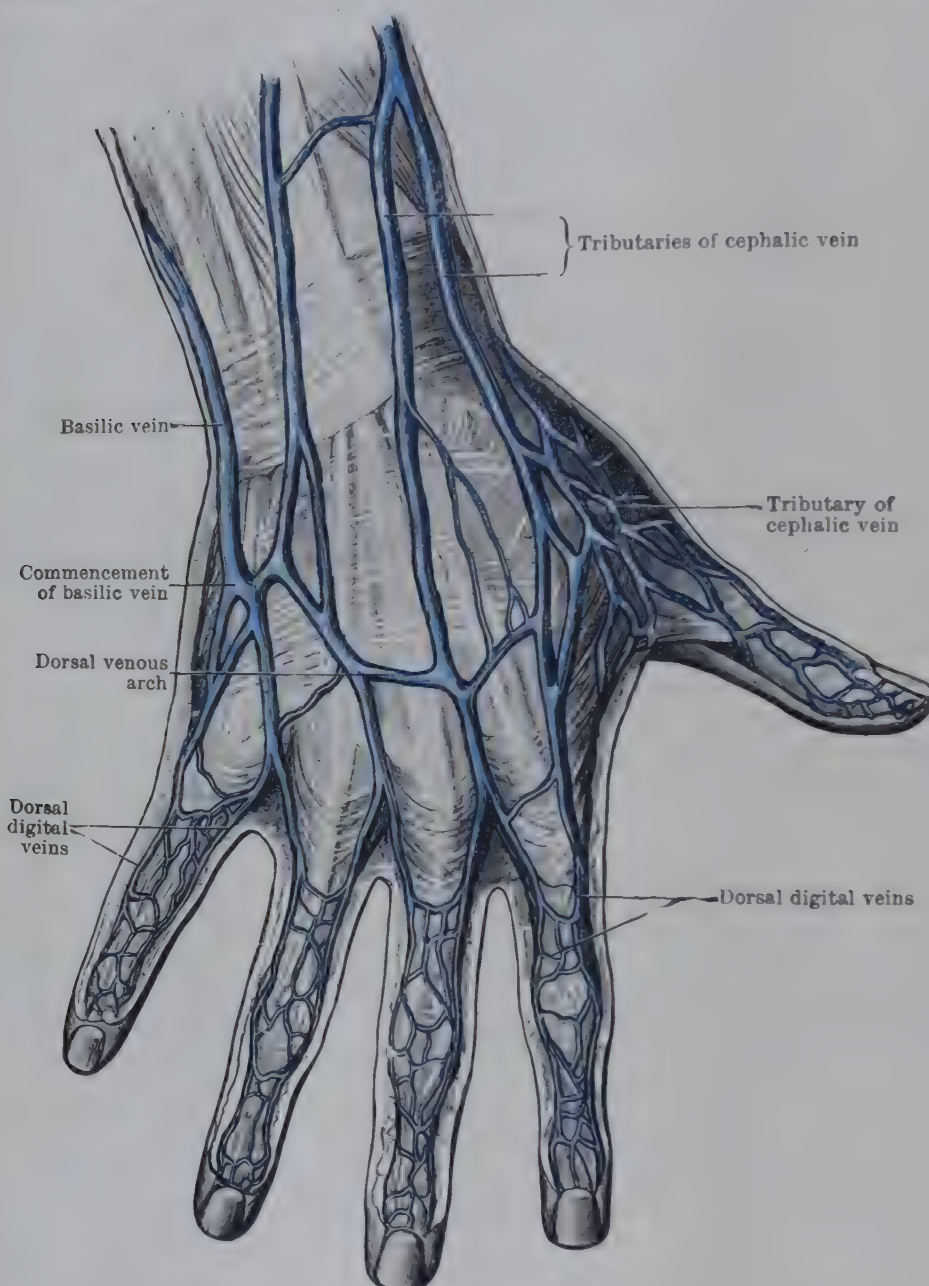

FIG. 1116.—SUPERFICIAL VEINS ON DORSUM OF HAND AND DIGITS.

pectoral nerve. To its medial side lie the lateral set of axillary lymph-glands and, in the distal part of the axilla, the medial cutaneous nerve of the arm.

Tributaries.—Its tributaries correspond with the branches of the axillary artery, except the acromio-thoracic. Besides these, it receives the venæ comitantes of the brachial artery at the lower border of the subscapularis; and the cephalic vein joins it above the upper border of the pectoralis minor muscle.

SUPERFICIAL VEINS OF UPPER LIMB

The superficial veins of the upper limb begin in the superficial fascia of the palm and dorsum of the hand and of the digits.

Veins of Digits and Hand.—The **palmar digital veins** are two or more fine longitudinal channels which lie in the superficial fascia of the palmar surfaces of the digits. They communicate, proximally, with a fine venous network which

lies in the superficial fascia of the palm, and, at the proximal ends of the inter-digital clefts, by means of anastomosing channels which pass backwards between the heads of the metacarpal bones, they open into the *dorsal digital veins.*

The **dorsal digital veins**, two in each digit, anastomose freely together on the dorsal surfaces of the digits. At the proximal ends of the interdigital clefts they communicate with the palmar digital veins, and then they unite together to form an indefinite series of *dorsal meta-carpal veins* which again unite on the lower part of the back of the hand in a **dorsal venous arch** which, however, is extremely variable in position and shape.

Veins of Forearm and Upper Arm.—The veins of the forearm emerge from the dorsal venous arch and from the palmar venous plexus, and they vary considerably in number and in size. As a rule there are two main longitudinal channels—the *cephalic vein* on the radial side and the *basilic vein* on the ulnar side. Sometimes there is a definite *median vein* on the front of the forearm.

The **cephalic vein** begins in the radial end of the dorsal venous arch. It receives the dorsal veins of the thumb, turns round the radial margin of the distal part of the forearm, and runs parallel with the anterior border of the brachio-radialis muscle to the front of the elbow. There, frequently much reduced in size, it turns laterally and runs along the lateral border of the prominence of the biceps to the interval between the deltoid and pectoralis major, along which, after piercing the deep fascia, it ascends to the infra-clavicular fossa. In the fossa, it crosses the pectoralis minor and passes medially under cover of the clavicular part of the pectoralis major in front of the clavi-pectoral fascia, which separates it from the first part of the axillary artery; then, turning backwards, it pierces that fascia and ends in the axillary vein. Occasionally, instead of piercing the clavi-pectoral fascia, it crosses the front of the clavicle, deep to the platysma, pierces the deep cervical fascia, and joins the lower part of the external jugular vein.

On the flexor aspect of the forearm a number of tributaries join its lateral border. Some of these arise from the dorsal venous arch of the hand and others in the superficial fascia of the dorsal aspect of the forearm.

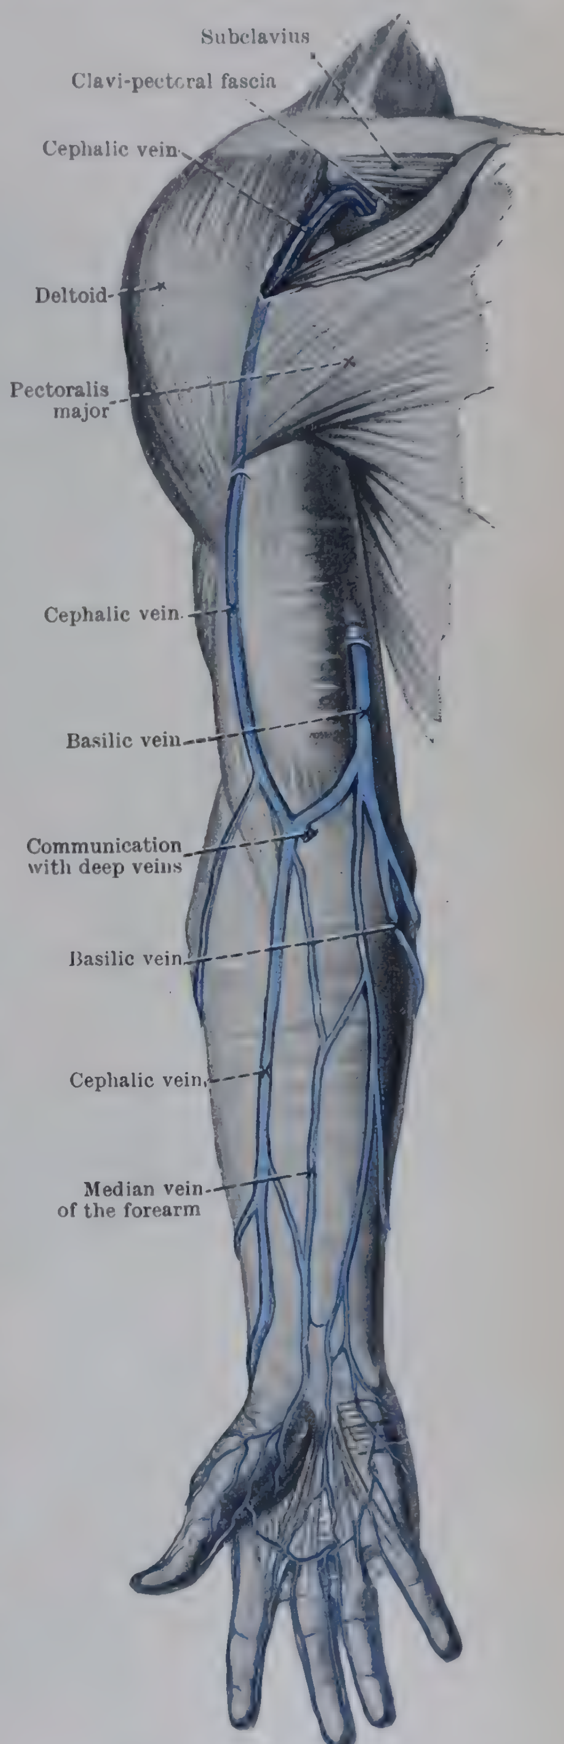

FIG. 1117.—SUPERFICIAL VEINS ON FLEXOR ASPECT OF RIGHT UPPER LIMB.

The median cubital vein connects the cephalic and basilic veins.

In front of the elbow it is connected with the basilic vein by a large obliquely placed anastomosing channel, called the *median cubital vein.* In the infra-

clavicular fossa it is joined by tributaries which correspond with the branches of the acromio-thoracic artery.

The **median cubital vein** (Fig. 1117) runs along the medial border of the distal part of the biceps-prominence, superficial to the bicipital aponeurosis which separates it from the brachial artery. It not only connects together the cephalic and basilic veins but it receives also a communicating tributary from the deep veins of the forearm, and one or more superficial veins of varying size which ascend on the front of the forearm.

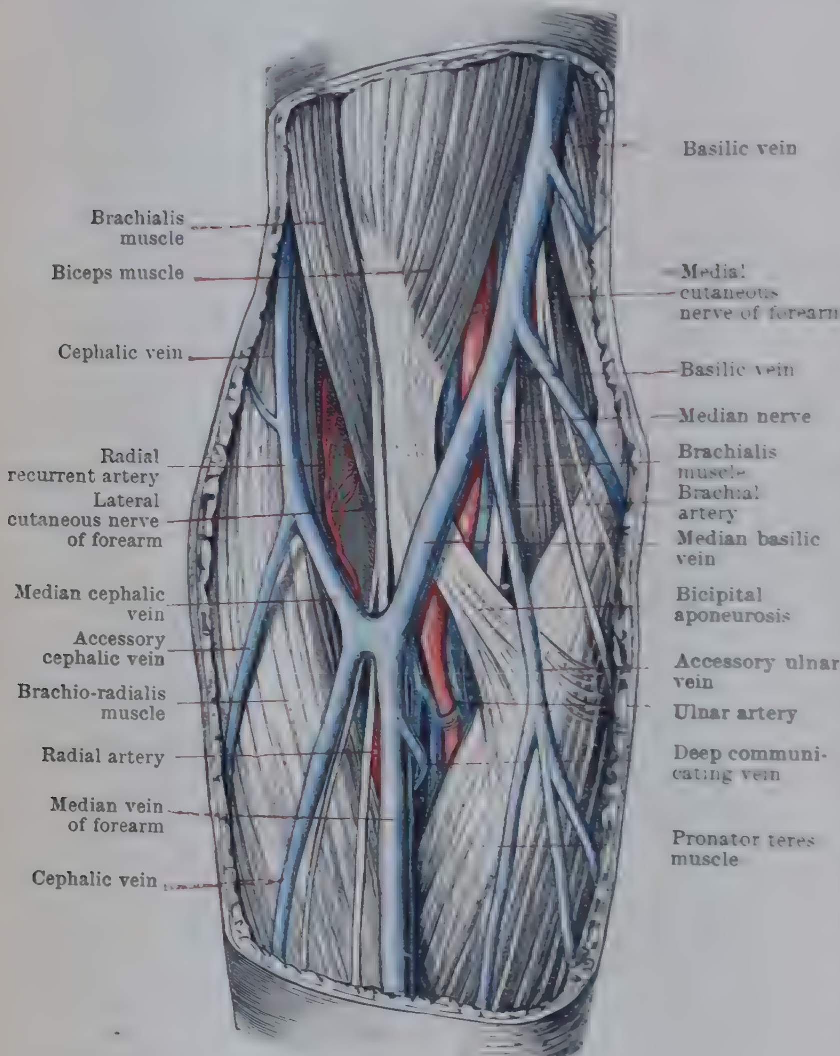

Fig. 1118.—Superficial Veins at Bend of Elbow in a Specimen in which the Median Vein was large.

Frequently the median cubital vein is relatively very large, and the upper part of the cephalic vein is then a comparatively small vessel.

The **basilic vein** begins in the ulnar end of the dorsal venous arch of the hand. It runs along the back of the forearm to the junction of the proximal and middle thirds, where it turns round the ulnar border of the forearm, and runs in front of the medial epicondyle of the humerus to the medial bicipital groove. At the middle of the upper arm it pierces the deep fascia. After piercing the fascia it runs along the medial border of the brachial artery to the axilla, and there becomes the axillary vein.

It is joined by tributaries from both surfaces of the forearm, and in front of the elbow by the median cubital vein, which connects it with the cephalic vein.

Median Vein of Forearm.—The median vein of the forearm, which begins in the palmar venous plexus and runs along the middle of the front of the forearm to the elbow, is occasionally a large vessel. At the bend of the elbow it receives the communication from the deep veins and then divides into two branches—the median cephalic and the median basilic veins (Fig. 1118). The *median cephalic vein* runs along the lateral bicipital sulcus and joins the cephalic vein. The *median basilic* passes along the medial bicipital sulcus and joins the basilic vein; it thus takes the place of the median cubital vein.

When venesection is performed in the forearm it is either the median cubital vein or the median basilic vein which is opened.

Variations.—The **superficial veins** of the forearm are extremely variable; any of them may be absent, but most commonly it is the median or the cephalic vein which is wanting. The median cephalic and the cephalic veins may be small or absent, and, on the other hand, the cephalic vein may be larger than usual. The cephalic vein may end in the external jugular vein, which was its original termination; or it may be connected with the external jugular vein

by an anastomosing channel which sometimes passes over the clavicle and sometimes through it. The basilic vein varies in size and in the level at which it pierces the deep fascia.

The **venæ comitantes** of the brachial artery usually end at the lower border of the subscapularis, where they join the axillary vein, but they may end above or below that level.

INFERIOR VENA CAVA

The **inferior vena cava** (Figs. 1119, 1120) is a large venous trunk which receives all the blood from the lower limbs, and the greater part of the blood from

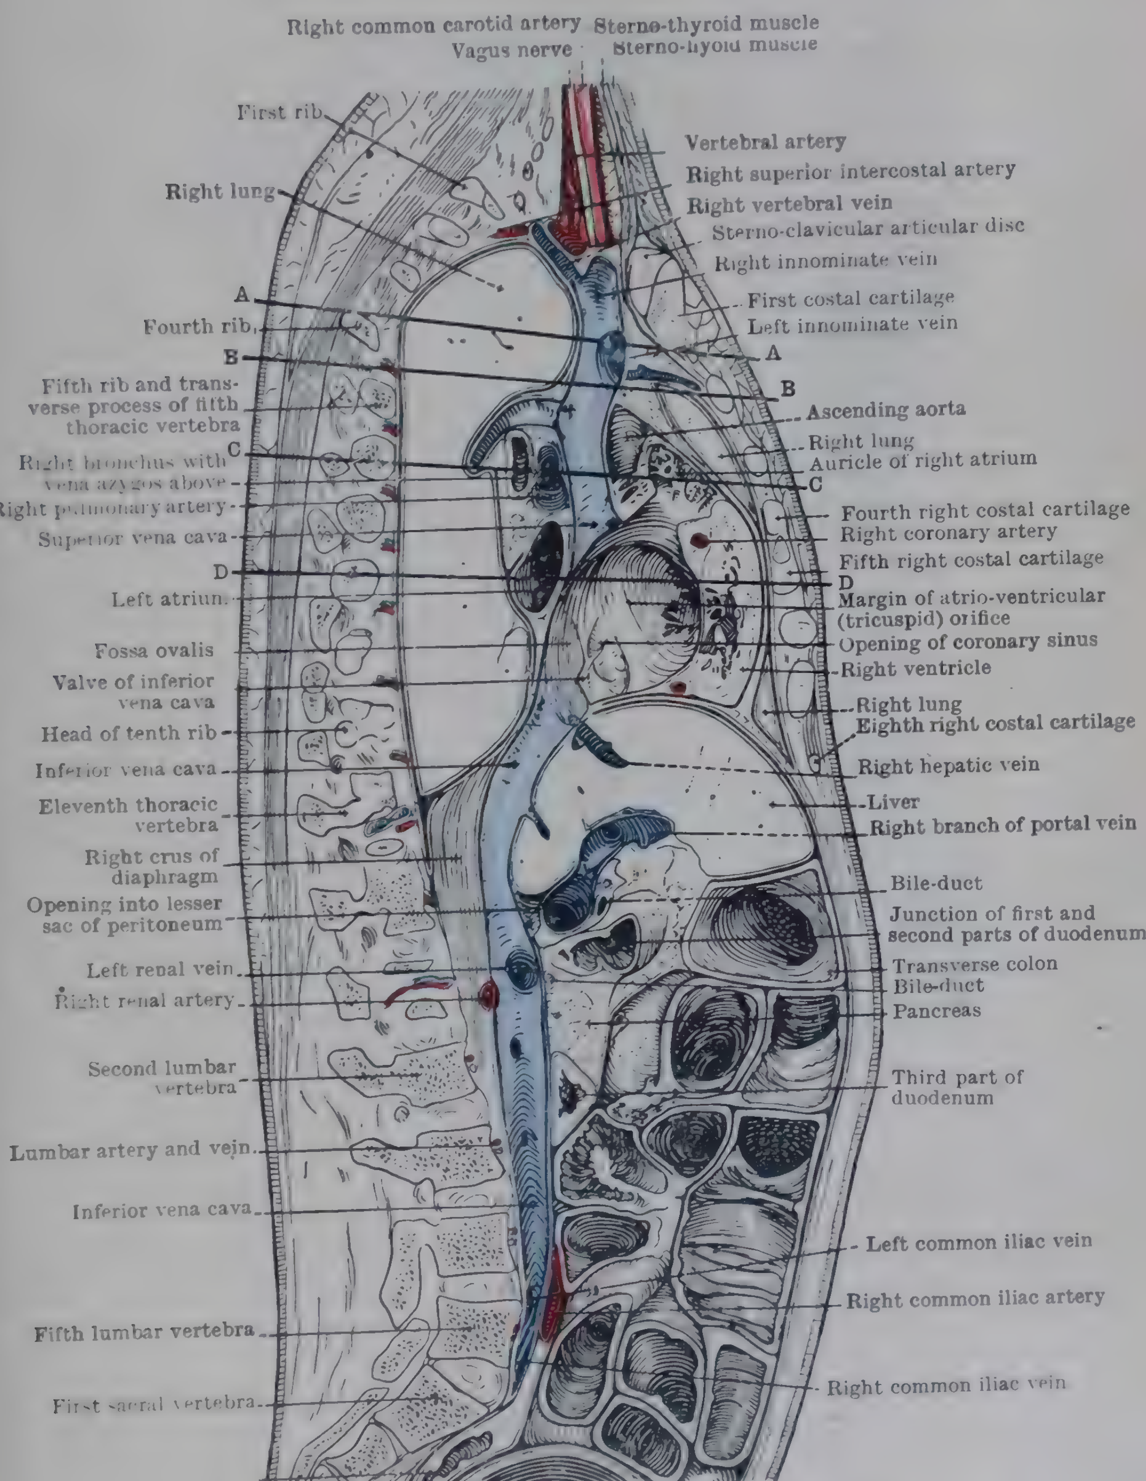

Fig. 1119.—Sagittal Section of Body of Young Man through Superior and Inferior Venæ Cavæ.

A-A. Plane of section of Fig. 1085.

D-D. Plane of section of Fig. 1063.

the walls and contents of the abdomen and pelvis. It begins on the body of the fifth lumbar vertebra, to the right of the median plane, behind the right common iliac artery. It ascends through the abdomen, over the front of the

vertebral column and the right crus of the diaphragm on the right of the median plane, and it pierces the central tendon of the diaphragm, between its middle and right leaflets, at the level of the lower part of the eighth thoracic vertebra. It then enters the middle mediastinum, pierces the fibrous pericardium, and terminates in the lower and posterior part of the right atrium of the heart. Its intrathoracic portion is very short, and its intrapericardial portion is covered in front and on its right and left sides by the parietal serous pericardium. Attached to the inferior and anterior margin of its atrial orifice is the *valve of the inferior vena cava*; that is a remnant of an important fold of endocardium by which, in the fœtus, the greater part of the blood from the inferior vena cava was directed through the foramen ovale into the left atrium.

Relations.—The inferior vena cava is in relation, *posteriorly*, with the bodies of the lower lumbar vertebræ and the corresponding part of the anterior longitudinal ligament, the anterior portion of the right psoas major muscle, the right lumbar sympathetic trunk, the trunks of the lower right lumbar arteries, the right crus of the diaphragm, the right renal artery, the right suprarenal artery, the right cœliac ganglion, the right phrenic artery, and the medial portion of the right suprarenal gland.

Anterior to it, from below upwards, are the following structures: the right common iliac artery, the lower end of the mesentery and the superior mesenteric vessels, the ileo-colic and right colic vessels, the right testicular or ovarian artery and the third part of the duodenum, the head of the pancreas and the bile-duct, the portal vein and the first part of the duodenum, the opening into the lesser sac of the peritoneum, and the liver—the vena cava being embedded in a deep groove on the back of that organ, so that the liver is to the right and left of it as well as in front. More superficially are coils of small intestine, the greater omentum, and the transverse colon and mesocolon.

To its *left side* are the aorta, the right crus of the diaphragm, and the caudate lobe of the liver.

On its *right side*, from below upwards, there are the right ureter, the right kidney, the right suprarenal gland (which is also behind), and the main part of the right lobe of the liver.

Variations and Abnormalities.—The lower part of the inferior vena cava is sometimes absent, in which case the common iliac veins ascend, one on the right of the aorta and the other on its left, to the level of the second lumbar vertebra, where the left common iliac vein receives the left renal vein and then crosses in front of or behind the aorta to join the corresponding vein of the right side; in such cases, therefore, the inferior vena cava begins at the level of the second lumbar vertebra, and it represents only the upper and last-formed part of the ordinary vessel; the common iliac veins, each of which receives the lumbar veins of its own side, are exceptionally long, and they may or may not be united at the pelvic brim by a small transverse anastomosing channel. Cases of this kind are sometimes described as partial doubling of the inferior vena cava.

Occasionally the inferior vena cava does not end in the right atrium but is continuous with the vena azygos, which is much enlarged, and all the inferior caval blood is then carried to the superior vena cava. In such cases the hepatic veins open into the right atrium by a channel which represents the upper end of the inferior vena cava (see p. 1289).

The lower part of the inferior vena cava sometimes lies to the left of the aorta instead of to the right of it; that condition is associated with a long right common iliac vein, which crosses obliquely from right to left to join the left common iliac vein. After receiving the left renal vein this misplaced inferior vena cava crosses in front of the aorta, reaching the right side at the level of the second or first lumbar vertebra. In other cases, however, the left inferior vena cava continues upwards through the left crus of the diaphragm, usurping the place of the inferior hemiazygos vein; having entered the thorax, it may cross to the opposite side and terminate in the vena azygos, or it may continue upwards on the same side, arch over the root of the left lung, and descend behind the left atrium to end in the right atrium in the situation of the coronary sinus. In that group of cases also the hepatic veins open separately into the right atrium.

The inferior vena cava may lie ventral instead of dorsal to the right testicular or ovarian artery.

The tributaries also of the inferior vena cava are subject to variation. Additional renal, testicular, ovarian, or suprarenal veins may be present. Two or three lumbar veins of one or both sides may unite into a common trunk which ends in the inferior vena cava, and the hepatic veins may open separately, or after fusing into a common trunk, into the right atrium near the opening of the inferior vena cava.

The variations of the inferior vena cava and its tributaries are due to persistence of portions of the primitive veins which usually disappear, and to the persistence of transverse anastomoses and tributaries which usually atrophy, or to other modifications of the embryonic veins which ordinarily take part in the formation of the inferior vena caval system (see p. 1384).

Tributaries.—In addition to the two common iliac veins, through which it receives blood from the pelvis and from the lower limbs, the inferior vena cava receives the following main tributaries: the hepatic veins, the right phrenic vein, the right suprarenal vein, the right and left renal veins, the right testicular or ovarian vein, and the third and fourth lumbar veins of both sides. It receives also a number of smaller tributaries, including one or two direct from the right ureter.

The **hepatic veins** (Fig. 1120) convey blood which has passed through the

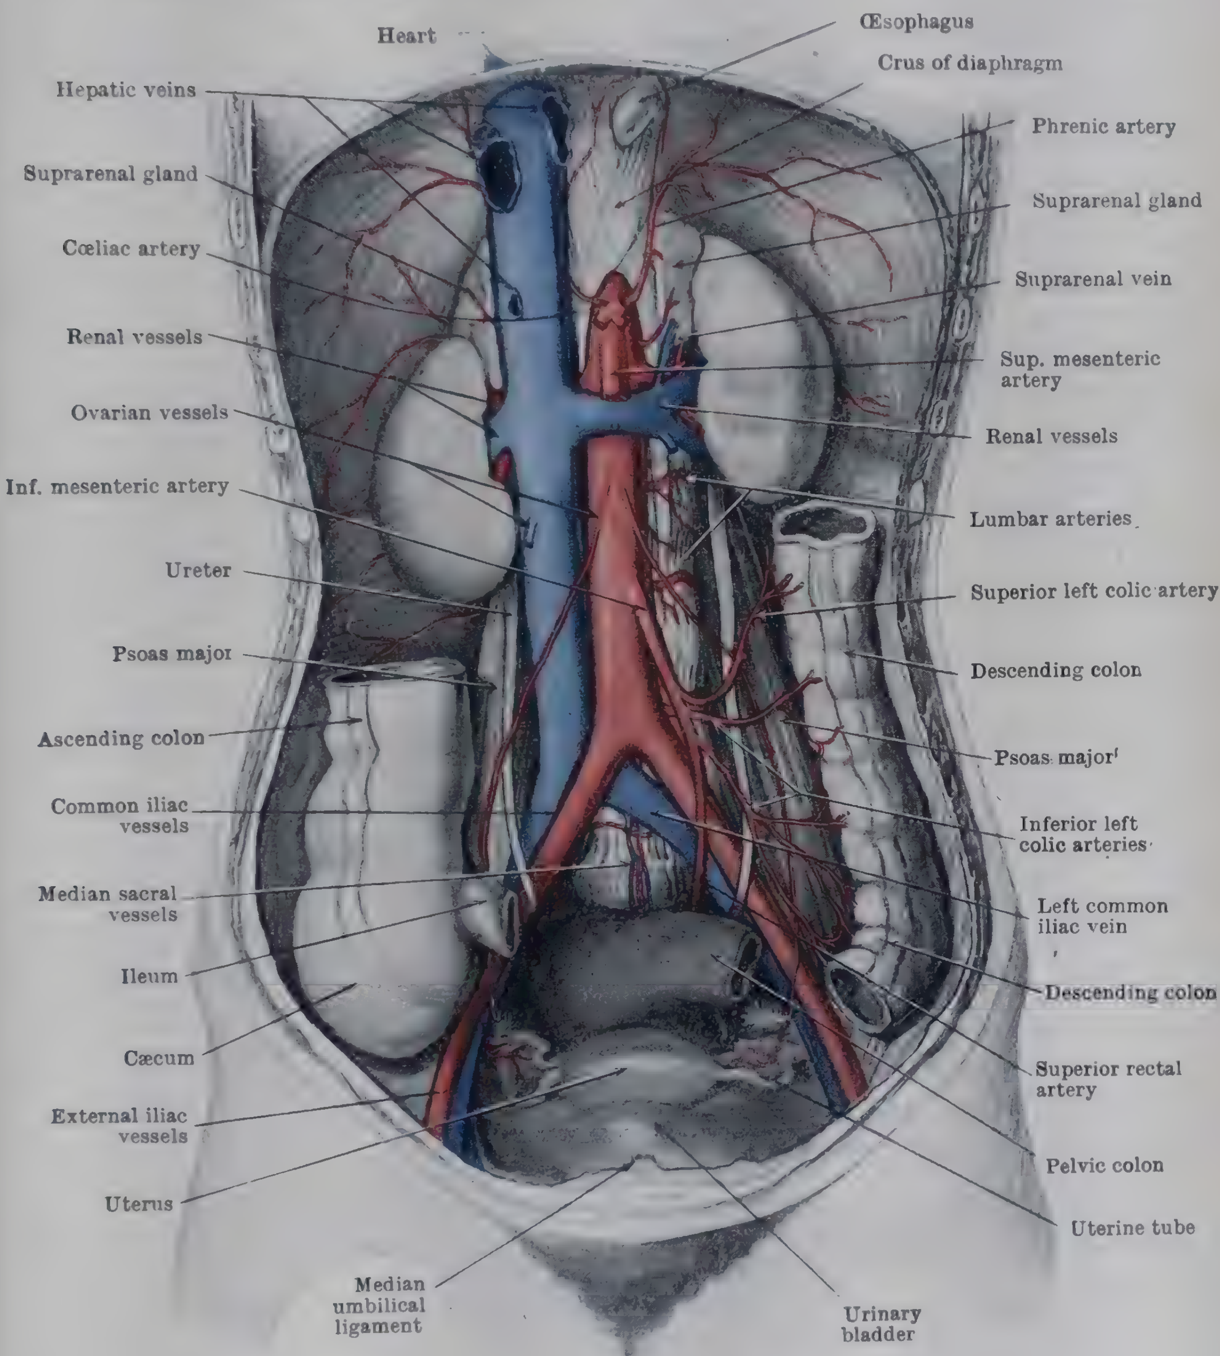

Fig. 1120.—Inferior Vena Cava and its Tributaries.

liver from the portal vein and from the hepatic artery, and they open into that portion of the inferior vena cava which lies immediately below the diaphragm and in the back of the right lobe of the liver. They form two groups, an upper group of two or three large trunks, and a lower group of smaller veins.

The upper group occasionally consists of only two veins, a right and a left; more frequently there are three vessels, a right, a left, and a middle vein, and in the latter case the middle vein issues from the caudate lobe.

The veins of the lower group vary in number from six to twenty; they return blood from the right and caudate lobes.

The hepatic veins begin as the *central* or *intralobular veins* of the lobules of

the liver; the central veins issue from the lobules, and unite together to form *sublobular veins*; and the sublobular veins unite with one another, as they converge towards the posterior surface of the liver, to form the larger hepatic veins.

The **phrenic veins** are formed by tributaries from the diaphragm and correspond to the phrenic arteries. The **right** vein ends in the upper part of the inferior vena cava. The **left** vein either descends to end in the left suprarenal or renal vein, or crosses behind or in front of the œsophagus to end in the inferior vena cava; both of these veins may be present.

A single **suprarenal vein** issues from the hilum of each suprarenal gland; the *right* vein is very short and runs slightly upwards to end in the back of the inferior vena cava; the *left* runs downwards and ends behind the body of the pancreas in the left renal vein.

The **renal veins** are formed by the union of five or six tributaries which issue from the hilum of each kidney, where they lie anterior to or are intermingled with the corresponding arteries.

The **right renal vein** is about 1 inch (25 mm.) long; it lies behind the second part of the duodenum, and ends in the right side of the inferior vena cava.

The **left renal vein** is about 3 inches (75 mm.) long. It crosses in front of the left psoas major, the left crus of the diaphragm, and the aorta immediately below the superior mesenteric artery. It lies behind the body of the pancreas and the fourth part of the duodenum, and runs above the third part of the duodenum to end in the left side of the inferior vena cava. The left testicular or ovarian vein, according to the sex, and the left suprarenal vein open into it.

The **testicular veins**, on each side, issue from the testis and epididymis and form the *pampiniform plexus*. The plexus is one of the constituents of the spermatic cord, and consists of from eight to ten veins, most of which lie in front of the vas deferens; it passes upwards through the scrotum and inguinal canal, and ends near the deep inguinal ring in two main trunks which ascend with the corresponding testicular artery, receiving tributaries from the ureter; the two veins soon unite together and a single terminal vein is formed. The terminal testicular vein on the right side opens into the inferior vena cava, that on the left side into the left renal vein. They are provided with valves, one of which usually lies near the termination of each vein, but occasionally the valve near the orifice of the left testicular vein is absent. The relations of the testicular veins are the same as those of the arteries (p. 1296), with the exception of the slight differences due to their modes of termination.

The much greater frequency of *varicocele* (see p. 1514) on the left side is associated with the fact that the left testicular vein joins the left renal at right angles; but it may be determined by the pressure of a loaded descending colon.

The **ovarian veins**, on each side, issue from the hilum in the mesovarian border of the ovary. They pass between the layers of the broad ligament, where they anastomose freely and form the *pampiniform plexus*, which extends to the brim of the pelvis. From the plexus two veins issue which accompany the ovarian artery and soon fuse together to form a single terminal vein which ends, on the right side, in the inferior vena cava, and on the left side in the left renal vein. As in the case of the testicular veins, the relations are the same as those of the arteries (p. 1297).

There are usually five **lumbar veins** on each side, one with each aortic lumbar artery and one with the lumbar branch of the median sacral artery. By their anterior and posterior tributaries the lumbar veins drain the lateral and posterior walls of the abdomen. The anterior tributaries begin in the lateral walls of the abdomen, where they communicate with the tributaries of the superior and inferior epigastric veins. The posterior tributaries issue from the muscles of the back in the lumbar region, and receive the intervertebral veins from the internal vertebral plexuses. The main stems pass forwards on the bodies of the vertebræ postero-medial to the psoas major muscle. The terminations of the lumbar veins are very variable. The upper two on each side may end in the ascending lumbar vein, or in the azygos or the hemiazygos vein. Usually the third

and fourth end in the inferior vena cava, those of the left side passing behind the aorta. The fifth ends in the ilio-lumbar vein. The lumbar veins of each side may all end in a median longitudinal channel (in the external vertebral plexus) which ascends behind the aorta in front of the vertebral bodies and branches to join the azygos and inferior hemiazygos veins; and they are all united together by a longitudinal anastomosing vessel—the ascending lumbar vein.

Each **ascending lumbar vein** passes upwards, between the psoas major and the roots of the transverse processes of the lumbar vertebræ. It begins in the lateral sacral vein of the same side, anastomoses with the ilio-lumbar vein, connects the lumbar veins together, receives tributaries from the anterior external vertebral plexus, and anastomoses with the inferior vena cava and the renal vein. The right ascending lumbar vein ends in the azygos vein and the left in the inferior hemiazygos vein.

Common Iliac Veins

The **common iliac veins** (Figs. 1097 and 1120), right and left, are formed by the union of the corresponding external and internal iliac veins. Each begins at the brim of the pelvis immediately behind the upper part of the internal iliac artery, and both veins pass upwards to the body of the fifth lumbar vertebra, at the right half of which, posterior to the right common iliac artery, they unite to form the inferior vena cava.

The **right common iliac vein** is much shorter than the left; it passes upwards anterior to the obturator nerve and the ilio-lumbar artery, and posterior to the corresponding common iliac artery.

The **left common iliac vein** is much longer than the right, and is placed more obliquely. It passes upwards and to the right, anterior to the body of the fifth lumbar vertebra and the median sacral artery. For some distance it runs along the medial side of the left common iliac artery, and then ends behind the right common iliac artery. Near its origin, it passes behind the mesentery of the pelvic colon and the superior rectal vessels.

Variations.—The **left common iliac vein** is short and the right long when the inferior vena cava lies on the left side. The common iliac veins may be absent, the internal iliac veins uniting to form the inferior vena cava, into which the external iliac veins open as lateral tributaries.

Tributaries.—Each common iliac vein receives the corresponding external iliac, internal iliac, and ilio-lumbar veins. The left common iliac vein receives, in addition, the median sacral vein.

The **ilio-lumbar vein** receives the fifth lumbar vein and tributaries from the iliac fossæ, from the lower parts of the vertebral muscles, and from the vertebral canal. It accompanies the corresponding artery only in the abdomen proper, for it passes behind the psoas major muscle and ends in the back of the corresponding common iliac vein.

The venæ comitantes of the median sacral artery begin by the union of tributaries which issue from the venous plexus on the pelvic surface of the sacrum, through which they communicate with the lateral sacral veins and receive blood from the interior of the sacral canal. They unite above into a single **median sacral vein**, which ends in the left common iliac vein.

The **internal iliac vein** (Fig. 1097) is a short trunk formed by the union of tributaries which correspond to all the branches of the internal iliac artery with the exception of the umbilical and the ilio-lumbar arteries.

It begins at the upper border of the greater sciatic notch and ascends to the brim of the pelvis; there it unites with the external iliac vein to form the common iliac vein. It lies immediately behind the internal iliac artery, is crossed laterally by the obturator nerve, and is in relation medially, on the left side with the pelvic colon, and on the right side with the lower part of the ileum.

Tributaries.—The tributaries, which are numerous, are conveniently divided into extra-pelvic and intra-pelvic groups.

The *extra-pelvic tributaries* are all **parietal**; they are the superior and inferior gluteal, the obturator, and the internal pudendal veins.

The **superior gluteal veins** are the venæ comitantes of the superior gluteal artery, formed by tributaries which issue from the muscles of the gluteal region. They accompany the artery through the greater sciatic foramen, and end in the internal iliac vein, often as a single trunk.

The **inferior gluteal veins** are the venæ comitantes of the inferior gluteal artery, which begin in the subcutaneous tissues on the back of the thigh; they ascend with the artery and pass into the buttock on the deep aspect of the gluteus maximus, where they receive numerous tributaries from the surrounding muscles. Entering the pelvis through the greater sciatic foramen, they unite into a single vessel which ends in the lower and anterior part of the internal iliac vein below the termination of the obturator vein.

The **obturator vein** is formed by the union of tributaries which issue from the hip joint and from the muscles of the proximal and medial part of the thigh. It enters the true pelvis through the obturator canal, runs backwards and upwards along the side-wall of the pelvis, medial to the obturator fascia, immediately below the corresponding artery, and passes lateral to the ureter and the descending branches of the internal iliac artery to end in the internal iliac vein.

The **internal pudendal veins** are the venæ comitantes of the internal pudendal artery: in the male they emerge from the lower part of the *prostatic plexus*, which lies below and behind the inferior pubic ligament. They follow the course of the internal pudendal artery, and usually join together into a single vessel which ends in the internal iliac vein. They receive blood from the corpus cavernosum by the deep vein of the penis or clitoris, veins from the bulb, perineal and inferior rectal veins, and veins from the muscles of the gluteal region.

The **inferior rectal veins** begin in the substance of the external sphincter of the anus and in the walls of the anal canal; they anastomose through the *rectal plexus* with the middle and superior rectal veins, and consequently connect the portal and vena caval systems together.

The *intra-pelvic tributaries* of the internal iliac vein are **parietal** and **visceral**: the former are the lateral sacral veins; the latter are the efferent vessels from the plexuses around the several pelvic viscera.

Lateral sacral veins accompany the lateral sacral arteries, and end on each side in the corresponding internal iliac vein. They are connected together by an *anterior sacral venous plexus.*

The **pelvic venous plexuses** form dense networks of thin-walled veins associated with the rectum, bladder, prostate, uterus, and vagina. They communicate freely with one another, and from them the visceral tributaries of the internal iliac veins arise.

The **rectal plexuses** lie in the submucous coat of the rectum and anal canal and on the outer surface of their muscular coats. They are drained by the superior, middle, and inferior rectal veins; the superior rectal vein joins the portal system; the middle and inferior are tributaries of the systemic veins. The rectal plexuses, therefore, form a link between systemic and portal veins.

The **middle rectal veins** are very irregular; sometimes they cannot be distinguished. When present they are formed by tributaries which begin in the submucous tissue of the rectum, where they communicate with the superior and inferior rectal veins in the rectal plexus; they pass through the muscular coat, and fuse together to form two middle rectal veins, right and left, each of which runs laterally beneath the peritoneum to end in the corresponding internal iliac vein. In the male each middle rectal vein receives tributaries from the seminal vesicle and vas deferens of its own side.

The **prostatic plexus** is situated mainly within the substance of the fascial sheath of the prostate (Fig. 651, p. 768). In front it receives the deep dorsal vein of the penis; its posterior part communicates with the vesical plexus and its extension around the seminal vesicles and vasa deferentia. Efferent vessels pass from it on each side to open into the internal iliac vein, but it drains mainly through the vesical plexus.

The **vesical plexus** *in the male* lies on the outer surface of the muscular coat of the bladder. It is densest round the neck of the bladder, where it is continuous with the prostatic plexus, and at the base, where it extends around the seminal vesicles and around the ends of the ureters and the vasa deferentia. Several **vesical veins** pass from it on each side to the internal iliac vein.

The **vesical plexus** *in the female*, which represents the vesical and prostatic plexuses of the male, surrounds the upper part of the urethra and the neck of the bladder. It communicates with the vaginal plexus and receives the dorsal vein of the clitoris; and its efferent vessels end in the internal iliac vein.

The **uterine plexuses** lie along the borders of the uterus; they receive tributaries,

which are entirely devoid of valves, from the uterus; and they communicate above with the ovarian pampiniform plexuses, and below with the vaginal plexuses.

The **uterine veins**, usually two on each side, issue from the lower parts of the uterine plexuses, above their communications with the vaginal plexuses. At first the uterine veins lie in the medial part of the root of the broad ligament above the lateral fornix of the vagina and the ureter; they then pass backwards with the artery and end in the internal iliac vein. For their relation to other venous plexuses in the pelvis, see p. 1367.

The **vaginal plexuses** lie at the sides of the vagina. They receive tributaries from the walls of the vagina. They communicate with the uterine plexuses above; with the veins of the bulb below; in front with the vesical plexus; and behind with the veins which issue from the middle and lower parts of the rectal plexus. A single **vaginal vein** issues from the upper part of the vaginal plexus on each side; it accompanies the corresponding artery, and ends in the internal iliac vein.

Dorsal Veins of Penis and Clitoris.—There are two dorsal veins of the penis—the superficial and the deep.

The **superficial dorsal vein** receives tributaries from the prepuce, and runs backwards, immediately beneath the skin, to the pubic symphysis, where it divides into right and left branches which end in the superficial external pudendal veins.

The **deep dorsal vein** lies on the dorsum of the penis, deep to the deep fascia. It begins in the sulcus behind the glans by the union of numerous tributaries from the glans and the anterior parts of the corpora cavernosa; and it runs backwards in the mid-dorsal line in the sulcus between the corpora cavernosa, from which it receives many additional tributaries. At the root of the penis the vein passes between the two layers of the suspensory ligament, and then between the inferior pubic ligament and the transverse ligament of the perineum; and it ends by dividing into two branches which join the lower part of the prostatic plexus.

The **dorsal vein of the clitoris** in the female has a similar course to that of the deep dorsal vein of the penis in the male. It ends in the lower part of the vesical plexus and communicates with the internal pudendal veins.

The **external iliac vein** (Figs. 1097, 1100, and 1120) is the upward continuation of the femoral vein. It begins, on the medial side of the end of the external iliac artery, immediately behind the inguinal ligament, and ascends along the brim of the pelvis to end, opposite the sacro-iliac joint and immediately behind the internal iliac artery, by joining the internal iliac vein to form the common iliac vein. It lies, at first, on the medial side of the external iliac artery but on a slightly posterior plane, and then directly posterior to the artery, whilst just before its termination it crosses the lateral side of the internal iliac artery and separates that vessel from the medial surface of the psoas major muscle. In its whole course the vein lies anterior to the obturator nerve. It is usually provided with one or sometimes two bicuspid valves; but both are usually incompetent. Its tributaries correspond to the branches of the external iliac artery; that is, the deep circumflex iliac and inferior epigastric veins open into it close to its commencement. In addition, it frequently receives the pubic vein.

The **pubic vein** forms a communication between the obturator vein and the external iliac vein. It varies in size, and may form the main termination of the obturator vein, from which it arises. It begins in the obturator canal and ascends alongside the pubic branch of the inferior epigastric artery to reach the external iliac vein.

VEINS OF LOWER LIMB

The veins of the lower limb, like those of the upper limb, are arranged in two groups, the **superficial** and the **deep**; and in the lower limb as in the upper the deep veins are associated with the arteries as venæ comitantes, whilst the trunks of the superficial veins, which lie at first in the subcutaneous tissues, ultimately end in the deep veins. There is therefore a general similarity in the arrangement of the veins of the upper and lower limbs, but there are differences in detail which are of some importance. Thus, in the upper limb, there are two deep veins with each artery from the fingers to the root of the limb, where a single trunk, the axillary vein, is formed; but in the lower limb each main artery has two venæ comitantes only as far as the knee, where a single trunk

is usually formed. That vessel, the **popliteal vein**, is the commencement of the main venous stem of the lower limb; it is continued upwards through the thigh, as the **femoral vein**, and along the brim of the pelvis as the **external iliac vein**.

In the upper limb all the blood which passes through the superficial veins is poured into the efferent trunk at the root of the limb—the axillary vein; but in the lower limb the superficial veins of the lateral parts of the leg and foot join the popliteal vein at the knee, whilst those of the medial part of the limb join the femoral vein near the root of the limb in the femoral triangle.

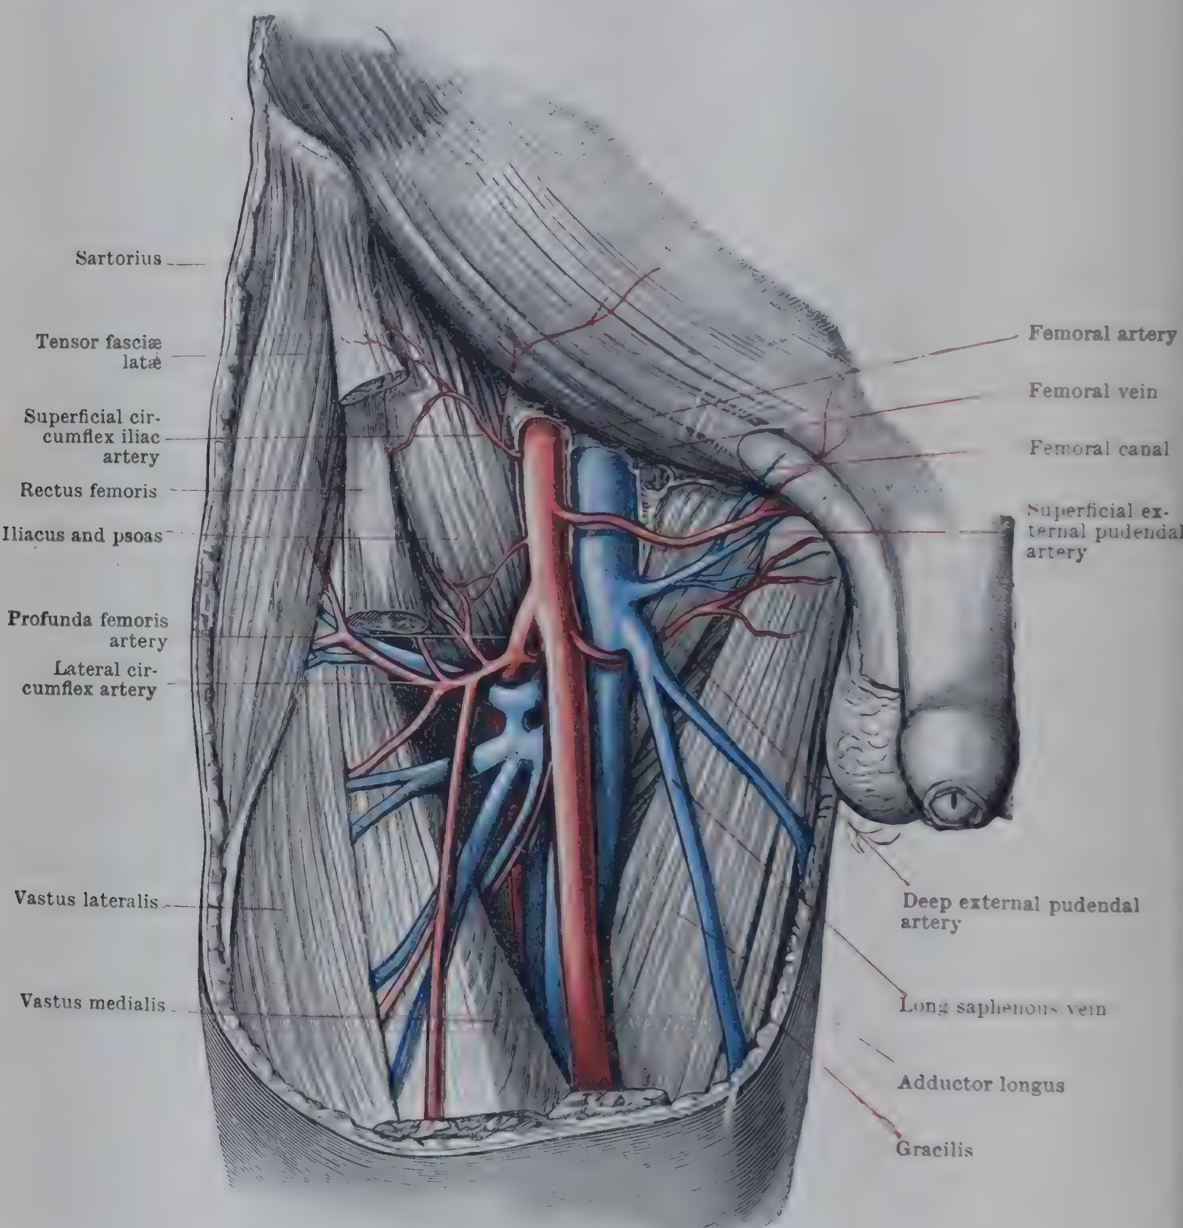

Fig. 1121.—Femoral Vessels in the Femoral Triangle.

In addition to these differences in the general arrangement of the veins of the limbs, it must be noted also that in the upper limb all the blood, from the shoulder-girdle region as well as from the free portion of the limb, is returned to the main efferent vein; but in the lower limb the greater part of the blood from the region of the pelvic girdle, and a considerable portion from the thigh, is returned by the gluteal, obturator, and internal pudendal veins to the internal iliac vein, which is not the main efferent vein of the limb.

Deep Veins of Lower Limb

Two *venæ comitantes* accompany all the arteries of the lower limb, except the popliteal and femoral trunks and the profunda femoris. They usually lie one on

each side of the artery; they are connected with one another by transverse channels which pass across the artery, and they are provided with numerous valves.

The **popliteal vein** (Figs. 1099, 1103, 1104) is formed, at the distal border of the popliteus muscle, by the union of the venæ comitantes of the anterior and posterior tibial arteries. At its commencement it lies to the medial side of, and slightly superficial to, the popliteal artery, and to the lateral side of the medial popliteal nerve; as it runs through the popliteal fossa it inclines laterally, and in the middle of the space it is directly posterior to the artery, separating the artery from the nerve which is still more posterior; and at the proximal part of the space it is postero-lateral to the artery, and still between it and the nerve. It then passes through the opening in the adductor magnus muscle and becomes the femoral vein.

The popliteal vein, which is provided with two or three bicuspid valves, is closely bound to the artery by a dense fascial sheath. Not uncommonly there are one or more additional satellite veins which anastomose with the popliteal vein, and in those cases the artery is more or less completely surrounded by venous trunks.

Tributaries.—In addition to venæ comitantes of the anterior and posterior tibial arteries, it receives tributaries which correspond with the branches of the popliteal artery, and it receives also one of the superficial veins of the leg—the short saphenous vein.

The **femoral vein** is the direct continuation of the popliteal vein. It begins at the junction of the middle and distal thirds of the thigh, at the opening in the adductor magnus muscle. It then ascends through the subsartorial canal and through the femoral triangle, and it ends a little medial to the middle of the inguinal ligament by becoming the external iliac vein.

In the subsartorial canal it lies at first postero-lateral to the femoral artery and then posterior to it, and it is anterior to the adductors magnus and longus, separated by the latter muscle from the profunda vessels. In the distal part of the femoral triangle it is still behind the artery, and immediately in front of the profunda vein which separates it from the profunda artery; but in the proximal part of the femoral triangle it is on the medial side of the femoral artery. About one and a quarter inches (30 mm.) below the inguinal ligament it enters the middle compartment of the femoral sheath, through which it ascends to its termination, lying between the compartment for the femoral artery on the lateral side and the femoral canal on the medial side. It usually contains two bicuspid valves—one near its termination and the other just proximal to the entrance of its profunda tributary.

Tributaries.—It receives: (1) the profunda femoris vein; (2) the long saphenous vein, which enters the femoral vein where that vessel lies in the middle compartment of the femoral sheath; (3) venæ comitantes of small unnamed arteries, of the descending genicular artery, of the lateral and medial circumflex arteries (branches of the profunda femoris), and of the deep external pudendal artery.

The **profunda femoris vein** lies in front of its artery and separates it from the adductor longus and the femoral vein. It receives the venæ comitantes of the muscular and perforating branches of its artery, but only occasionally those of the circumflex arteries, for they usually join the femoral vein direct. It is connected through the *perforating veins* with the veins of the back of the thigh.

Superficial Veins of Lower Limb

The superficial veins of the lower limb terminate in two trunks, one of which, the **short saphenous vein**, passes from the foot to the back of the knee; whilst the other, the **long saphenous vein**, extends from the foot to the groin. These veins are often enlarged and tortuous—the condition known as 'varicose veins'.

The superficial veins of the sole of the foot form a fine plexus, immediately under cover of the skin, from which anterior, medial, and lateral efferents pass. The anterior efferents end in a transverse **plantar venous arch** which lies in the furrow at the roots of the toes, and the medial and lateral efferents pass round the sides of the foot to the long or the short saphenous vein. The venous arch receives also small *plantar digital veins* from the toes, and it communicates between the heads of the metatarsals with the veins on the dorsum of the foot.

The superficial veins on the dorsal aspect of each toe unite to form two **dorsal digital veins**, which run along the borders of the dorsal surface. The dorsal digital veins of the adjacent borders of the interdigital clefts unite, at the apices of the clefts, to form four **dorsal metatarsal veins** which end in the dorsal venous arch of the foot. The dorsal digital vein from the medial side of the big toe ends in the long saphenous, and that from the lateral side of the little toe in the short saphenous vein.

FIG. 1122.—LONG SAPHENOUS VEIN AND ITS TRIBUTARIES.

The dorsal venous arch lies in the subcutaneous tissue, between the skin and the dorsal digital branches of the musculo-cutaneous nerve, opposite the anterior parts of the shafts of the metatarsal bones. It ends, medially, by uniting with the medial dorsal digital vein of the big toe to form the long saphenous vein, and laterally by joining the lateral dorsal digital vein of the little toe to form the short saphenous vein. The dorsal venous arch receives the dorsal metatarsal veins and interdigital efferents from the plantar venous arch; and numerous tributaries from the dorsum of the foot, which anastomose freely together forming a wide-meshed *dorsal venous network*, open into it from behind.

The **long saphenous vein** is formed by the union of the medial end of the dorsal venous arch with the medial dorsal digital vein of the big toe. It passes in front of the medial malleolus, crosses the medial surface of the distal third of the shaft of the tibia obliquely, and ascends, immediately behind the medial margin of the tibia, to the knee, where it lies medial to the posterior end of the medial condyle of the femur; continuing upwards, with an inclination forwards and laterally, it gains the proximal part of the femoral triangle, where it perforates the cribriform fascia and the femoral sheath and ends in the femoral vein. In the foot and leg it is accompanied by the saphenous nerve, and for a short distance distal to the knee by the saphenous branch of the descending genicular artery. In the thigh, branches of the medial cutaneous nerve lie in close relation with it. It has from eight to twenty bicuspid valves, but these become incompetent if the vein is varicose.

Tributaries.—It communicates freely, through the deep fascia, with the deep, intermuscular veins. In the foot it receives tributaries from the medial part of the sole and from the dorsal venous plexus. In the leg it is joined by tributaries from the

dorsum of the foot, the medial and ,posterior parts of the heel, the front of the leg and the calf; and it anastomoses freely with the short saphenous vein. In the thigh it receives numerous unnamed tributaries and superficial veins from the groin, which are the last tributaries to enter the long saphenous vein. They are the **superficial circumflex iliac**, **superficial epigastric**, and **superficial external pudendal veins**. They accompany the corresponding arteries, and end in the long saphenous vein immediately before it perforates the cribriform fascia. The superficial circumflex iliac vein receives blood from the lower and lateral part of the abdominal wall and the proximal and lateral parts of the thigh. The superficial epigastric vein drains the lower and medial part of the abdominal wall. The superficial external pudendal vein receives blood from the dorsum of the penis and the scrotum or from the labium majus.

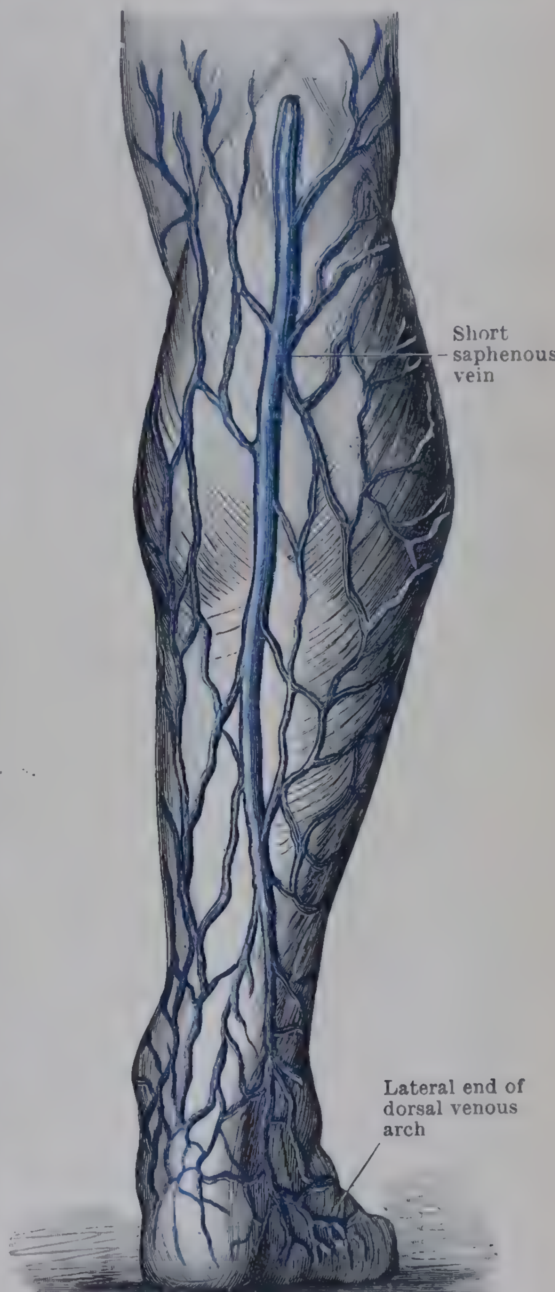

Fig. 1123.—Short Saphenous Vein and its Tributaries.

The tributaries of the superficial epigastric vein communicate above with the tributaries of the lateral thoracic veins which join the axillary vein. These communications thus unite main vessels which pass to the inferior vena cava and the superior vena cava respectively; and they may enlarge if there is any obstruction to the flow of blood in either of the venæ cavæ.

The **short saphenous vein** is formed by the union of the lateral end of the dorsal venous arch with the lateral dorsal digital vein of the little toe. At first it passes backwards in company with the sural nerve, along the lateral side of the foot and below the lateral malleolus, lying on the peroneal retinacula; then it ascends behind the lateral malleolus, and along the lateral border of the tendo calcaneus, still in company with the nerve, to the middle of the calf, whence it proceeds between the heads of the gastrocnemius to the popliteal fossa, where it pierces the deep fascia and ends in the popliteal vein. It communicates, round the medial side of the leg, with the long saphenous vein, and through the deep fascia with the deep veins. It contains from six to twelve bicuspid valves.

Tributaries.—It receives tributaries from the lateral side of the foot, the lateral side and back of the heel, the back of the leg, and, occasionally, a descending tributary from the back of the thigh. Just before it pierces the popliteal fascia it frequently gives off a small branch which ascends round the medial side of the thigh and unites there with a vein of some size to form the *accessory saphenous vein*, a channel through which a communication is established between the long and short saphenous veins. This communication may become enlarged and constitute the main continuation of the short saphenous vein.

Variations.—The **venæ comitantes** are generally described as ending at the distal part of the popliteal fossa, but they may ascend as far as the femoral triangle; one or more small additional veins usually accompany the popliteal and femoral arteries, although, as a rule, there is only one large popliteal and one large femoral vein. In a few cases the popliteal vein does not pass through the opening in the adductor magnus, but ascends behind that muscle and becomes continuous with the profunda vein, the femoral artery being unaccompanied by any large vein during its passage through the subsartorial canal.

The **long saphenous vein** is not subject to much variation, but the **short saphenous vein**

may end by joining the long saphenous, or, after piercing the deep fascia in the distal part of the thigh, it may ascend and join the inferior gluteal vein or one of the tributaries of the profunda vein.

PORTAL SYSTEM OF VEINS

The veins which form the **portal system** are the portal, the superior and inferior mesenteric and the splenic veins and their tributaries. They convey blood to the liver: (1) from the whole of the abdominal and pelvic parts of the alimentary canal, except the terminal part of the anal canal, (2) from the pancreas, and (3) from the spleen. The right branch of the portal vein receives the vein from the gall-bladder; and its left branch receives para-umbilical veins which pass along the round ligament of the liver and constitute one of the anastomoses between the portal and systemic veins. The tributaries of origin of the portal vein correspond with the branches of the splenic and the superior and inferior mesenteric arteries, after which they are named and which they accompany for a considerable distance. The larger or terminal veins leave their associated arteries; the **inferior mesenteric vein** joins the **splenic vein**, and the latter unites with the **superior mesenteric vein** to form the **portal vein**, which passes to the liver. All the larger vessels of this system, including the superior rectal vein, are devoid of valves, but valves are present in the tributaries in the fœtus, and some of them may remain in an imperfect condition in the smaller tributaries in the adult.

Unlike other veins, the portal vein ends like an artery by breaking up into branches which ultimately terminate in the sinusoidal capillaries in the substance of the liver; from the capillaries, which receive also the blood conveyed to the liver by the hepatic artery, the hepatic veins arise; and, as the hepatic veins open into the inferior vena cava, the portal blood ultimately reaches the general systemic circulation.

The portal vein conveys products of digestion to the liver, and, in addition to this important function, the whole portal system also acts as a reservoir of blood for the needs of the general circulation. It has been calculated that the portal system can contain about one-third of the total amount of blood in the body; and the amount of blood present can be varied by contraction or relaxation of the arteries by which it enters the system and of the terminal parts of the hepatic veins by which it leaves it. The spleen may be regarded as a specialized portion of the portal reservoir.

The **portal vein** is a wide venous channel, about three inches long (75 mm.). It begins by the union of the superior mesenteric and the splenic veins behind and to the left of the neck of the pancreas, at the level of the body of the first lumbar vertebra, and either anterior to the left border of the inferior vena cava, or in front of the upturned extremity of the uncinate process of the head of the pancreas. It ascends in front of the inferior vena cava and behind the neck of the pancreas and the first part of the duodenum, to the lower border of the opening into the lesser sac of the peritoneum, where it passes forwards above the duodenum and enters the lesser omentum. Continuing its upward course, it lies behind the bile-duct and hepatic artery, and in front of the opening into the lesser sac; it ultimately reaches the right end of the porta hepatis, where it ends by dividing into a short and wide right branch and a longer and narrower left branch.

The **right branch** generally receives the **cystic vein** and then enters the right lobe of the liver, in which it breaks up into numerous branches which end as *interlobular veins*, which are connected to the *sublobular* rootlets of the hepatic veins by the sinusoidal capillaries in the substance of the liver lobules (Fig. 563, p. 662).

The **left branch** runs from right to left, in the porta hepatis, giving off branches to the caudate and quadrate lobes; it crosses the fissure for the ligamentum teres, and it ends in the left lobe of the liver in the same manner as the right branch.

As it crosses the fissure, the left branch of the portal vein is joined in front

by the **round ligament** of the liver and some small accompanying veins, and behind by the **ligamentum venosum**. The round ligament is a fibrous cord which passes from the umbilicus to the left branch of the portal vein. It is the remains of the umbilical vein of the fœtus. The small *para-umbilical veins* which accompany it connect the left branch of the portal vein with the superficial veins round the umbilicus. The ligamentum venosum connects the left branch of the portal vein

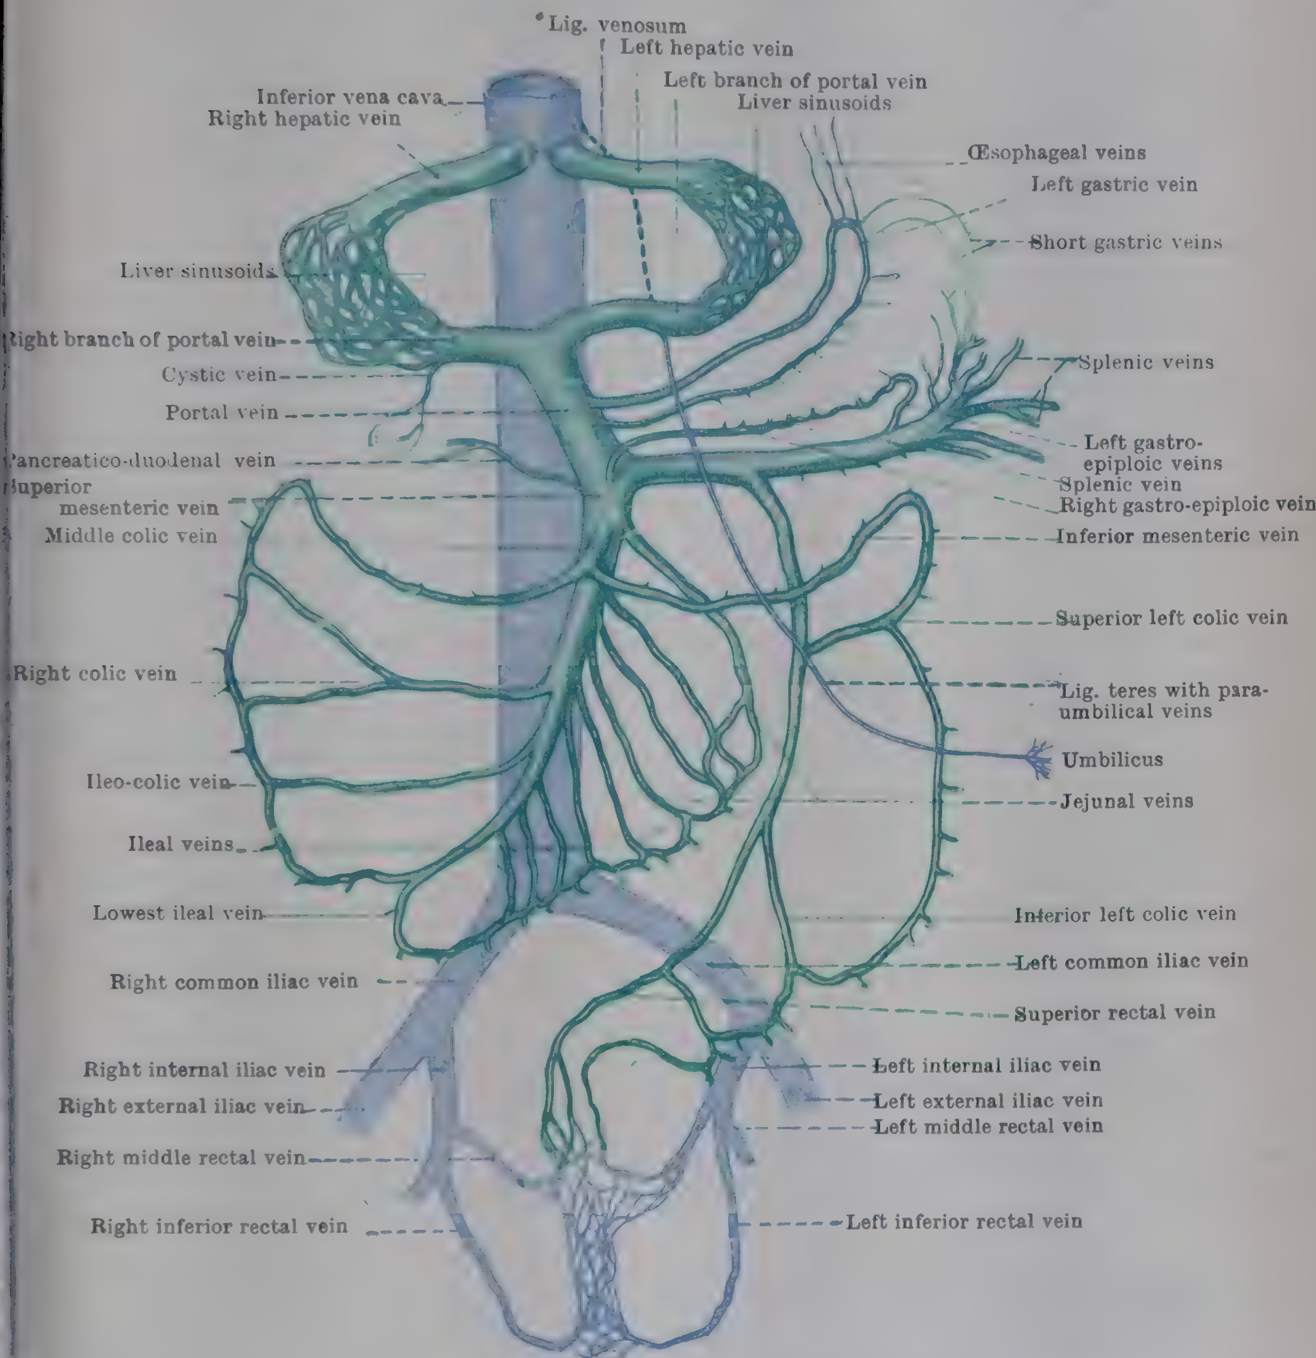

FIG. 1124.—SCHEME OF PORTAL SYSTEM OF VEINS (*green*) AND ITS CONNEXIONS WITH SYSTEMIC VEINS (*blue*).
It must be remembered that systemic blood carried by the hepatic artery also enters the liver capillaries ; therefore the hepatic veins contain both portal and systemic blood.

with the upper part of the inferior vena cava. It is the remains of a fœtal blood-vessel—the **ductus venosus**—through which blood, carried from the placenta by the umbilical vein, passed to the inferior vena cava without going through the liver. The portal vein is accompanied by numerous lymph-vessels, and it is surrounded, in the lesser omentum, by filaments of the hepatic plexus of nerves.

Tributaries.—Soon after its formation the portal vein receives the left and right gastric veins, and the cystic vein opens into its right branch.

The **left gastric vein** begins in the lesser omentum by the union of tributaries from both surfaces of the stomach. It runs with the left gastric artery along the lesser curvature of the stomach to the œsophagus, from which it receives tributaries. It then turns backwards and reaches the posterior wall of the abdomen, where it again changes its direction to run from left to right behind the lesser sac of the peritoneum to open into the portal vein as it passes forwards into the lesser omentum.

The **right gastric vein** is a small vessel which is formed by the union of tributaries from the upper parts of both surfaces of the pyloric portion of the stomach. It runs from left to right along the lesser curvature, between the layers of the lesser omentum, and ends in the portal vein after that vessel has entered the lesser omentum. It receives the **pre-pyloric vein** which marks the position of the pylorus (see p. 610).

The **cystic vein** is formed by the union of tributaries which accompany the branches of the cystic artery on the anterior and posterior surfaces of the gall-bladder; it ascends along the cystic duct and ends as a rule in the right branch of the portal vein. Some small veins pass directly from the gall-bladder into the substance of the liver.

The **superior mesenteric vein** begins in the right iliac fossa, and ascends along the right side of the superior mesenteric artery. In the greater part of its course it lies in the root of the mesentery, and crosses the right ureter and testicular or ovarian vessels, the inferior vena cava and the third part of the duodenum. There, it leaves the mesentery, ascends in front of the uncinate process of the pancreas, and, crossing behind the root of the transverse mesocolon, it ends behind the neck of the pancreas by uniting with the splenic vein to form the portal vein.

Tributaries.—It receives the veins that accompany the branches of the superior mesenteric artery, and also the right gastro-epiploic vein and pancreatico-duodenal veins, which enter it near its termination The **appendicular** and **anterior** and **posterior cæcal** veins unite to form it. The **ileal** and **jejunal** veins run from the small intestine to the root of the mesentery to join it. The **ileo-colic** and **right colic** veins enter it below the duodenum. It receives the **middle colic** vein where it crosses the root of the mesocolon.

The **right gastro-epiploic vein** runs from left to right along the greater curvature of the stomach, between the anterior two layers of the greater omentum. It receives tributaries from both surfaces of the stomach. Near the pylorus it turns backwards, and ends in the superior mesenteric vein.

The **pancreatico-duodenal veins** receive tributaries from the head of the pancreas and the adjacent parts of the duodenum; the lower vein may join the right gastro-epiploic; the upper vein ascends along the superior pancreatico-duodenal artery, and, before it ends in the upper part of the superior mesenteric vein or in the portal vein, receives a fairly large tributary that runs upwards on the left of the bile-duct.

The **splenic vein** is formed by the union of five or six tributaries which issue from the hilum on the gastric surface of the spleen. It passes backwards and medially, in the lieno-renal ligament, to the kidney, turns to the right and runs behind the body of the pancreas and below the splenic artery; it crosses the front of the abdominal aorta immediately below the origin of the cœliac artery, and ends behind the neck of the pancreas by joining the superior mesenteric vein to form the portal vein.

Tributaries.—It receives the short gastric veins, the left gastro-epiploic vein, the pancreatic veins, and the inferior mesenteric vein. Occasionally the left gastric vein ends in it.

The **short gastric veins** are a series of small vessels which gather blood from the region of the left portion of the greater curvature of the stomach; they pass backwards towards the spleen, in the gastro-splenic ligament, and end either in the trunk of the splenic vein or in its main tributaries.

The **left gastro-epiploic vein** runs from right to left along the greater curvature of the stomach between the anterior two layers of the greater omentum. It enters the gastro-splenic ligament, through which it passes towards the hilum of the spleen, and ends by joining the commencement of the splenic vein. It receives tributaries from both surfaces of the stomach.

The **pancreatic veins** issue from the pancreas, and end at once in the splenic vein.

The **inferior mesenteric vein** is the continuation of the **superior rectal vein**, and it receives the **inferior left colic veins** from the pelvic colon and iliac portion of the descending colon, and the **superior left colic vein** from the upper part of the descending colon and the left flexure. It begins on the middle of the left common iliac artery. It runs upwards along the left side of its own artery and the aorta, to the right of the ureter, on the front of the left psoas major muscle, crossing superficial to the left testicular or ovarian vessels, and superficial or deep to the inferior and superior left colic arteries. In most of its course it is directly behind the peritoneum, but near its upper end it passes behind the duodeno-jejunal flexure, and then, crossing in front of the left renal vein, it ends in the splenic vein behind the pancreas. Occasionally it bends to the

right to end in the junction of the splenic and superior mesenteric veins. It is longer than its companion artery, as it ascends to a higher level than the origin of the artery.

The **superior rectal vein** drains the greater part of the blood from the rectum. It arises by the union of tributaries from the rectal venous plexuses, through which it communicates with the middle and inferior rectal veins. It ascends, in company with the superior rectal artery and between the layers of the pelvic mesocolon, to the inlet of the pelvis, where it ends on the front of the left common iliac artery by becoming the inferior mesenteric vein.

Communications between Portal and Systemic Veins.—Important venous anastomoses take place between the outlying tributaries of the portal system and systemic veins. The most notable of these communications occur at the lower end of the œsophagus (between the left gastric vein and œsophageal veins which join the azygos system) and in the rectal plexus of veins (between the superior rectal vein and the middle and inferior rectal veins, which pass to the internal iliac). In both of these situations the communicating veins may enlarge; in the region of the anal canal such varicose enlargements of the veins are known as *hæmorrhoids* or piles. Owing to the free anastomoses between the venous plexuses in the pelvis, portal obstruction may affect plexuses other than those of the rectum; this may be of clinical importance in the case of the uterine veins (Wermuth, 1939).

The communication with superficial veins around the umbilicus by para-umbilical veins which reach the left branch of the portal vein along the round ligament of the liver has been mentioned already. Obstruction to the passage of blood through the liver is often indicated by the appearance of enlarged superficial veins radiating from the umbilicus—the so-called *caput medusæ*. Enlarged veins may also appear in the falciform ligament or on the "bare area" of the liver and communicate with the veins of the diaphragm and the internal mammary veins. Other communications occur on the posterior wall of the abdomen between intestinal tributaries of the portal vein and the renal or lumbar veins or small retroperitoneal tributaries of the inferior vena cava.

DEVELOPMENT OF BLOOD-VASCULAR SYSTEM

DEVELOPMENT OF HEART AND ARTERIES

In the general account of the development of the embryo (pp. 89-92) it has been pointed out that the primitive vascular system, from which the main blood-vessels of the adult are derived, consists of :—

(1) A tubular heart, separated by constrictions into six parts named, from the caudal to the cephalic end, the sinus venosus, the atrium, the atrio-ventricular canal, the ventricle, the bulbus cordis, and the truncus arteriosus.

(2) Two ventral aortæ.

(3) Two dorsal aortæ fused in parts of their extent to form a median descending aorta.

(4) Six pairs of aortic arches, of which four pairs, the first to the fourth, connect the ventral aortæ with the unfused portions of the dorsal aortæ; one pair, the fifth, connects the ventral aortæ, for a short time, with the dorsal parts of the sixth arches; and the remaining pair, the sixth, connects the truncus arteriosus with the unfused parts of the dorsal aorta.

(5) Seven pairs of venous trunks, the vitelline, the umbilical, the anterior cardinal, the posterior cardinal, the ducts of Cuvier (common cardinals), the subcardinals, and the supracardinals, of which only three pairs—the vitelline veins, the umbilical veins, and the ducts of Cuvier—open directly into the venous sinus of the heart (Fig. 104, p. 90).

It was noted also : (*a*) that the dorsal aortæ give off a series of paired branches through which blood passes from the aortæ to networks of capillary vessels from which it is collected into the veins; (*b*) that the venous trunks are connected with their fellows of the opposite side, across the median plane, by transverse anastomoses; and (*c*) that anastomoses are formed between the posterior cardinal, the subcardinal, and the supracardinal veins (p. 91).

The further changes in the development of the heart and the blood-vessels have now to be considered.

Development of Heart.—The development of the heart is a complex process of which only an outline is given here. Full accounts, with bibliographies, are provided in special works on Human Embryology (see list of References, p. 101); and the models of His (1886) and Born (1889), illustrating their classical accounts, are to be found in most Anatomical Museums. For the early stages, consult Davis (1927); for the external form of the heart and the separation of its chambers, Waterston (1918); and for a standard general account, see Tandler (1912, 1913).

In the early part of the fourth week, when the embryo is about 2 mm. long, the heart is formed, in the septum transversum and the dorsal wall of the pericardium, by the fusion of the caudal parts of the ventral aortæ (Figs. 102, 103, p. 89).

The sinus venosus lies for a time in the septum transversum, where it receives the ducts of Cuvier, the vitelline veins, and the umbilical veins; and, after a short period, it begins to project out of the septum transversum into the dorsal part of the pericardium.

After its formation the heart elongates more rapidly than the pericardium and therefore

bends into the form of a loop, of which the cephalic limb is formed by the truncus arteriosus and the bulbus cordis, the apex, which lies ventrally, by the ventricle, and the caudal limb by the atrium and the sinus venosus (Fig. 1125). The interval between the cephalic and caudal limbs is filled by a fold of the lining pericardium which constitutes the mesocardium.

As the heart folds longitudinally it is also bent in the transverse plane, so that, for a time, the more cephalic part of the ventricle, with the bulbus cordis and the truncus arteriosus, lies towards the right of the more caudal part of the ventricle and the atrium and sinus venosus, and the atrio-ventricular orifice enters what, for a period, is the left limb of the ventricle (Fig. 1125).

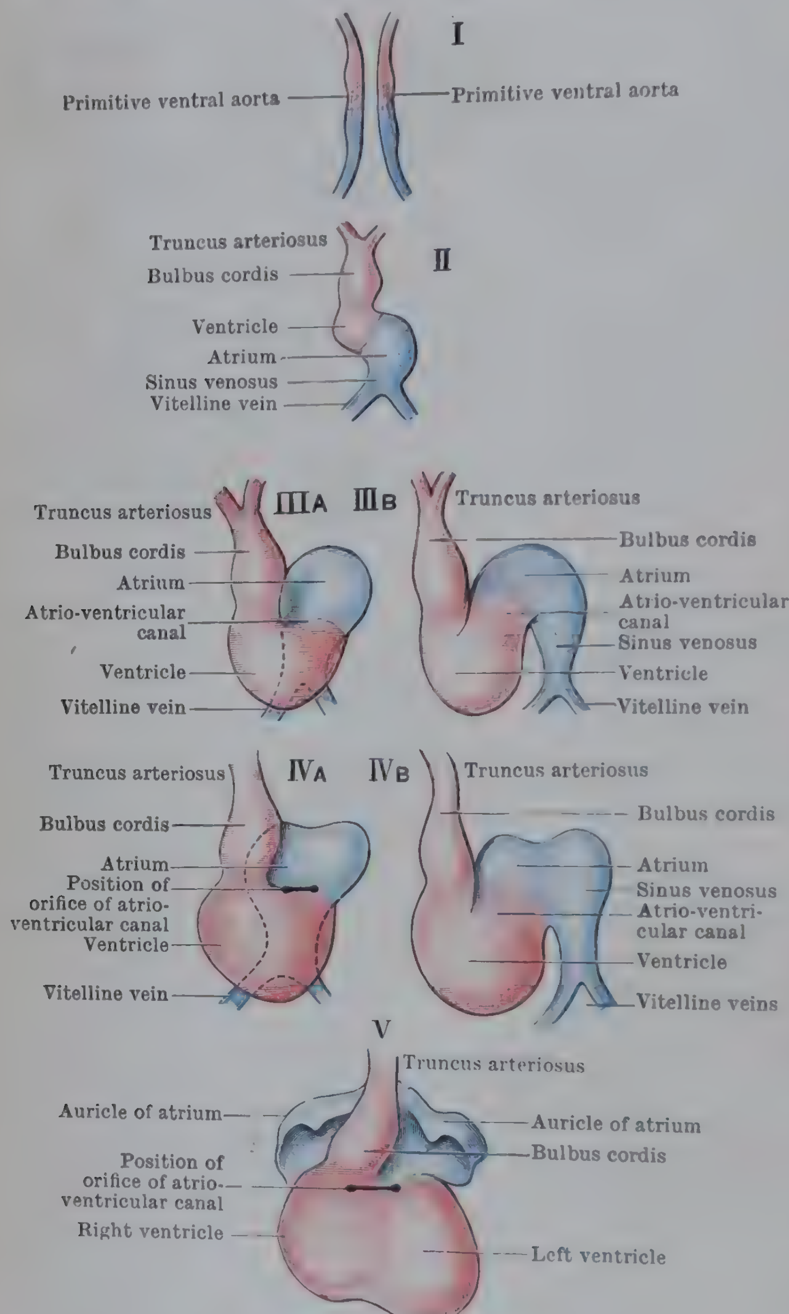

FIG. 1125.—DEVELOPMENT OF THE HEART.

Diagrams showing the changes in form and relation of parts at different stages. Modified from His's models. IIIB and IVB are side views; the other figures represent the heart as seen from the front.

Afterwards, as the ventricle enlarges mainly ventrally, laterally, and headwards, the atrio-ventricular orifice is transposed to the middle of its dorsal wall, the right segment of the sinus venosus is absorbed into the atrium, and the atrium, thus reinforced, expands round the sides of the bulbus cordis and the truncus arteriosus (Fig. 1125).

Subsequently the bulbus cordis is absorbed, partly into the ventricle and partly into the truncus arteriosus, and thereafter the truncus itself is divided into the pulmonary trunk and the ascending part of the aorta, whilst the mesocardium, which lay in the angle between the truncus arteriosus and the atrium, disappears, leaving an aperture—the transverse sinus of the pericardium—through which the right and left halves of the pericardial cavity communicate with each other on the dorsal and cephalic side of the ventricle, on the dorsal side of the ascending aorta and the pulmonary trunk, and on the ventral side of the atrium.

While the changes in position and shape of the heart, the disappearance of the mesocardium, and the division of the truncus arteriosus are taking place, the cavities of the atrium, the atrio-ventricular canal, and the cavity of the ventricle are all being divided into right and left halves by means of septa, which it is convenient to consider separately although they are formed simultaneously and fuse with one another in parts of their extent.

Division of Atrio-Ventricular Canal.—After the longitudinal folding of the primitive cardiac tube has occurred, the atrio-ventricular canal runs dorso-ventrally (from behind forwards in the erect posture) from the atrium to the ventricle. At first it is cylindrical in form, but gradually its cephalic and caudal walls are thickened to form *endocardial cushions*, which project into the middle of the lumen of the canal and convert it into a cleft (Figs. 1126, 1128). Finally the cushions fuse, forming an atrio-ventricular septum but leaving the right and left margins of the canal intact as the *right* and *left atrio-ventricular orifices*.

Later, partly by invagination into the ventricle and partly by the growth of the margins of the atrio-ventricular orifices into the ventricles, the cusps of the atrio-ventricular valves are formed (Fig. 1128).

Occasionally, the atrio-ventricular cushions obliterate not only the middle of the lumen of the atrio-ventricular canal but also one of its margins. In such cases only a single atrio-ventricular

orifice is found in the later stages, right or left as the case may be. When such an abnormality occurs it is usually associated with incomplete formation of the atrial and ventricular septa.

Division of Atrium.—The division of the primitive atrium into right and left atria is brought about by the formation and fusion of two septa—the septum primum and the septum secundum — and the fusion of both with the atrial end of the septum of the atrio-ventricular canal.

The *septum primum* is so called because it appears and partially disappears before the septum secundum is developed. It grows ventrally from the dorsal and cephalic walls of the atrium until it meets and fuses with the septum of the atrio-ventricular canal, and, as it grows, the area of communication between the right and left parts of the atrium is gradually reduced to an aperture. The aperture is called the *ostium primum* (Fig. 1126). It is obliterated when the septum primum fuses with the septum of the atrio-ventricular canal, but, before that fusion occurs, an aperture called the *ostium secundum* (Born, 1889) or *foramen ovale* appears in the dorsal and caudal part of the septum primum (Fig. 1126).

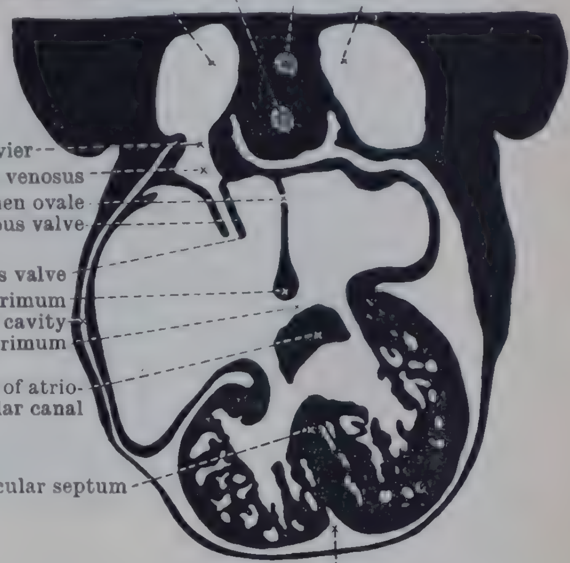

Fig. 1126.—Section of Heart of Human Embryo, showing Development of Septa. (Edinburgh University collection.)

The *septum secundum* grows from the cephalic and ventral walls of the atrium, immediately to the right of the septum primum.

When the growth of the septum secundum has caused its dorsal margin to pass beyond the dorsal margin of the foramen ovale, the latter margin acts as a flap-valve which permits blood to pass through the foramen ovale, from the right to the left atrium, but prevents its return. That condition is retained until a short time after birth, when the right surface of the septum primum fuses with the left surface of the septum secundum and the orifice is permanently closed.

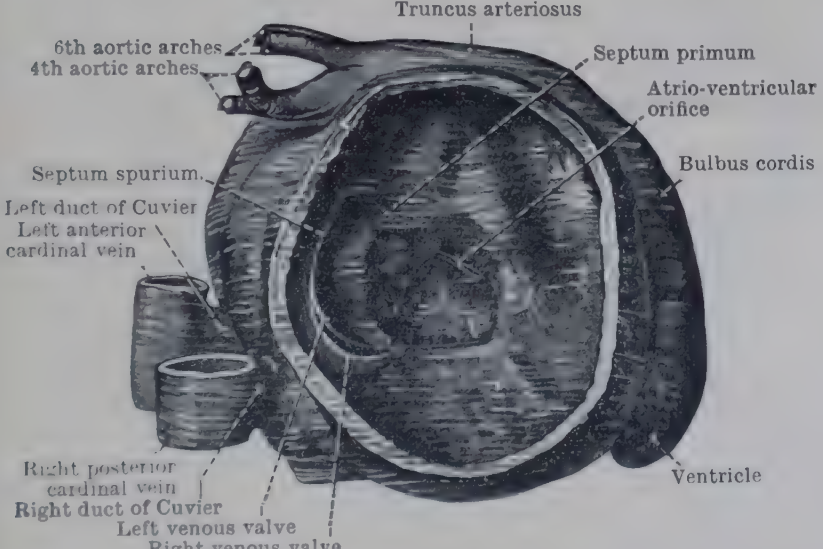

Fig. 1127.—Interior of Right Atrium of Human Embryo, 5·5 mm. long. (Edinburgh University collection. Reconstruction model by C. C. Wang.)

As a result of incomplete development the atrial septum may be absent and the common atrium then communicates with both ventricles. In other cases the septum is incompletely formed, and one or other, or both, of the interatrial foramina persist to adult life.

If the ventral end of the septum primum fails to fuse with the septum of the atrio-ventricular canal, the ostium primum persists, and is found as an aperture which lies between and immediately dorsal (posterior in the erect posture) to the atrio-ventricular apertures.

If the right surface of the septum primum fails to fuse with the left surface of the septum secundum, a more or less reduced foramen ovale persists. Such a condition is found in 10 per cent of adults examined in the post-mortem room.

Division of Truncus Arteriosus and Cranial Part of Bulbus Cordis.—It has already been noted that the bulbus cordis is absorbed partly into the truncus arteriosus and partly into the ventricular segment of the heart. As the absorption proceeds, endocardial cushions develop in the truncus arteriosus and pass spirally along its inner wall into the ventricle. At the apex of the truncus, where it gives off the ventral aortæ and the sixth aortic arches, four endocardial cushions are found. They are placed ventrally, dorsally, and right and left.

The ventral and dorsal cushions disappear in normal cases, but the right and left cushions

pass spirally along the vessel into the ventricle, and they fuse together to form a septum which divides the lumen of the truncus arteriosus into two passages.

At the apex of the truncus, the septum (formed from right and left cushions) divides the arterial trunk into a ventro-cranial (anterior in the erect posture) or aortic passage, which communicates with the ventral aortæ, and a dorso-caudal or pulmonary passage, which remains continuous with the sixth pair of aortic arches, which become parts of the pulmonary arteries.

At that level the septum has ventro-cephalic and dorso-caudal surfaces and right and left borders. But as it passes towards the ventricle it twists like a right-handed spiral, its right border first becoming dorsal, next left lateral, and finally ventral; consequently the surface which was originally dorso-caudal becomes ventro-cephalic, and as a result, when the ventricular end of the septum passes into the ventricle, the blood from the right part of that chamber is directed into the sixth pair of aortic arches, which become parts of the pulmonary arteries, and that from the left part into the ventral aortæ and the four anterior aortic arches, which help to form the main arterial trunks of the head, neck, and upper limbs of the adult.

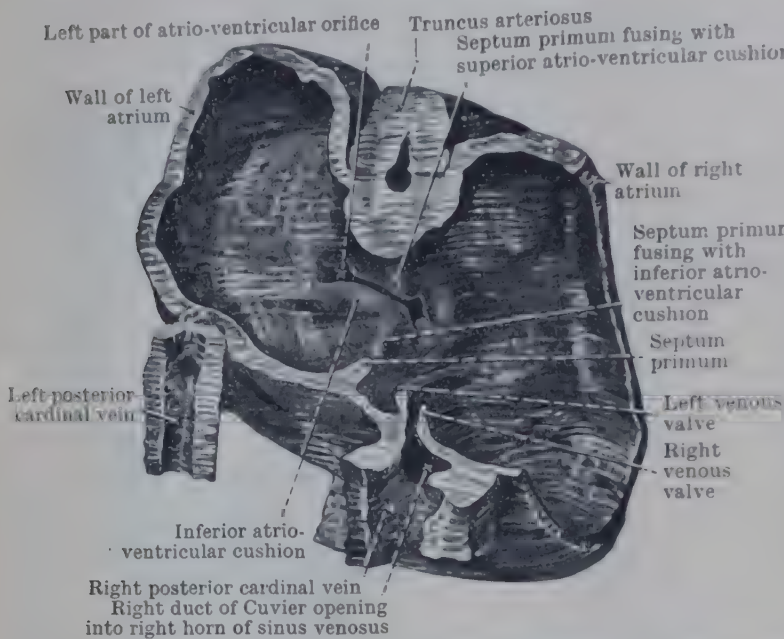

FIG. 1128.—INTERIOR OF ATRIA OF HUMAN EMBRYO 5·5 MM. LONG, VIEWED FROM BEHIND. (Edinburgh University collection. Reconstruction model by C. C. Wang.)

After the septum is completed it is split longitudinally, and so the truncus arteriosus is divided into the ascending aorta and the pulmonary trunk.

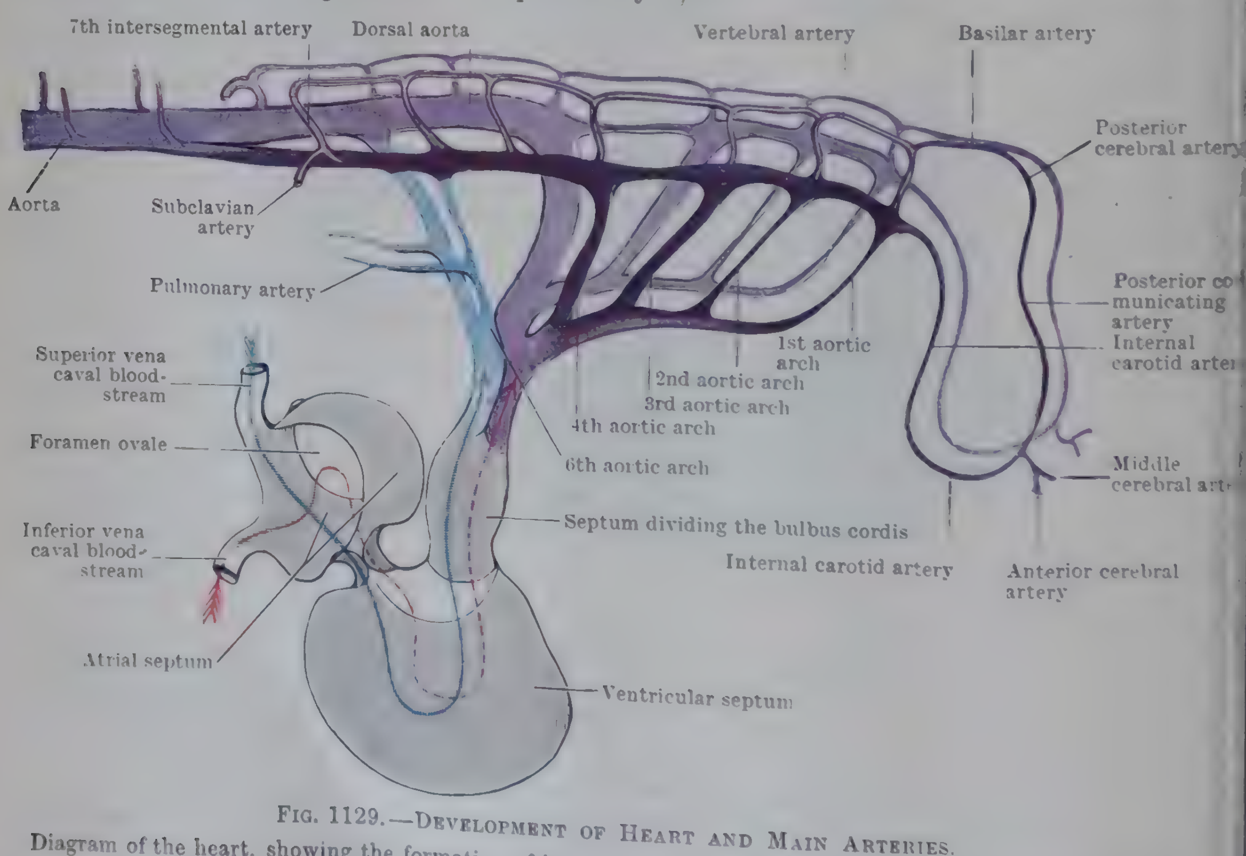

FIG. 1129.—DEVELOPMENT OF HEART AND MAIN ARTERIES.
Diagram of the heart, showing the formation of its septa, and of the cephalic portion of the arterial system.

Division of Ventricle.—As the bulbus cordis is absorbed (p. 1368), and the cavities of the truncus arteriosus and the atrium are divided by the formation of septa, the septum which divides the ventricle into right and left parts also appears.

It begins as a fold of the ventricle wall, immediately to the right of its most ventral

point, and its position is indicated on the surface by a sulcus (Fig. 1126) which sometimes remains to produce a bifid apex of the heart. The fold takes form mainly as a result of the active outgrowth of the right and left ventricles; it consists of the muscular substance as well as the endocardial lining, and it projects into the cavity not only from its ventral but also from its cephalic and caudal walls; hence the septum, in the early stages, is semilunar in form.

The cephalic horn of the semilune advances along the wall of the ventricle until it meets the cephalic margin of the ventricular part of the septum of the truncus arteriosus, with which it fuses. The caudal margin travels along the caudal wall of the ventricle until it meets and fuses with the septum of the atrio-ventricular canal (Fig. 1129). The concave margin of the semilunar septum lies ventral to the aperture leading into the truncus arteriosus; therefore, for a time, there exists an aperture, ventral to the truncus, through which the right and left ventricles communicate with each other. The aperture is closed by proliferation of the atrio-ventricular cushions to meet and fuse with the dorsal concave margin of the ventricular septum below and the septum of the truncus arteriosus above (Odgers, 1938).

The ventricular septum of the adult consists, therefore, of two parts—a ventral and larger muscular part, formed from the wall of the ventricle, and a dorsal and smaller membranous part (pars membranacea), formed from an extension of the atrio-ventricular cushions.

The more common abnormalities which result from the non-completion or the modification of the developmental processes in the ventricular area are :—

(1) The proliferation of the atrio-ventricular cushions may fail, in which case the pars membranacea septi is absent and an interventricular foramen exists through which the cavities of the two ventricles communicate with each other, and each ventricle opens into both the aorta and the pulmonary artery.

(2) The muscular part of the ventricular septum may be absent. There is then only one ventricular cavity, which receives blood from both atria and projects it into both the pulmonary trunk and the aorta.

(3) The septum of the truncus arteriosus may form a left-handed instead of a right-handed spiral, with the result that the pulmonary trunk communicates with the left ventricle and the aorta with the right ventricle.

(4) The spiral twist of the septum of the truncus arteriosus may be incomplete, so that its ventral margin meets the dorsal margin of the ventricular septum more or less at right angles, then the pulmonary trunk and the aorta both communicate with each of the ventricles.

Many other abnormalities, due to interference with or alterations of the ordinary processes of development, occur; for accounts of them readers who are interested must consult monographs on malformation of the heart (Keith, 1909; Walmsley, 1929; Abbott, 1936).

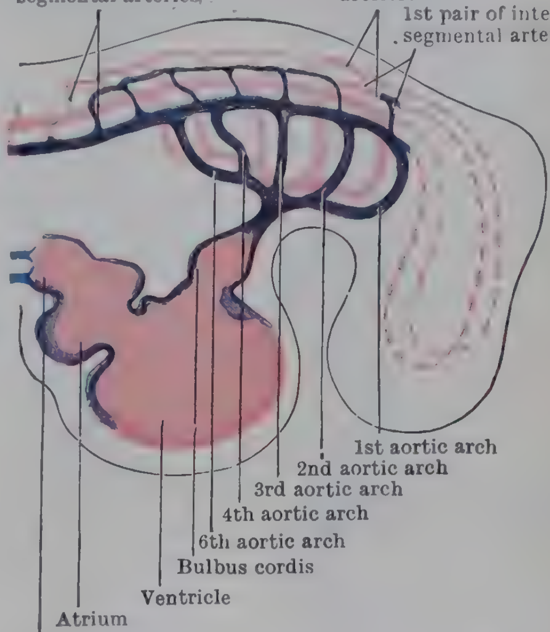

Fig. 1130.—Scheme of Stage of Five Aortic Arches. The cardinal veins and ducts of Cuvier are not shown.

Fate of Sinus Venosus.—The sinus venosus, which constituted the most caudal part of the primitive heart, was formed, in the septum transversum, by the fusion of the terminal parts of the common vitello-umbilical venous trunks. It consists of a single chamber possessing a right and a left horn and a middle section.

Each horn, at that time, receives a duct of Cuvier, a vitelline vein and an umbilical vein. Later, as the longitudinal folding of the cardiac tube occurs, the sinus venosus emerges from the septum transversum and appears in the caudal part of the pericardium. There it lies dorsal to the atrium into which its right horn opens through an orifice guarded by right and left venous valves (Figs. 1127, 1128) which fuse with each other at their cephalic and caudal ends.

As development proceeds, the right horn of the sinus venosus is absorbed into the right atrium, the whole of the left and the cranial part of the right venous valves disappearing, whilst the caudal part of the right valve becomes the valve of the inferior vena cava, which is the modified termination of the right vitelline vein (see Development of the Portal System, p. 1377).

The left horn of the sinus venosus remains as the coronary sinus of the fully developed heart, and the dorsal wall of the middle section is projected ventrally towards the right atrium, to form the valve of the coronary sinus, which lies at the right margin of the opening through which the coronary sinus communicates with the right atrium (Fig. 1060, p. 1229).

Fate of Ventral Aortæ, Aortic Arches, and Unfused Parts of Dorsal Aortæ.—When five pairs of aortic arches have developed (p. 91), the first and second pairs connect the ventral aortæ with the unfused parts of the dorsal aortæ, whilst the third, fourth, and sixth pairs—the transitory fifth pair appear later—arise from a common stem which springs from the apex of the truncus arteriosus and also join the unfused dorsal aortæ (Fig. 1130).

As the embryo increases from 5 mm. to 9 mm. in length: (1) the third and fourth pairs of arches are transferred to the ventral aortæ; (2) a transitory fifth pair of arches appears and for a time connects the ventral aortæ with the dorsal parts of the sixth pair of arches; (3) the first two pairs of arches have begun to disappear; and (4) the right and left pulmonary arteries have grown from the corresponding sixth pair into the rudiments of the lungs (Fig. 1131).

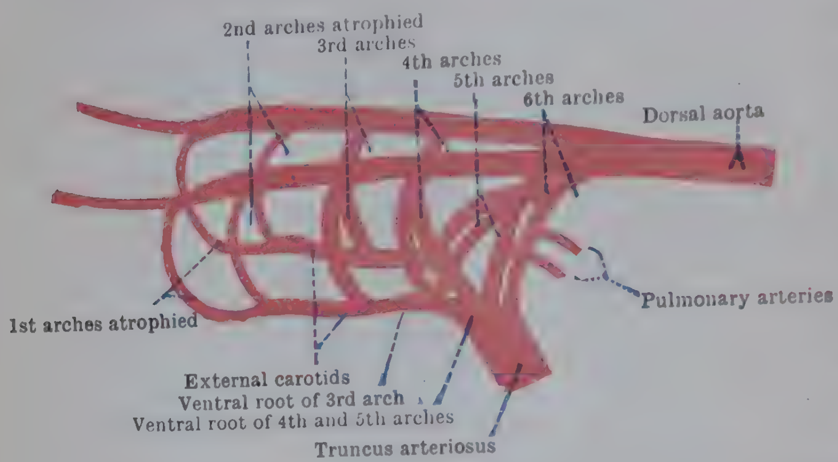

FIG. 1131.—SCHEME OF AORTIC ARCHES OF EMBRYO 9 MM. LONG. (After Tandler, 1909, modified.) The first and second arches have atrophied and the transitory fifth has appeared.

As soon as two or more arches arise from the ventral aortæ it is customary, for convenience of description, to speak of the parts of the ventral aortæ which lie caudal to the various arches as the ventral roots of those arches, and the corresponding parts of the dorsal aortæ are called the dorsal roots of the arches; therefore, at the 9 mm. stage, if the fifth pair of arches are left out of consideration on account of their very transitory and unimportant nature, it may be said that the first four pairs of arches have ventral roots. The sixth pair of arches spring from the apex of the truncus arteriosus, and therefore are devoid of ventral roots; but all the arches have dorsal roots, and the dorsal roots of the sixth pair end in the descending aorta, which was formed by the fusion of the more caudal portions of the primitive right and left dorsal aortæ.

The main events of the subsequent changes which occur before the embryo is 15 mm. long may be summarized as follows:—

(1) The following parts have disappeared:

(*a*) The dorsal roots of the third pair of arches.
(*b*) The dorsal roots of the right fourth and sixth arches.
(*c*) The dorsal part of the right sixth arch.

(2) In the meantime the truncus arteriosus has been divided into the ascending aorta, which passes from the left ventricle to the ventral roots of the fourth pair of arches, and the pulmonary trunk which connects the right ventricle with the sixth pair.

(3) The ventral root of the right fourth arch has become the innominate artery.

(4) The ventral root of the left fourth arch and the fourth arch itself have been converted into part of the arch of the aorta.

(5) The right fourth arch has become the right subclavian artery.

(6) The ventral roots of the third pair have become the common carotid arteries.

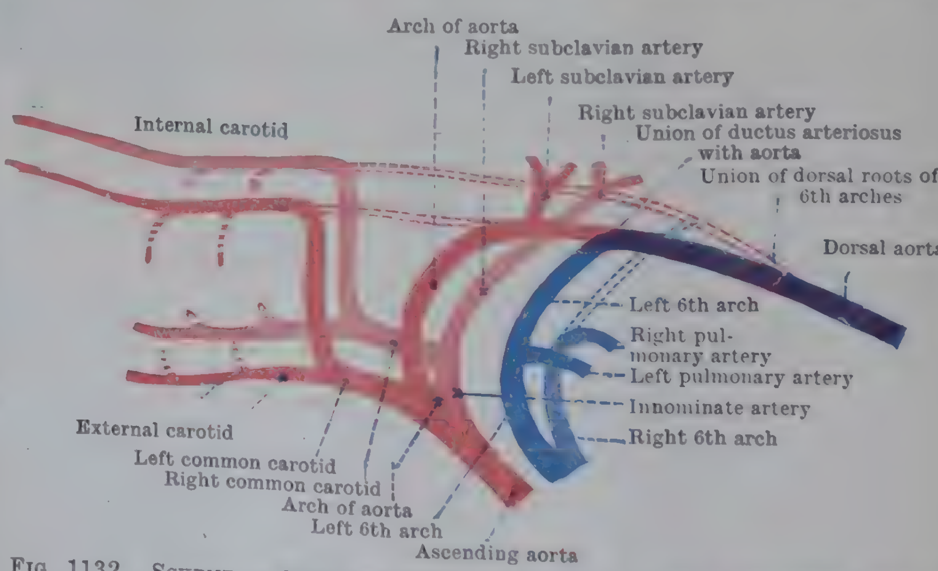

FIG. 1132.—SCHEME OF PART OF ARTERIAL SYSTEM OF FŒTUS SEEN FROM LEFT SIDE. Parts of the first and second arches, the dorsal roots of the third arches, the dorsal part of the right sixth arch, and the dorsal roots of the right fourth and fifth arches have atrophied. The position of the fifth arch is not indicated; see Fig. 1131.

(7) The ventral roots of the first and second pair have become the external carotid arteries.

(8) The third pair of arches and the dorsal roots of the first and second pairs of arches have formed the internal carotid arteries.

(9) The dorsal root of the left fourth arch has become part of the arch of the aorta.

(10) The dorsal root of the left sixth arch has become the first part of the descending aorta.

(11) The dorsal part of the left sixth arch has become the ductus arteriosus, through which blood, which has passed from the right ventricle into the pulmonary trunk, is transmitted into

the aortic arch until birth; then the dorsal part of the left sixth arch becomes the ligamentum arteriosum; the ventral part of the left sixth arch becomes the extra-pulmonary part of the left pulmonary artery.

(12) The dorsal part of the right sixth arch disappears and the ventral part becomes the extra-pulmonary portion of the right pulmonary artery.

For the transformation of the system of aortic arches, consult Congdon (1922), and for the development of the cranial arteries, Padget (1948).

Many variations of the main stems of the adult arterial system are the result of modifications of the ordinary developmental changes which have been noted. Parts which usually disappear may remain; parts which usually remain may disappear; and fusions and absorptions of parts which usually remain distinct may occur.

If the dorsal roots of the right fourth and sixth arches persist, in addition to the persistence of the same parts of the left side, both right and left aortic arches are formed, and the more cephalic part of the descending aorta is doubled, an arrangement which is found in adult reptiles.

If the dorsal roots of the right fourth and sixth arches persist and the corresponding parts on the left side disappear, the arch of the aorta is transposed from the left to the right side. That is the regular occurrence in birds.

If the right fourth arch disappears, and the dorsal roots of the right fourth and sixth arches persist—a not uncommon variation—then the right subclavian artery arises from the descending aorta caudal to the origin of the left subclavian artery.

If the ventral roots of the fourth pair of arches fuse, a common stem is formed, which arises from the arch of the aorta and gives origin to the right subclavian and both common carotid arteries.

If the ventral roots of the third and fourth pairs of arches all fuse, a common stem is formed, which springs from the arch of the aorta; it gives off the right subclavian artery and the external and internal carotid arteries of both sides.

High division of the common carotid, on either side, may be due to the disappearance of the third arch and the dorsal roots of the second and third arches, and the persistence of the second arch.

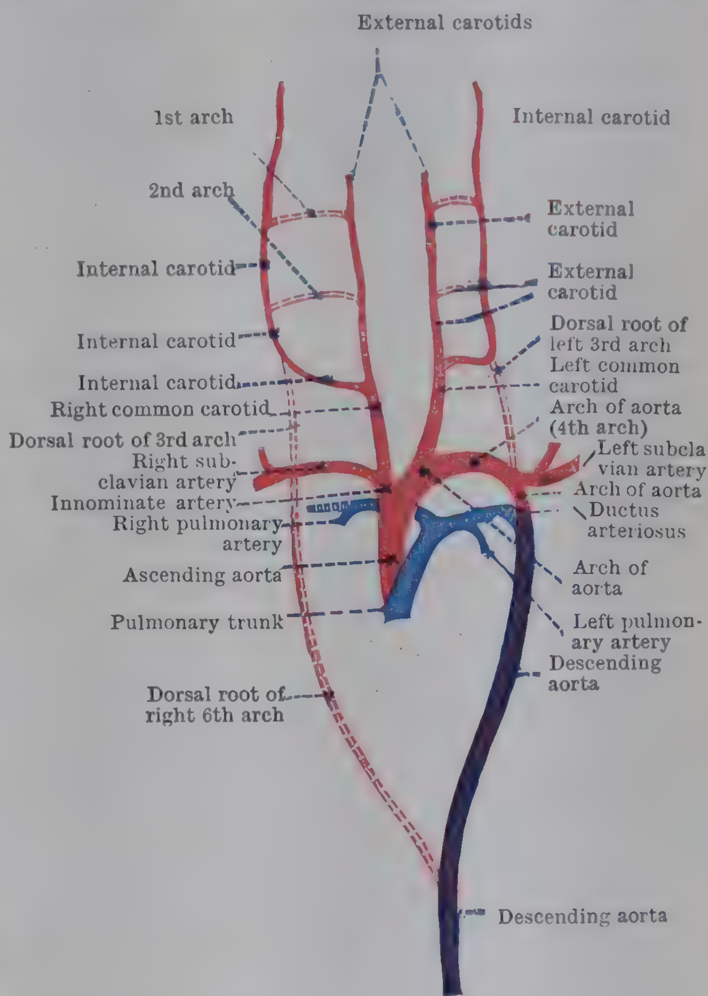

FIG. 1133.—SCHEME OF PART OF ARTERIAL SYSTEM OF FŒTUS SEEN FROM THE FRONT. The positions of the first and second arches, the dorsal roots of the third arches on both sides, and the dorsal roots of the fourth and sixth arches on the right side are shown by dotted lines. The positions of the fifth arches are not shown.

Branches of External Carotid Artery.—All the typical branches of the external carotid artery are present in embryos about 15 mm. long; little is known, however, regarding the details of their development. It is probable that the maxillary artery and its branches are evolved partly from the ventral part of the first aortic arch and partly from an anastomosis with the branches of a temporary *stapedial artery*, which develops from the dorsal end of the second arch; but it is not known whether the other branches of the external carotid spring as offsets from the ventral roots of the first or second arches or from the ventral parts of the arches themselves.

Descending Aorta.—The greater part of the descending aorta is formed by the fusion of the primitive dorsal aortæ. In embryos with twenty-three mesodermal somites the primitive dorsal aortæ are fused together from the tenth to the sixteenth segment (Fig. 104, p. 90). At a later period the fusion is continued caudalwards to the twenty-third body segment—the level of the fourth lumbar vertebra—where the common iliac arteries arise. Still later the small terminal portions of the primitive dorsal aortæ fuse together to form the median sacral artery, which runs to the end of the coccygeal region.

If the three somites which lie nearest the head-end, in embryos possessing twenty-three somites, are cephalic somites, then the point of commencement of the median aorta would be situated at the level of the seventh body somite, that is, at the situation of the future seventh cervical vertebra. The position of the anterior point of fusion of the primitive dorsal aortæ is indicated in the adult by the origin of the abnormal right subclavian artery, and is situated at the level of the fifth thoracic vertebra; therefore the anterior end of that part of the descending

aorta which is formed by the fusion of the primitive dorsal aortæ must move tailwards during the developmental period.

Branches of Dorsal Aortæ.—The branches given off from the primitive dorsal aortæ are dorsal, lateral, and ventral.

Some of the **dorsal branches** arise in the head region, cephalic to the point where the first mesodermal somite is formed, and hence are presegmental. The others arise more caudally in the head, and in the neck and trunk regions, where they lie opposite the intervals between the mesodermal somites, and are therefore *intersegmental.*

They supply the neural tube and its surroundings, the tissues of the head and neck, the body wall and the limbs. But they do not send branches to the viscera; therefore they are somatic arteries. They anastomose with one another by a series of longitudinal channels which lie ventral and dorsal to the dorsal portions of the costal elements of the skeleton, and dorsal to the transverse processes of the vertebræ.

An account of their branches and anastomoses and the transformations which affect them, and more especially of those which result in the formation of the vertebral arteries and the arteries of the limbs, is given in the description of the morphology of the vascular system (see pp. 1387 ff.). But it may be stated here that the main arteries of the adult which are derived from the dorsal branches of the primitive dorsal aortæ and their anastomoses and branches, are: (1) the intercostal and lumbar arteries and their posterior (dorsal) branches; (2) parts of the subclavian arteries; (3) the axillary arteries and their continuations in the upper limbs; (4) the vertebral arteries; (5) the spinal arteries; (6) the basilar artery; (7) the superior intercostal arteries; (8) the internal mammary and the superior and inferior epigastric arteries.

As a rule, the dorsal branches of the primitive dorsal aortæ remain separate from each other, even in the regions where the primitive dorsal aortæ themselves fuse, but occasionally in the thoracic and lumbar regions they fuse, with the result that intercostal and lumbar arteries of opposite sides arise from common stems.

The **lateral branches of the dorsal aortæ** are distributed to organs developed from the intermediate cell-masses: that is, to the pronephros and mesonephros (p. 788), which form the temporary kidneys; to the metanephros, which becomes the permanent kidney; and to the suprarenal and genital glands. They become the renal, testicular, and ovarian arteries.

The **ventral branches of the dorsal aortæ** are neither definitely segmental nor intersegmental. They pass to the walls of the entodermal portion of the alimentary canal and its diverticula, and also, in the early stages of development, to the walls of the yolk-sac and the chorion and its placental derivative. They are connected together by longitudinal anastomosing channels which lie in the dorsal mesentery of the gut and also upon the wall of the gut itself. As the yolk-sac atrophies, the prolongations of the ventral branches to its walls disappear, and simultaneously the portions of the corresponding vessels of opposite sides, which lie in the mesentery, dorsal to the gut, and the longitudinal anastomoses which connect them, fuse together to form unpaired stem-trunks from which the three great vessels of the abdominal part of the alimentary canal are derived, namely, the cœliac, the superior mesenteric, and the inferior mesenteric arteries. But the original stem of each of these three important vessels is not that which eventually forms its origin from the abdominal part of the aorta; for the cœliac artery, which originally arose opposite the seventh cervical segment, wanders tailwards to the twelfth thoracic segment as the roots of origin of the ventral vessels, which are situated nearer the head, disappear; and, in the same manner, the superior mesenteric is transposed from the level of the second thoracic to the level of the first lumbar segment, and the inferior mesenteric wanders from the twelfth thoracic to the third lumbar segment.

Of the three arteries mentioned, the superior mesenteric retains longest its connexion with the yolk-sac, and it occasionally happens that a fibrous strand, representing the original channel, extends from one of the ileal branches of the superior mesenteric past the side of the intestine to the umbilicus.

Umbilical and Iliac Arteries.—The umbilical arteries arise, when the embryo is less than 1·5 mm. long, about the level where the fourth cervical mesodermal somite is developed at a later stage. They spring from plexuses formed, on the lateral walls of the caudal part of the primitive gut, by the anastomoses of some of the most caudally situated ventral or vitelline branches of the primitive dorsal aorta (Fig. 1101). The origins of the arteries are gradually moved tailwards as the embryo grows, until, eventually, they spring from the primitive dorsal aorta opposite the twenty-third body somite, that is, the fourth lumbar segment. As each umbilical artery passes from its origin on the ventral wall of the primitive dorsal aorta to the body-stalk it lies to the medial side of the pronephric duct. The ventral origin is, however, but temporary; for, by the time the embryo has attained a length of 5 mm., and the primitive dorsal aortæ have fused to form the permanent descending

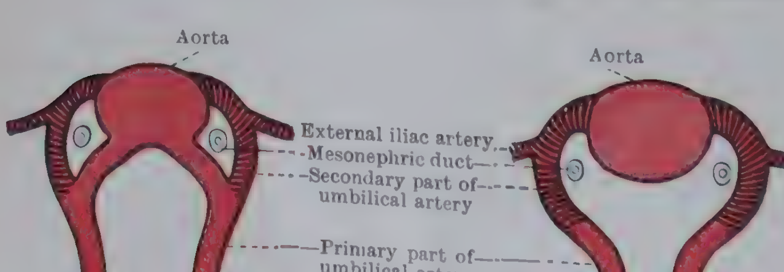

FIG. 1134.—DIAGRAMS SHOWING FORMATION OF SECONDARY PART OF PRIMITIVE UMBILICAL ARTERY.

aorta, a new vessel has arisen, on each side, from the lateral part of the caudal end of the aorta. This new vessel passes ventrally to the lateral side of the mesonephric duct, and then unites, on a plane ventral to the aorta, with the primitive umbilical artery of the same side. After the union has taken place the ventral origin of the umbilical artery disappears, and the primitive umbilical artery then arises from the side of the caudal end of the aorta. From the newly formed vessel, which now constitutes the only origin of the umbilical artery, the **inferior gluteal artery**, which is the primitive main artery of the lower limb, arises. At a later period, and at a more dorsal level, a second branch arises from the dorsal root of origin of the umbilical artery; this is the second main vessel of the lower limb, which becomes the **external iliac** and the **femoral arteries** of the adult. As soon as the external iliac artery is formed, that portion of the umbilical stem which lies dorsal to it becomes the **common iliac artery**, and the more ventral part, which descends into the true pelvis, becomes the **internal iliac artery**. But that portion of the original umbilical artery which runs along the side of the true pelvis to the ventral wall of the abdomen, then to the umbilicus and through the umbilicus to the placenta, is still called the umbilical artery. After birth, when the placental circulation ceases, the greater part of the intra-abdominal portion of the umbilical artery atrophies and becomes converted into the **lateral umbilical ligament**; but a portion of the part which lies in the pelvis remains pervious, and from it springs the **superior vesical artery**.

Arteries of Upper Limb.—It appears probable that, in the earliest stages of development,

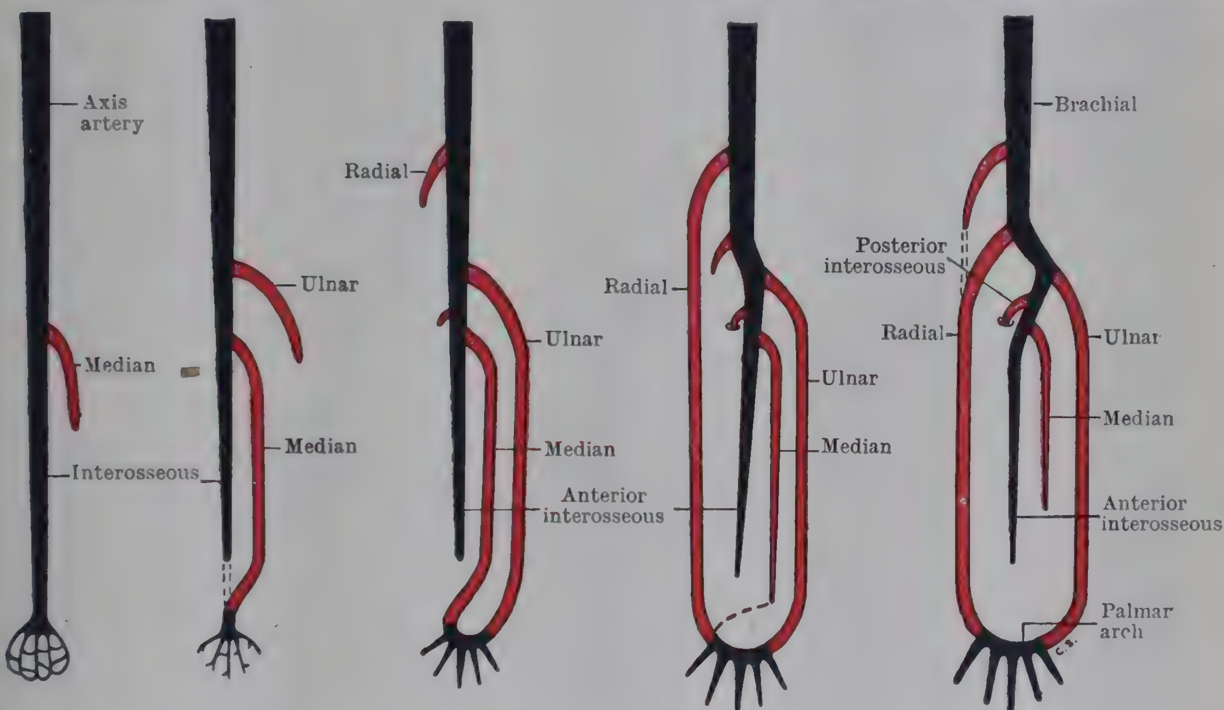

Fig. 1135.—Diagrams of Stages in Development of Arteries of Upper Limb. (After Arey, 1946.)
The original axial artery is *black* and the later-formed arteries *red*.

a number of branches arise from the sides of the primitive dorsal aortæ and pass to the rudiments of the upper limbs, where they end in vascular plexuses which are drained into the anterior cardinal veins.

At a later period the number of connexions with the aorta, on each side, is reduced to one, and that is transferred from the aorta to the ventral branch of the seventh intersegmental artery, whilst, at the same time, the original plexus in the limb is reduced to a single trunk or **axial artery**, which is divisible into subclavian, axillary, brachial, and interosseous segments. The first secondary vessel to be formed is the **median artery** which appears as a branch of the part of the axial artery that becomes the **anterior interosseous**. The median artery joins the hand-plexus but is replaced by the ulnar and radial arteries. The origin of the **radial artery** is moved distally; its final point of origin from the axial artery becomes the bifurcation of the brachial, and the portion of the **ulnar artery** which lies between that point and the origin of its common interosseous branch is part of the original stem vessel (Fig. 1113).

Arteries of Lower Limb.—The development of the arteries of the lower limb has been investigated by Senior (1919, 1920), and readers who wish to follow the details of an intricate process, in order to understand the evolution of the arterial variations met with in the lower limbs, should refer to his work; only a general outline of the phenomena can be given here (Fig. 1136).

In the first place, a primary **axial artery** is developed. It springs from the secondary umbilical artery, leaves the pelvis through the greater sciatic foramen, descends through the thigh between the rudiments of the hamstring and adductor muscles, passes through the popliteal fossa, where its distal part is in front of the rudiment of the popliteus muscle, and descends along the interosseous membrane to the foot, where it ends in a capillary plexus.

gluteal artery and its sciatic branch (which becomes the companion artery of the sciatic nerve), the proximal or femoral part of the popliteal artery, and the distal part of the peroneal artery.

After the axial artery is established, a new branch springs from the secondary umbilical artery above the origin of the axial artery. This new vessel—the external iliac artery—runs along the inlet of the pelvis, passes above the superior pubic ramus, and enters the front part of the thigh, where it becomes the **femoral artery** and is joined by a recurrent branch of the axial artery (*ramus communicans superior*) which pierces the rudiment of the adductor magnus so that the continuity between femoral and popliteal arteries is established.

All the arteries of the leg and foot of the adult, except the distal part of the peroneal artery and a small segment of the anterior tibial artery, are formed by branches of the primitive axial artery and anastomosing channels between them (Fig. 1136).

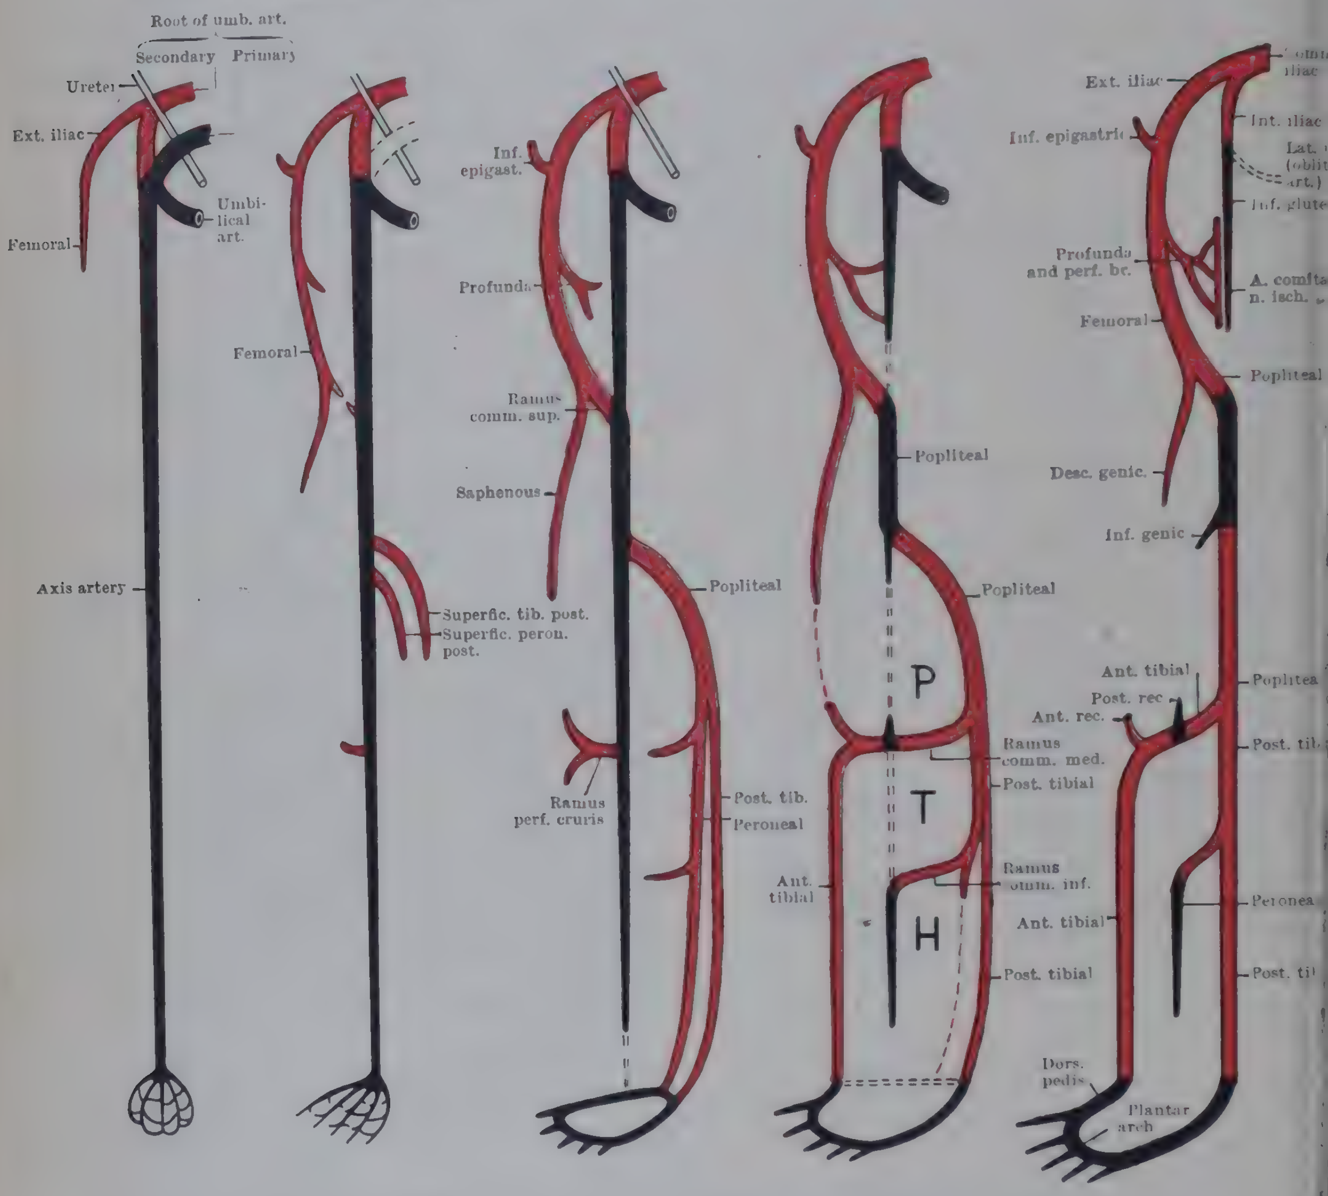

FIG. 1136.—DIAGRAMS OF STAGES IN DEVELOPMENT OF ARTERIES OF LOWER LIMB. (After Senior, 1919, and Arey, 1946.)

The original umbilical artery and the axial artery are *black*, the later-formed arteries *red*. The development of the arteries of the foot is schematic and details are not shown. P, T, and H = position of popliteus, tibialis posterior and flexor halluois longus muscles.

The distal part of the **popliteal artery** and the proximal part of the **posterior tibial artery** are produced by the fusion of two branches of the axial artery. The **anterior tibial artery** arises from the "perforating" branch of the axial artery and is joined to the popliteal by the *ramus communicans medius*. The **peroneal artery**, the distal part of which is derived from the axial artery itself, obtains its connexion with the posterior tibial through the *ramus communicans inferior* (Fig. 1136).

DEVELOPMENT OF VEINS

During the period of embryonic life many venous plexuses and veins appear: some of them are represented in the adult as parts of permanent vessels, others by fibrous cords, and some disappear leaving, in ordinary circumstances, no trace of their existence.

Those which appear may be classified in two groups: (1) Those which are partly extra-

embryonic and partly intra-embryonic. (2) Those which are entirely intra-embryonic. The main features of the history of the first group are well established, but there is considerable difference of opinion regarding the history of those members of the second group which lie in the lower part of the thorax and in the abdomen. It must be understood, therefore, that the account here given is based on a previous tentative, personal summary of knowledge and opinion (Robinson, 1931).

Veins Partly Intra-Embryonic and Partly Extra-Embryonic

It has previously been noted (p. 82) that the earliest veins to appear are the *vitelline veins*, which return blood from the yolk-sac, and the *umbilical veins*, which return purified blood from the placenta. Their further history may now be considered. They are paired veins, right and left, and between them there are transverse anastomoses.

Vitelline and Umbilical Veins, Portal Vein, Hepatic Veins, and Cardiac End of Inferior Vena Cava.—In the early stages of development the **vitelline veins**, right and left, convey blood from the yolk-sac part of the entodermal vesicle first to the caudal ends of the corresponding primitive ventral aortæ, and next, after the caudal parts of the primitive ventral aortæ have fused, to the sinus venosus of the primitive heart.

After the entodermal vesicle is separated into the embryonic alimentary canal, the yolk-sac, and the vitello-intestinal duct, each vitelline vein passes along the duct to the corresponding side of the cephalic margin of the umbilical orifice, where it enters the embryo, passing at once into a mass of mesoderm called the septum transversum; there it unites, for a time, with the cardiac end of the corresponding umbilical vein to form a common vitello-umbilical trunk, which terminates in the sinus venosus (Figs. 102, 103, p. 89). At that period the sinus venosus also is situated in the septum transversum.

Subsequently, as the sinus venosus leaves the septum transversum and passes into the pericardial cavity, the common vitello-umbilical trunk is absorbed into it, and each vein thus acquires its own separate opening into the sinus.

The septum transversum is a mass of mesoderm which intervenes between the pericardium and the ventral portion of the abdominal cavity along the line of the cephalic border of the umbilical orifice. From it are derived the caudal (lower) wall of the pericardium, the ventral part of the central and lateral parts of the diaphragm, the falciform ligament of the liver, the areolar tissue and vascular parts of the liver, and the lesser omentum.

The liver is developed from the branchings of a diverticulum from the ventral wall of the duodenum in the mesoderm of part of the septum transversum. Therefore the portions of the vitelline and umbilical veins which lie in the liver area of the septum transversum are expanded as the liver tissue grows, and at the same time broken up into a great number of anastomosing channels, which form for a period the main part of the liver substance and constitute what is called **sinusoidal tissue**.

The sinusoidal tissue consists of relatively wide anastomosing blood-vessels whose walls are formed at first of endothelium surrounded by areolar tissue. Intervening between the channels of adjacent sinuses, and spreading through the areolar tissue, there are ramifying strands of liver cells which multiply and increase in size and invade the sinusoidal blood-spaces until they are, for the main part, reduced to the size of capillaries, and the liver becomes a comparatively solid organ. At the same time the endothelial lining of the spaces loses its continuity so that liver cells come into direct contact with the blood.

While the formation of the sinusoidal spaces is taking place in the liver area the parts of the fore-gut are defined, and as the duodenal and gastric parts recede from the liver the lesser omentum is evolved from the caudal part of the septum transversum. As the duodenum is delimited, the vitelline veins pass along its sides on their way to the liver, and become connected around the duodenum by three transverse anastomoses, two of which lie ventral and one dorsal to it. On the liver side of the anastomoses each vitelline vein is broken up into: a caudal part, the *vena advehens*, which enters the liver substance; an area of sinusoidal channels in the liver substance; and a cephalic part, the *vena revehens*, which passes from the liver to the heart. After a time the **left vena revehens** loses its direct connexion with the heart, moves across towards the right, and opens into the cephalic end of the right vena revehens. When that change has occurred, all the blood passing to the liver by the vitelline veins reaches the heart by the **right vena revehens,** which now becomes the terminal part of the inferior vena cava. This also receives the ductus venosus—a new channel, which is evolved from the sinusoidal spaces, and which carries the major part of the blood from the left umbilical vein to the inferior vena cava.

In the meantime degeneration takes place in the ventral and caudal parts of the vitelline veins and in parts of the two loops formed by the three transverse anastomoses between them. The ventral parts of the veins disappear with the degeneration of the yolk-sac, and the right half of the caudal loop and the left part of the cephalic loop also disappear (Fig. 1137). Simultaneously the superior mesenteric vein, which has been evolved in association with the formation of the intestine from the mid-gut, opens into the left vitelline vein, caudal to the dorsal transverse anastomosis, and, a little later, the splenic vein enters at the same point. The final result is the formation of the permanent **portal vein,** which is formed from: (1) the cephalic end of the left limb of the caudal loop between the vitelline veins; (2) the dorsal anastomosis between the vitelline veins; (3) the right limb of the cephalic loop formed by the vitelline veins. The

formed from the left vena advehens, and the more cephalic of the two ventral anastomoses between the vitelline veins. It is connected with the ligamentum teres of the liver, because the left umbilical vein, which opened at one time into the left horn of the sinus venosus of the heart, and afterwards into the sinusoids of the liver, finally becomes connected with the left vena advehens, at the level of the cephalic ventral anastomosis between the two vitelline veins; at the same point it is connected with the ductus venosus so that a channel may exist by which the blood from the placenta can pass to the right vena revehens without much admixture with the venous blood passing to the liver through the left branch of the portal vein and the left vena

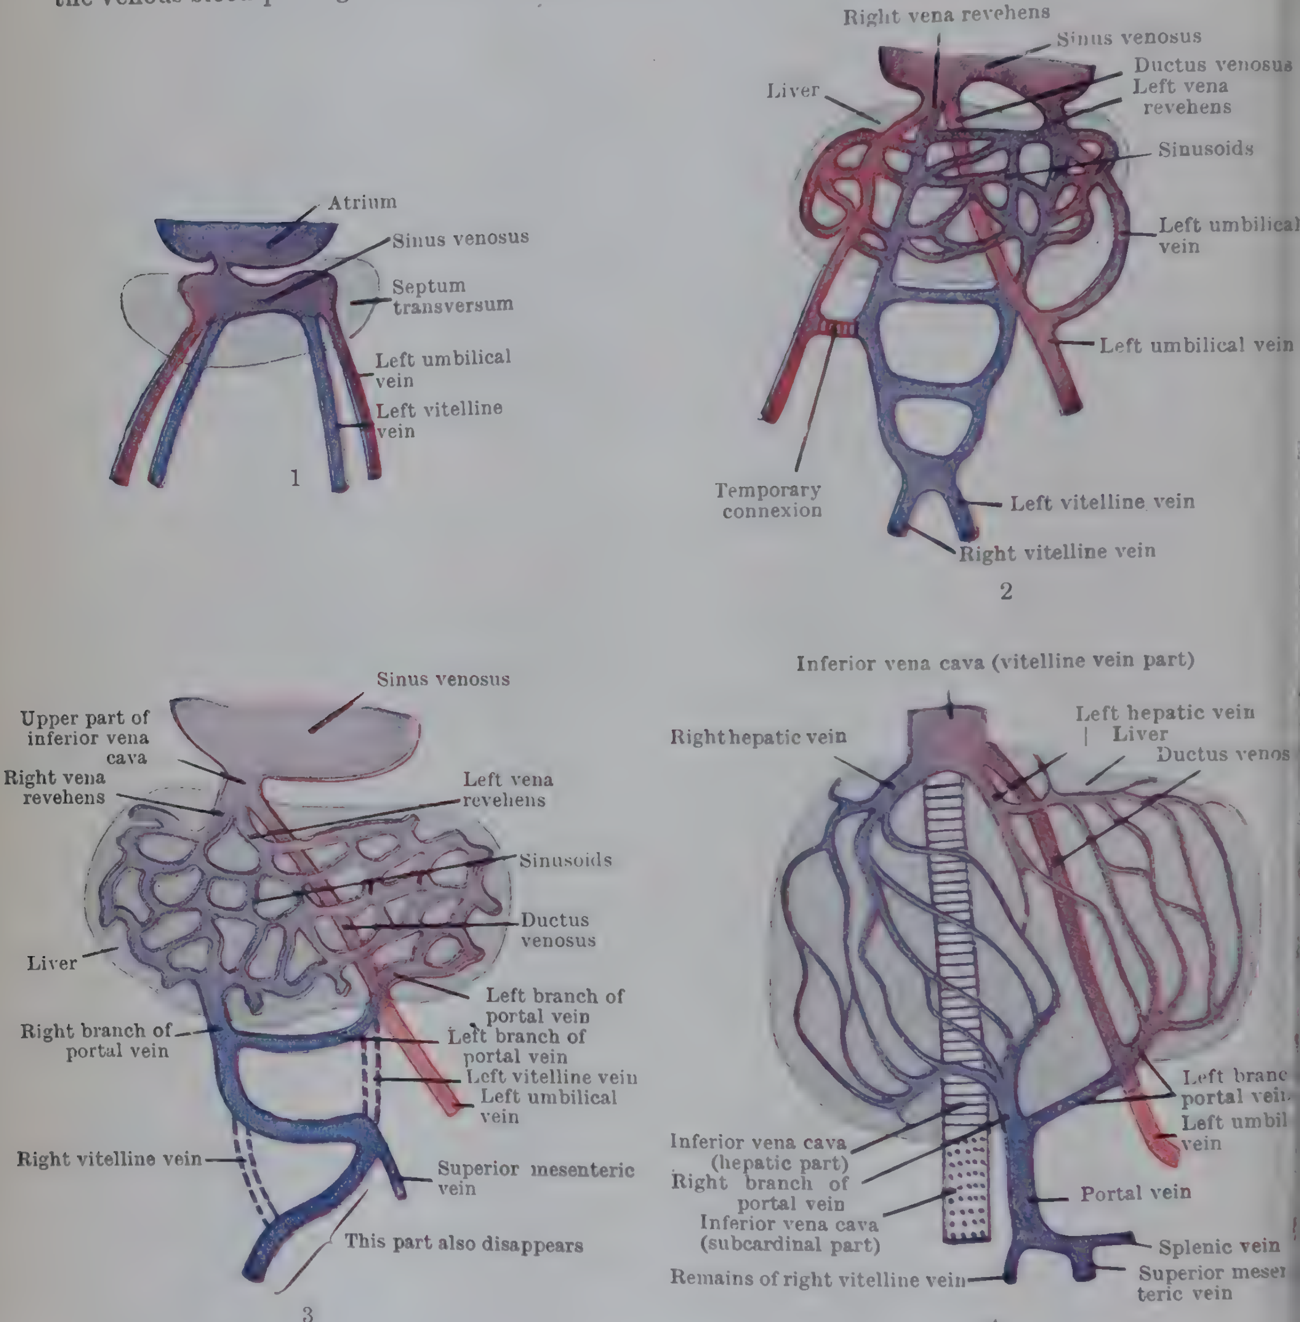

Fig. 1137.—Diagrams showing Four Stages of Development of Portal System and Parts of Inferior Vena Cava.

advehens. But it should be noted that the left branch of the portal vein and the vessels to the liver that ultimately belong to it appear in the fœtus to be branches of the umbilical vein; and it is probable that the umbilical vein dominates the circulation through the liver to a greater extent than is indicated in Fig. 1137, 4.

The **venæ revehentes**, which transfer the blood from the liver to the heart, are the cephalic ends of the primitive vitelline veins. The left vena revehens, as already stated, eventually loses its connexion with the heart and ends in the right vena revehens, which receives the ductus venosus also. The right vena revehens thus becomes the only channel by which blood is returned to the heart from the alimentary canal and from the placenta: that is, it becomes the anterior or cephalic end of the inferior vena cava. The intrahepatic part of the stem of the right vena revehens becomes the **right hepatic vein**, and the left vena revehens becomes the **left hepatic vein**, which are the two vessels which pour, into the inferior vena cava, the blood which was carried from the alimentary canal to the liver by the portal vein and its branches.

As the cephalic part of the right vitelline vein is transformed from the right vena revehens into the anterior end of the inferior vena cava, some of the sinusoids in the dorsal part of the liver are fused together to form the hepatic part of the inferior vena cava, from the caudal end of which an outgrowth passes caudally to anastomose with the right subcardinal vein and to take part in the formation of the pre-renal part of the inferior vena cava (see p. 1384).

Umbilical Veins.—In the earliest stages of development there are three umbilical veins, the vena umbilicalis impar and its branches the left and right umbilical veins. The vena umbilicalis impar and the left umbilical vein persist until birth; the right umbilical vein disappears entirely at an early stage of development.

The vena umbilicalis impar passes from the placenta to the caudal boundary of the umbilical orifice, where it divides into the left and right umbilical veins. Each of the latter unites, for a time, with the corresponding vitelline vein in the septum transversum; then it becomes directly connected with the corresponding horn of the sinus venosus of the heart, and still later with sinusoidal spaces of the liver. The right umbilical vein has also a temporary secondary connexion with the right vitelline vein, but at an early period it undergoes atrophy and all parts of it completely disappear.

The left umbilical vein, which is connected first with the left vitelline vein, next with the heart, still later with the liver, and finally with the left vitelline again, at the point where the latter becomes the left vena advehens, persists until birth, and, after the disappearance of the right umbilical vein, it conveys the blood from the placenta to the liver, where part of the placental blood passes into the left vena advehens and so through the left vena revehens to the inferior vena cava, and part passes into the ductus venosus, by which it reaches that portion of the cephalic part of the right vena revehens which becomes the cephalic or anterior end of the permanent inferior vena cava.

After birth, when the placental circulation ceases, the left umbilical vein becomes the ligamentum teres of the liver.

Ductus Venosus.—The ductus venosus is developed as the left umbilical vein loses its direct connexion with the liver and becomes united to the left vena advehens. It is formed from the sinusoidal spaces of the rudimentary liver and connects the commencement of the left vena advehens with the cephalic part of the right vena revehens. It forms the more direct channel by which the greater part of the blood from the placenta is passed to the heart through that part of the right vena revehens which becomes the upper end of the inferior vena cava. After birth it is converted into the fibrous *ligamentum venosum*, which connects the left branch of the portal vein with the upper end of the inferior vena cava.

Intra-Embryonic Veins

The consideration of the history of the veins of the second group—the intra-embryonic veins—and especially of those members of the group which appear in the lower part of the thorax and in the abdomen, is complicated by the names which have been given to them, and by insufficient definition of the exact positions of the vessels to which the names are applied; it is thus sometimes difficult to decide whether or not the vessel which two different observers describe under the same term is really the same vessel, and whether or not the same vessel has been described under different names.

The main terms used to indicate the vessels which have been noted are *anterior cardinal veins*, *posterior cardinal veins*, *subcardinal veins*, *supracardinal veins*, *thoraco-lumbar veins*, the *prevertebral* (*subvertebral*) *plexus*, and the *azygos venous lines*.

In the subsequent account the embryo and fœtus are considered as being in the quadruped position. Therefore the terms *anterior* and *posterior* are equivalent to *cephalic* and *caudal*, and to *upper* and *lower* in the erect posture; and the prefixes *sub-* and *supra-* are equivalent to *ventral* and *dorsal*, and to *anterior* and *posterior* in the erect posture.

Anterior Cardinal Veins.—The history of the anterior cardinal veins is relatively simple; they are the first purely intra-embryonic longitudinal veins to appear, and they extend from the region of the eye to the sinus venosus of the heart, one on each side. Each anterior cardinal vein is separable into three parts—a cephalic part, and nuchal and thoracic parts. In the earliest stages the *cephalic part* extends from the optic stalk, along the medial side of the trigeminal ganglion, the otic vesicle, and the seventh to the eleventh cranial nerves into the neck. At a later period the part which lies medial to the otic vesicle and the seventh to the eleventh cranial nerves disappears and is replaced by a new vessel which lies lateral to the vesicle and the nerves. The new vessel follows the course of the facial nerve, and in part of its course is extracranial. At the anterior end of the neck it ends in the nuchal portion of the anterior cardinal vein which has now become the internal jugular vein. After the secondary channel is established the stem-vessel of the head is termed the **primary head-vein**. Its anterior part, which lies medial to the trigeminal ganglion, becomes the cavernous sinus; its posterior part disappears, but before that disappearance occurs many changes take place in the tributaries of the primary head-vein.

The most anterior tributaries of the primary head-vein are derived from the region of the optic vesicle and remnants of them become converted into the ophthalmic vein. But in addition to the anterior tributaries there are numerous dorsal or upper tributaries which become arranged in three main groups: an *anterior plexus* associated with the regions of the fore-brain and the mid-brain; a *middle plexus* associated with the cerebellar region of the hind-brain; and a

The vessels of each plexus tend to run together as they approach the stem of the primary head-vein and so three *stems* are formed, the *anterior*, *middle*, and *posterior* (Fig. 1138); they were described by Mall in 1904. That condition persists until the embryo attains a length of about 18 mm. when an anastomosis forms, above the otic vesicle, between the stems from the middle and posterior plexuses (Fig. 1139), and at the same time that part of the primary head-vein which lay lateral to the otic vesicle and the 7th, 8th, 9th, 10th, and 11th cranial nerves disappears (Fig. 1139).

By the time the embryo has become 21 mm. long the anastomosis mentioned has become very important, and a separation has occurred between the lower and the upper portions of

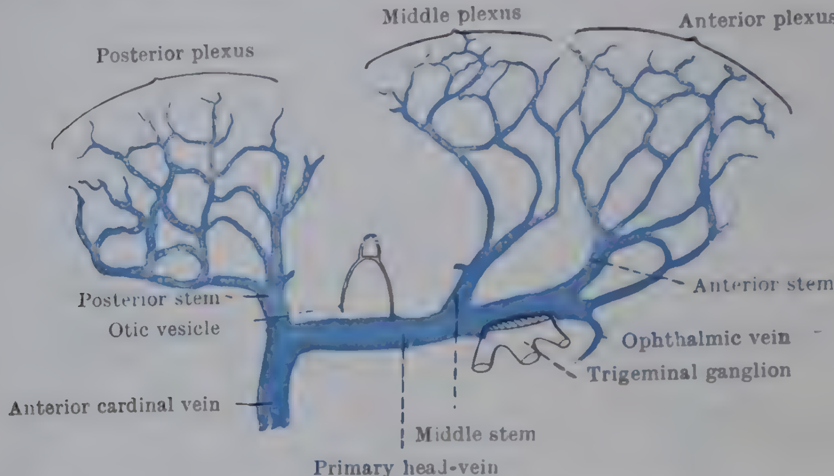

Fig. 1138.—Diagram of Primary Head-Vein and its Tributaries. (After Streeter, 1915.)

the anterior stem tributary; therefore, at that period, the blood from the eye-region flows backwards to the anterior end of the primary head-vein, then upwards along what was the lower part of the middle stem tributary, next backwards along the anastomosis above the otic region to the posterior stem tributary, down which it passes to the nuchal portion of the anterior cardinal vein which has now become the internal jugular vein (Fig. 1139). At

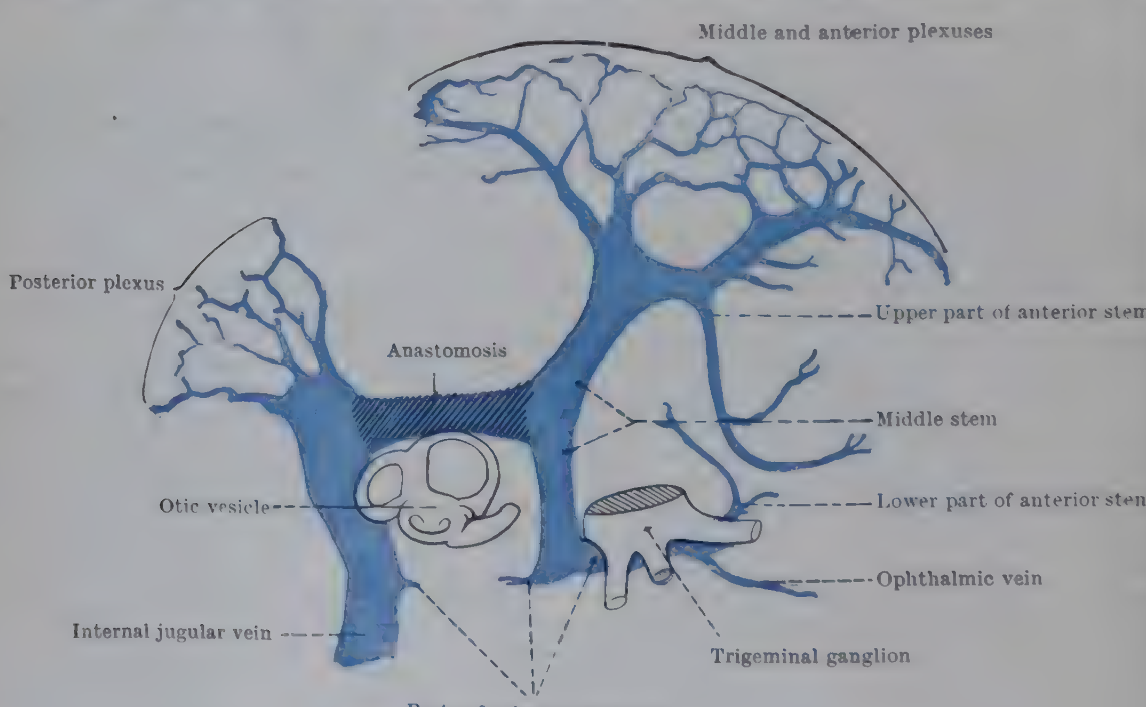

Fig. 1139.—Diagram of Head-Veins of 21 mm. Embryo. (After Streeter, 1915.)

this time the blood from the anterior and middle plexuses reaches the supra-otic anastomosis through the upper or dorsal part of the middle stem tributary (Fig. 1139).

With the formation of the subdural and subarachnoid spaces the main parts of the venous plexuses are carried away from the brain, with the membrane which will be transformed into the dura mater; but in part the plexuses still retain their connexions with the pia mater, and they afterwards establish new connexions with the veins which appear on the surfaces of the developing cerebral hemispheres. In the meantime, on each side, the upper or dorsal tributaries of the anterior and the middle plexus anastomose together (Fig. 1140 B).

When the cerebral hemispheres increase in size the dura-matral tissue is compressed between

them, and between the cerebral hemispheres above and the mid- and hind-brain below, in the form of folds (Figs. 1141 A and B). As the folds are formed the conjoined anterior and middle plexuses of one side are carried into relation with those of the opposite side in the median plane of the head; there the vessels of opposite sides unite together and are finally resolved into the superior and inferior sagittal sinuses and the straight sinus (Figs. 1141 A and B); at the same time some of the smaller vessels of the plexuses which retain their connexion with the pia mater are transformed into the internal cerebral veins and the great cerebral vein; and from some of the lower or ventral tributaries, on each side, is produced the inferior cerebral vein of the embryo which probably becomes the basal vein of the adult (Figs. 1141 A and B).

While the changes last mentioned are taking place, the growth of the hemispheres forces the upper part of the middle stem tributary on each side backwards and then downwards until it becomes the transverse sinus (Fig. 1142); and the anastomosis above the otic region and the posterior stem tributary are converted into its continuation—the sigmoid sinus (Fig. 1142).

By the time this stage is attained the anterior portion of the primary head-vein which lies to the medial side of the trigeminal ganglion has become the cavernous sinus, and the lower or ventral part of the middle stem tributary has been converted into the superior petrosal sinus (Fig. 1142).

The inferior petrosal sinus appears to be an independently formed anastomosis which

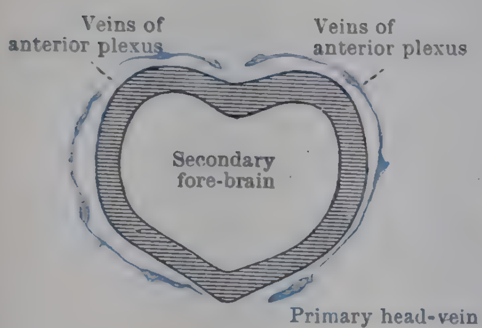

Fig. 1140 A.—Diagram of Transverse Section of Secondary Fore-Brain and Venous Plexuses.

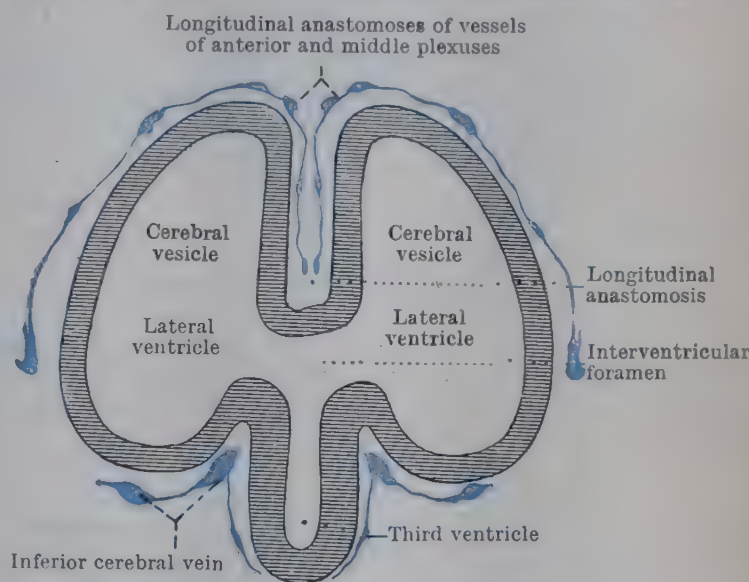

Fig. 1140 B.—Diagram of Transverse Section of Brain, showing Folding of Upper Parts of Plexuses between Cerebral Hemispheres.

connects the posterior end of the cavernous sinus with the upper end of the internal jugular vein across the medial side of the otic region (Fig. 1142).

The history of the *nuchal* and *thoracic* parts of the anterior cardinal veins is different, to a certain extent, on opposite sides. On both sides the anterior cardinal vein is joined, at the root of the neck, by the chief vein of the upper limb. The part cephalic to the junction becomes the internal jugular vein. Caudal to the junction, in the cephalic part of the thorax, a transverse anastomosis forms between the two anterior cardinal veins. The part cephalic to the anastomosis and caudal to the junction with the vein of the limb, on the right side, becomes the right innominate vein; on the left side it becomes part of the left innominate vein, the remainder of the left innominate vein being formed by the transverse anastomosis. On the right side the part caudal to the transverse anastomosis is joined, after a time, by the posterior cardinal vein of that side. The part cephalic to that junction becomes the extrapericardial part of the superior vena cava. The part caudal to the junction is a *common cardinal vein* and is generally called the *duct of Cuvier*; it becomes the intrapericardial part of the superior vena cava. On the left side the part of the anterior cardinal vein caudal to the transverse anastomosis opens, at first, into the left horn of the sinus venosus of the heart; after the anterior cardinal is joined by the posterior cardinal its caudal part becomes the left duct of Cuvier (represented by the ligament of the left vena cava and oblique vein of the left atrium), whilst the cephalic part becomes part of the left superior intercostal vein, which opens into the left innominate vein.

The **external jugular vein** is a new formation which receives for a time the cephalic vein of the upper limb; but the cephalic vein, which is a secondary vessel, is eventually transposed to the axillary vein, which is a part of the primitive upper limb vein.

Posterior Cardinal, Subcardinal, and **Supracardinal Veins, Thoraco-Lumbar Veins, Prevertebral Venous Plexus, Azygos Venous Lines,** and **Inferior Vena Cava.** All these veins extend from the abdomen into the thorax; and all of them, with the exception of the posterior cardinals, are evolved from more or less well-marked venous plexuses. They communicate freely with one another, and they receive in turn, as they supplant one another, the intersegmental veins which open first into the posterior cardinals, and finally in the thoracic region and in some cases, and to a variable extent, in the lumbar region into the adult

The **Posterior Cardinal Veins** appear shortly after the anterior cardinals. They extend from the pelvic region along the dorsal wall of the abdomen, dorsal to the mesonephros and the remnants of the pronephros, into the septum transversum, where they unite with the anterior cardinals. They receive the intersegmental veins and the veins from the mesonephros, and, for a time, the veins of the upper limbs. When the subcardinal veins appear they form numerous anastomoses with the posterior cardinals; but the two most important anastomoses are situated—(1) near the cephalic ends, and (2) near the caudal ends, of the posterior cardinals; thereafter, between those two points, the posterior cardinals disappear. Their remaining caudal parts on both sides become the common iliac and internal iliac veins, the transverse part of the left common iliac vein being the remains of a transverse anastomosis between the two posterior cardinals. The cephalic part of the right posterior cardinal vein remains in the adult as the terminal portion of the vena azygos; and the cephalic part of the left posterior cardinal becomes the caudal part of the left superior intercostal vein.

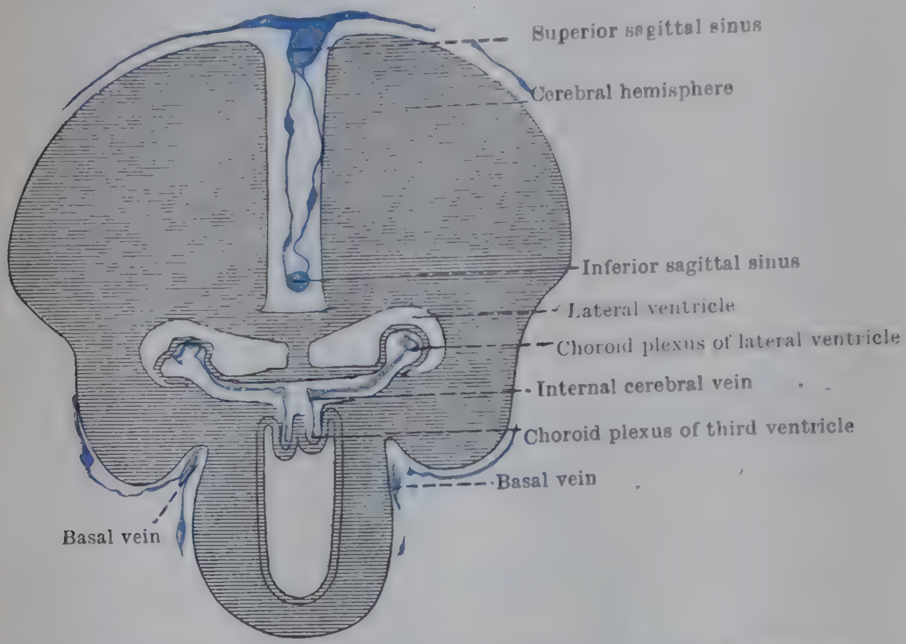

Fig. 1141 a.—Diagram of Transverse Section of Brain showing Sagittal Sinuses still connected by Remains of the Plexuses.

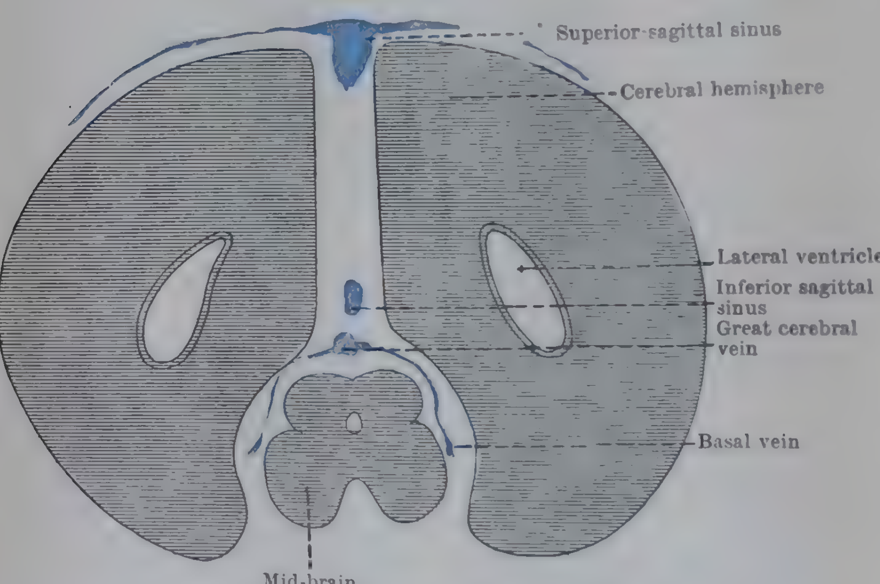

Fig. 1141 b.—Diagram of Transverse Section of Brain after Completion of Sagittal Sinuses.

The **Subcardinal Veins** appear later than the posterior cardinals, and in the dorsal part of the thorax and abdomen, ventro-lateral to the aorta and ventro-medial to the mesonephros. They anastomose freely together dorsal to the superior mesenteric artery, and ventral to the aorta, that is between the two kidneys, which by this time have attained their abdominal position. At each end they anastomose also with the posterior cardinals (see above). After the appearance of the subcardinals the posterior cardinals begin to disappear, and the intersegmental and mesonephric veins which previously passed to them are transferred to the subcardinals. The right subcardinal forms a junction also with a downgrowth from the hepatic part of the inferior vena cava, and each receives the vein from the corresponding kidney.

The thoracic parts of the subcardinals disappear. The cephalic abdominal portion of each of them becomes the corresponding suprarenal vein, and part of the caudal portion enters into the formation of the testicular or ovarian vein (M'Clure & Butler, 1925). The anastomosis between the right subcardinal and the downgrowth from the hepatic part of the inferior vena cava and a part of the right subcardinal itself become part of the pre-renal and inter-renal part of the inferior vena cava. The transverse anastomosis between the two subcardinal veins dorsal to the superior mesenteric artery, becomes part of the left renal vein. The remaining parts of both subcardinals disappear.

Supracardinal Veins.—These veins have been defined by Huntington & M'Clure (1920) as bilateral and originally symmetrical venous channels which develop " dorso-medial to the

[Facing p. 1383

primitive postcardinal veins by longitudinal anastomosis between somatic postcardinal tributaries ". They describe an anastomosis between the supracardinal and subcardinal veins at the level of the intersubcardinal anastomosis between the kidneys; and this "circum-aortic venous ring" or "renal collar" plays a part in the formation of the inferior vena cava. In the opinion of these observers, the right supracardinal vein takes part in the formation of the post-renal portion of the inferior vena cava, and both, in their thoracic sections, become converted into parts of the azygos system of veins. Unfortunately, the relationship of the supracardinal veins to the sympathetic trunks and their ventral branches (splanchnic and aortic) was not stated, and, as Reagan (1927) has pointed out, the inferior vena cava lies lateral to the nervous structures mentioned and the azygos vein lies medial; therefore the inferior vena cava is not in the azygos venous line, and if the right supracardinal is in the inferior caval line, it cannot be a forerunner of the azygos vein.

It may, however, be stated that each supracardinal vein, when fully formed, anastomoses: (1) with the corresponding posterior cardinal vein in the upper thoracic and lower abdominal regions; (2) with the corresponding subcardinal vein at the caudal border of the intersubcardinal anastomosis; (3) with its fellow of the opposite side; and (4) with the prevertebral plexus. Further, in the abdominal part of its extent it receives the intersegmental veins. As

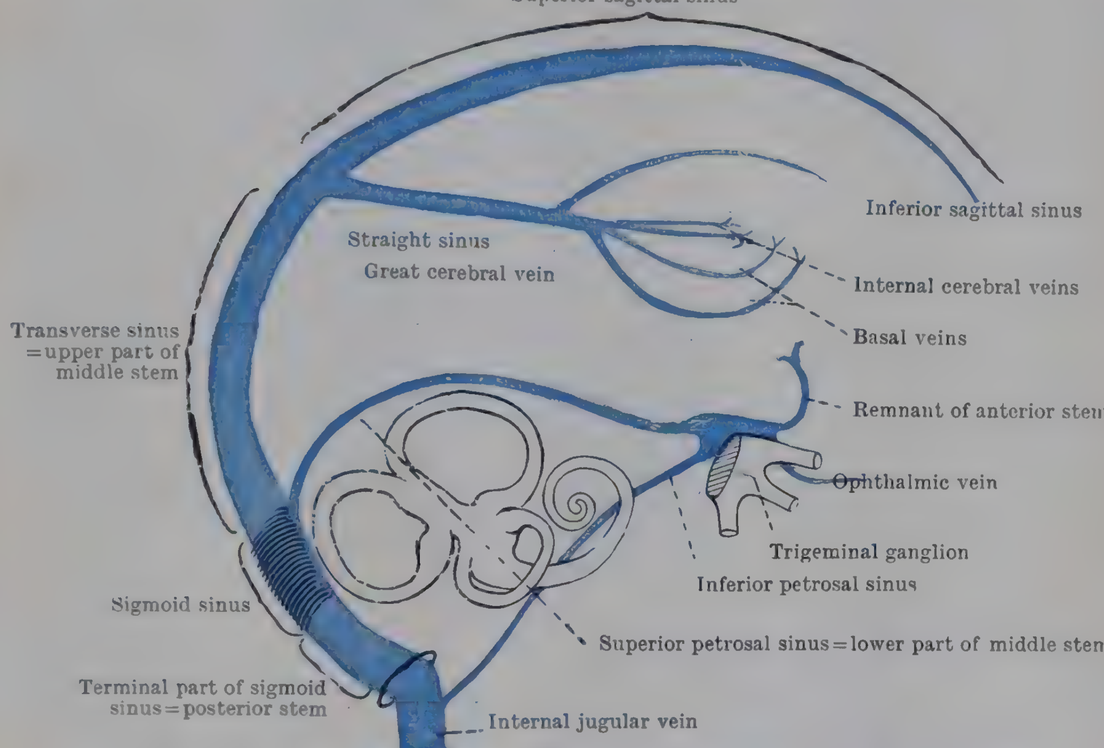

FIG. 1142.—DIAGRAM OF COMPLETION OF DEVELOPMENT OF VENOUS SINUSES.

a rule the left supracardinal disappears almost entirely, but a considerable part of the right supracardinal and the anastomosis between it and the subcardinal persists and becomes the post-renal part of the inferior vena cava.

The **Thoraco-Lumbar Veins** are described, by Reagan (1927), as bilateral longitudinal venous channels which lie lateral to the sympathetic trunks and parallel with the azygos venous line. They are transitory structures which serve as transmitters of blood from the intersegmental veins, "caudally into the inferior vena cava pending the establishment of an azygos line". When their function terminates they disappear, leaving no adult derivative.

Prevertebral Plexus and Azygos Veins.—The prevertebral plexus lies ventral to the bodies of the vertebræ and dorsal to the aorta, in the thoracic and lumbar regions, and to a less extent at the sides of and ventral to the aorta. Its lateral components have been termed *prevertebral* and *circumganglionic* and its median part *subcentral*. It communicates with the subcardinals, precardinal, and thoraco-lumbar venous channels and, as the major parts or the whole of those vessels disappear, their intersegmental tributaries open into it. Simultaneously its lateral parts become transformed into the rudiments of the azygos and hemiazygos veins, and its median part, not uncommonly and especially in the lumbar region, becomes a pre- or sub-central vein. The azygos venous line, on each side, lies lateral to the intersegmental arteries and medial to the sympathetic trunk and its ventral branches, and the precentral vein lies between the intersegmental arteries of opposite sides.

The thoracic part of the right azygos venous line forms the vena azygos, except its terminal part which is a remnant of the right posterior cardinal vein. In the lumbar region it not uncommonly persists as the right lumbar azygos vein, which extends from the inferior vena cava at the level of the renal veins through the aortic opening in the right crus of the diaphragm to the commencement of the azygos vein, the connexion with the inferior vena cava being formed by the persistence of an anastomosis between the azygos venous line and the right

The remains of the left azygos venous line are the superior and inferior hemiazygos veins, and the caudal part of the left superior intercostal vein. The transverse parts of the hemiazygos veins are remnants of the intermediate part of the subvertebral plexus; they are occasionally connected together by a median anastomosis which represents part of a precentral vein.

The lumbar part of the left azygos venous line forms the left lumbar azygos vein which is frequently found, in the adult, passing from the left renal vein, through the left crus of the diaphragm to the inferior hemiazygos vein.

The **inferior vena cava** is a compound structure. Its terminal part is the end of the right vitelline vein; the hepatic part is developed from the liver sinusoids; between the liver and the renal veins it is formed from: (1) an outgrowth from the hepatic part; (2) an anastomosis between the outgrowth and the right subcardinal vein; (3) part of the right subcardinal vein; the post-renal part is a persistent portion of the right supracardinal vein (Fig. 1143).

The intersegmental veins of the thoracic and abdominal regions drain the wall of the trunk and, in the earliest stages, they terminate in the posterior cardinal veins; at successively later periods they are transferred to the subcardinal, the supracardinal, the thoraco-lumbar veins, and finally to a greater or less extent to the azygos lines of veins. Eventually those which lie in the thoracic region enter one or other of the azygos veins or the superior intercostal veins.

The lumbar intersegmental veins have various terminations. The lower lumbar veins on the right side frequently end in the inferior vena cava, the connexion with the right supracardinal vein being retained; the upper right lumbar veins end, not uncommonly, in the right lumbar azygos vein; but cases occur in which all the right lumbar veins end in a vessel, called the right ascending lumbar vein, which connects the right ilio-lumbar vein with the azygos vein; it is a precostal anastomosis between the lumbar intersegmental veins. In such cases the connexions with the right supracardinal and the right lumbar azygos have been obliterated.

The left lumbar intersegmental veins may end: (1) in a left ascending lumbar vein which connects the left ilio-lumbar vein with the inferior hemiazygos vein; (2) in a precentral vein which ends in the azygos vein, or the hemiazygos vein or both; (3) the lower lumbar veins may end in the inferior vena cava, reaching it by transverse anastomoses developed from the prevertebral plexus, and the upper left lumbar veins may end in the left lumbar azygos vein.

The above account of the development of the thoracic and abdominal parts of the venous system is, as already stated, mainly a personal and tentative summary of knowledge by Robinson (1931). The reader who wants to form his own opinion on disputed points should consult Huntington & M'Clure (1920); M'Clure & Butler (1925); Butler (1927); M'Clure & Huntington (1929); Gladstone (1929); Reagan (1927); Seib (1934); Franklin (1948); and, from the historical point of view, Reagan (1929). These communications contain references to all the literature to date dealing with the development of the posterior thoracic and abdominal veins.

FŒTAL CIRCULATION

During fœtal life, food and oxygen are transmitted from the maternal blood to the fœtal blood in the placenta, where the maternal blood flows in near relation to the walls of the fœtal blood-vessels; and the effete products produced by the cells of the fœtal tissues, including carbon dioxide, are passed from the fœtal blood to the maternal blood in the same place. The umbilical arteries and the umbilical vein persist therefore till birth in order to carry the blood from the fœtus to the placenta and back again.

Lungs are present in the fœtus, but they do not function as respiratory organs until birth; and, although the blood-vessels necessary for pulmonary respiration are present, the only blood that flows through them is that which is necessary for their nutrition and growth, the bronchial vessels being apparently, as yet, insufficient for the purpose. The foramen ovale and the ductus arteriosus, therefore, remain patent till birth, so that most of the blood may be transmitted to the aorta without passing through the lungs.

As a consequence, the course of the circulation is different before and after birth (Pl. LXXXVIII, p. 1387). After birth, blood passes from the body as a whole into the right atrium, which passes it on into the right ventricle, whence it is forced, through the lungs, to the left atrium, and thence to the left ventricle, by which it is propelled through the systemic vessels back to the right atrium.

In the fœtus, on the other hand, blood laden with food and oxygen is carried from the placenta by the umbilical vein, and transmitted to the inferior vena cava, partly directly through the ductus venosus, and partly indirectly through the liver by branches which are ultimately taken over by the left branch of the portal vein (Fig. 1137 and Pl. LXXXVII, Fig. 3). In the inferior vena cava it mixes with venous blood returning from the lower limbs, the lower parts of the trunk, the renal organs, and the genital glands; and so it becomes mixed blood. The mixed stream is then delivered by the inferior vena cava into the right atrium and the greater part of it is directed by the valve of the inferior vena cava through the foramen ovale into the left atrium, whence it passes to the left ventricle, which ejects it into the aorta (Fig. 1143 and Pl. LXXXVII, Fig. 1 A).

Some of the blood that enters the right atrium from the inferior vena cava takes another route. The whole stream is not directed by the valve of the inferior vena cava straight through the foramen ovale, but it impinges on the edge of the annulus ovalis so that a small part of it (probably about one-fourth—see references on p. 1386) passes forwards and is carried into the right ventricle with the stream of blood from the superior vena cava (Pl. LXXXVII, Fig. 1 B).

On the other hand, the blood from the head and neck, the upper limbs, and the upper parts

of the trunk, returning by the superior vena cava to the right atrium, passes wholly into the right ventricle, which ejects it into the pulmonary trunk. Only a small quantity of this stream enters the pulmonary arteries for the supply of the lungs; the greater part of it passes through the ductus arteriosus—which is in direct line with the pulmonary trunk (Fig. 1144)—into the

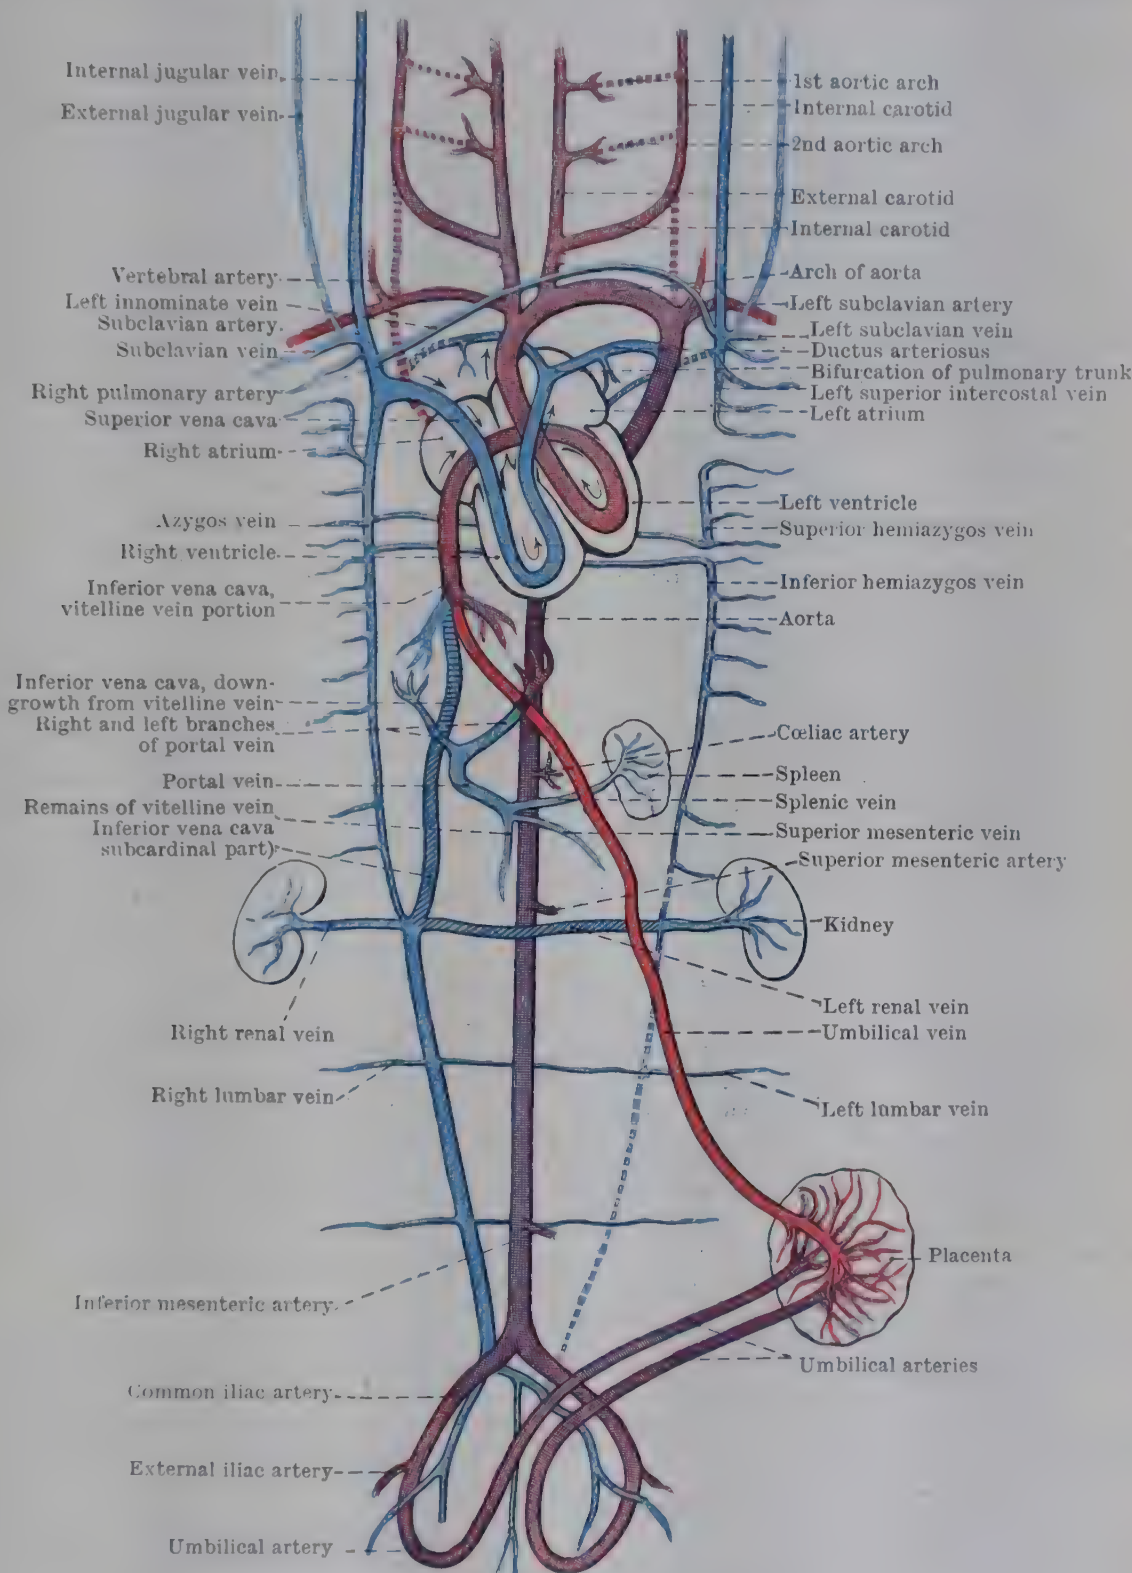

FIG. 1143.—DIAGRAM OF FŒTAL CIRCULATION.

The inferior vena caval blood is represented as passing wholly through the foramen ovale into the left atrium, but recent work (see p. 1384) has confirmed the older view that part of it is directed by the annulus ovalis through the right atrio-ventricular orifice into the right ventricle.

aorta, beyond the origin of the left subclavian artery, where it mixes with the blood from the **left ventricle** (Pl. LXXXVII, Fig. 2 A).

There has been much discussion on the part played by the "intervenous tubercle" (p. 1230) in directing the stream from the superior vena cava through the right atrio-ventricular orifice, and there is no doubt that many statements, based on Lower's original description in 1669, have exaggerated its anatomical and functional importance in the human heart. The factors that

through the two venæ cavæ are the different directions of the two streams and the relation of the valve of the inferior vena cava to the foramen ovale and the annulus ovalis. Doubts about the separation of the two streams of blood seem finally to have been set at rest by the researches of Barcroft and Barclay and their colleagues on the fœtal circulation as demonstrated by X-ray cinematography (Pls. LXXXVII, LXXXVIII). Their observations were directed primarily to the problem of the closure of the ductus arteriosus (see below), but the method of injecting radio-opaque media into the blood-stream of fœtal sheep has given a clear picture of the routes taken by the blood through the living heart. For the original account of these researches, see Barclay, Barcroft, Barron and Franklin (1939), and for further details and references to the full series of papers and the literature in general, Barclay, Franklin and Prichard (1944).

In the fœtus, therefore, pure oxygenated blood is found only in the left umbilical vein and the ductus venosus and that is mixed with venous blood in the inferior vena cava. The mixed stream from the inferior vena cava is delivered into the aorta via the left atrium and ventricle, and most of it passes into the head and neck and the upper limbs; the remainder passes into the descending aorta and is joined, beyond the origin of the left subclavian artery, by the venous stream from the head and neck and the upper limbs, which has passed from the superior vena cava through the right atrium (where it receives a small contribution from the inferior vena cava), the right ventricle, the pulmonary trunk, and the ductus arteriosus.

From the descending aorta part of the blood passes to the walls of the thorax, to the abdomen and its contents, and to the lower limbs; the remainder passes through the internal iliac arteries and their umbilical branches to the placenta.

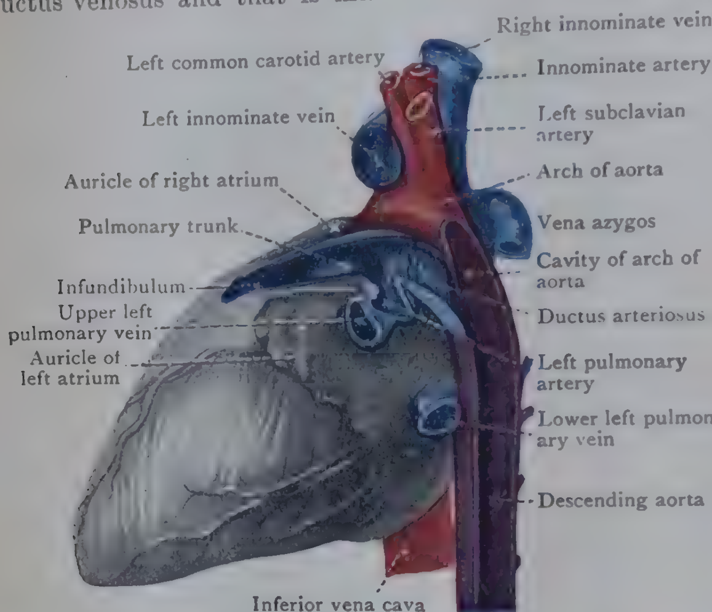

Fig. 1144.—Dissection of Heart and Great Vessels of Fœtus, showing the Angular Junction of Ductus Arteriosus with Aorta.

It is obvious, from what has been stated, that the blood in the descending aorta, which is supplied to the lower part of the trunk and the lower limbs, contains relatively less oxygen and food-material and more effete matter than the blood in the ascending aorta and the arch of the aorta, which is transmitted to the head and neck and the upper limbs.

TRANSITION FROM FŒTAL TO ADULT CIRCULATION

The changes that occur in the vascular system at birth depend on the expansion of the lungs with the onset of breathing and on the cessation of the circulation through the placenta. The flow of blood is altered in several ways, and these functional changes are followed sooner or later by anatomical alterations which affect the pulmonary arteries, the foramen ovale, the ductus arteriosus, the umbilical arteries, the umbilical vein, and the ductus venosus.

As the lungs expand, a greater amount of blood is drawn from the pulmonary trunk into the pulmonary arteries and correspondingly less passes through the ductus arteriosus into the aorta. The **pulmonary arteries** dilate and the ductus contracts; and the increased flow of blood through the lungs raises the pressure in the left atrium so that it at least equalizes the pressure in the right. The **foramen ovale** thus ceases to function as a passage for the blood from the inferior vena cava, and the opposing surfaces of that valve-like aperture come together and begin to unite; and in time the surfaces are usually completely fused so that the foramen is structurally as well as functionally closed. Even if an aperture persists, as it may do throughout life (pp. 1229, 1369), it is of little importance unless it is part of some gross malformation of the heart.

The functional closure of the **ductus arteriosus** appears to occur almost at once by sphincter-like action of its muscular wall (Pl. LXXXVII, Fig. 2 B), possibly assisted by a change in its direction due to rotation of the heart which occurs as the lungs expand. Thereafter, the lumen of the ductus is gradually obliterated and it is transformed into the *ligamentum arteriosum*.

The cessation of the placental circulation, completed by the actual ligature of the umbilical cord, leads to the obliteration of the **umbilical arteries** and **vein**. The arteries, beyond the points at which the superior vesical branches arise, are transformed into the ***lateral umbilical ligaments*** (p. 1311), and the vein becomes the *round ligament of the liver*. The closure of the **ductus venosus**, like the closure of the ductus arteriosus, seems in the first instance to be due to active sphincteric contraction (Pl. LXXXVII, Fig. 3 B), and, like the other fœtal vessels no longer required, it is gradually reduced to a fibrous cord—the *ligamentum venosum*.

In general it may be noted that the sudden change at birth from placental to pulmonary

respiration is accompanied by equally sudden functional adaptation of the circulatory system, and that the permanent structural changes follow gradually.

MORPHOLOGY OF BLOOD-VESSELS

In conformity with the general plan of the vertebrate body, the vascular system is essentially segmental and intersegmental in character. The intersegmental character of the intercostal and lumbar vessels is obvious; that of the vessels of the head, neck, and pelvis is less obvious but is still distinguishable in the vessels of the head.

The intersegmental arteries and veins form a series of bilaterally symmetrical vessels. Each of those intersegmental vessels is connected with its cephalic and caudal neighbours by a portion of a longitudinal vessel which lies in the region of a segment and, therefore, may be called a segmental channel. Consequently, in a sense in the adult, the segmental channels anastomose with one another, through the intersegmental vessels which they connect together. The longitudinal trunks of the body are mainly, though not exclusively, segmental. From them the main stem-vessels of the adult are formed, and the intersegmental vessels appear to proceed from or to them as branches or tributaries.

In the course of development the longitudinal trunks become the most important trunks in the body, and they are formed before the branches and tributaries make their appearance.

SEGMENTAL ARTERIES AND THEIR ANASTOMOSES

The main longitudinal trunks are the primitive aortæ. The descending aorta is formed, in the greater part of its extent, by the fusion of the dorsal parts of the primitive aortæ, and from it the intersegmental, lateral, and ventral arteries arise in pairs.

In a typical portion of the body of the embryo there are three arteries on each side. One arises from the dorsal surface of the primitive dorsal aorta, *i.e.*, from the dorsal longitudinal trunk, and runs laterally and ventrally in the tissues developed from the somatic mesoderm; it is distributed to the body-wall, including the vertebral column and its contents, and is termed a **somatic intersegmental artery.** A second vessel arises from the side of the primitive dorsal aorta; it is distributed to the structures developed from or in the region of the intermediate cell-mass—the suprarenal gland, the kidney, and the ovary or the testis—and it is accordingly termed **a lateral or intermediate visceral artery.** The third artery, which is known as the **splanchnic artery,** springs from the ventral surface of the aorta. It runs in the tissues developed from the splanchnic mesoderm, and supplies the wall of the alimentary canal.

The **somatic intersegmental arteries** form, in the early embryo, a regular series of paired vessels throughout the cervical, thoracic, lumbar, and sacral regions. It is, however, only in the thoracic and lumbar regions that their original characters are retained. The paired vessels pass dorsally, by the sides of the vertebræ, and divide into dorsal and ventral branches which accompany the posterior and anterior primary rami of the spinal nerves.

The **ventral branches** run ventro-laterally, between the ribs, in the thoracic region, and in

corresponding positions in the lumbar region, and together with the stems they form the main parts or trunks of the vessels in the thoracic and lumbar regions. They are connected together, near their commencements, by a series of pre-costal anastomoses which pass in front of the necks of the ribs; and they are also connected together, near their terminations, by ventral anastomosing channels which run, in the thoracic region behind the costal cartilages, and in the lumbar region behind or in the substance of the rectus abdominis muscle. Each ventral branch gives off a lateral offset which is distributed like the lateral cutaneous branch of a spinal nerve. The ventral branch together with the stem of the intersegmental artery forms the trunk of an intercostal or lumbar artery in the adult.

The **dorsal branches**, which are present before the ventral branches, run backwards between the transverse processes of the vertebræ, and form the posterior branches of the intercostal and lumbar arteries of the adult; they are connected, behind the necks of the ribs, by post-costal anastomoses, and again, behind the transverse processes of the vertebræ, by post-transverse anastomosing channels. Moreover, each dorsal branch, as it passes by the corresponding intervertebral foramen, gives off a spinal offset which enters the vertebral canal, along the corresponding nerve-root, and

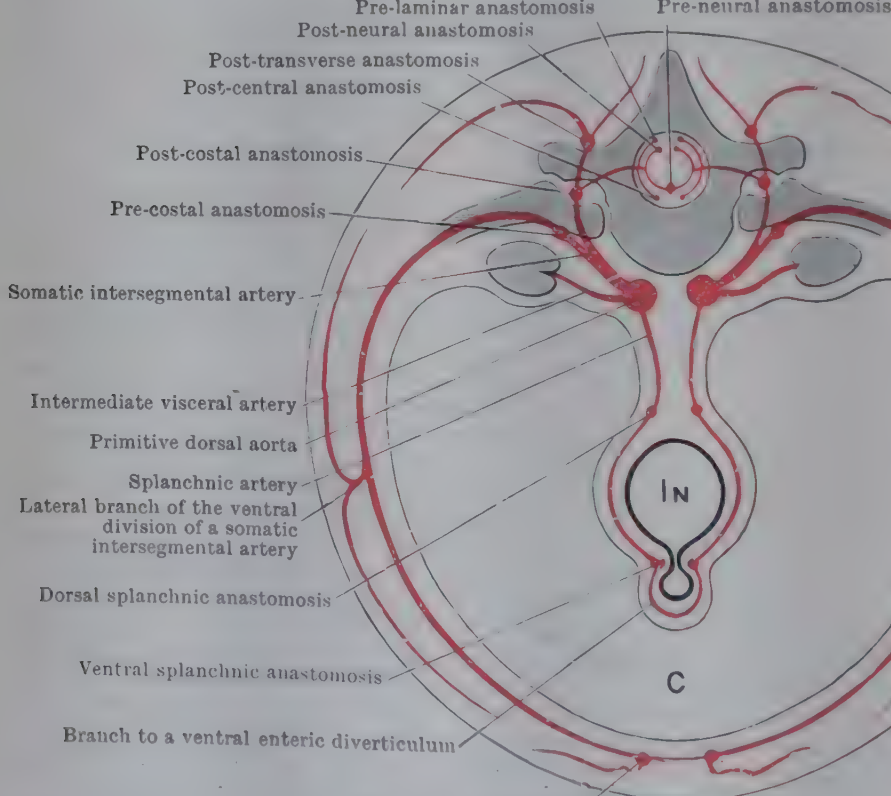

Fig. 1147.—Diagram of Arrangement and Communications of Segmental and Intersegmental Arteries at Early Stage of Development.

C, Cœlom; In, Intestine.

divides into a dorsal, a ventral, and a neural branch. The dorsal branches of those spinal arteries are connected together along the ventral surfaces of the laminæ by pre-laminar anastomoses, and the ventral branches are united on the dorsal surfaces of the vertebral bodies (or centra) with their fellows above and below by post-central anastomoses; they are also

united with their fellows of the opposite side by transverse communicating channels. The neural branches of the spinal arteries divide similarly into dorsal and ventral branches; the dorsal branches of each side are connected together by post-neural anastomoses, which form the posterior spinal arteries; and the ventral branches unite, in the median line, both with their neighbours above and below and with their fellows of the opposite side, forming a single longitudinal pre-neural trunk—the anterior spinal artery.

In the thoracic and lumbar regions of the body the somatic intersegmental arteries persist, and form the posterior intercostal and lumbar arteries. Those vessels spring from the dorsal aspect of the descending aorta, usually in pairs. The corresponding vessels of opposite sides occasionally fuse together at their origins, simultaneously with the fusion of the dorsal longitudinal trunks to form the descending aorta, and then the arteries of opposite sides arise by common stems.

The pre-costal anastomoses between the ventral branches of the somatic intersegmental arteries persist only in the thoracic region, where they are represented by the superior intercostal arteries; in the lumbar region they disappear entirely. The anastomoses between the terminal portions of the ventral branches of the somatic intersegmental arteries persist as the internal mammary and superior and inferior epigastric arteries.

The lateral offsets of the ventral branches are represented by the cutaneous arteries which accompany the lateral cutaneous branches of the spinal nerves; the lateral branch of the seventh somatic intersegmental artery forms the greater part of the arterial stem of the upper limb.

The post-costal and post-transverse anastomoses usually disappear in the thoracic and lumbar regions, but the post-costal anastomoses occasionally persist in the upper thoracic region, and take part in the formation of the vertebral artery, which in such cases arises from the first or second aortic intercostal artery. In some carnivora the post-costal longitudinal vessels persist in the headward part of the thoracic region, and form, on each side, a trunk which is connected with the first aortic intercostal, and supplies the first five intercostal spaces.

The pre-laminar, the post-central, and the pre- and post-neural anastomoses persist, the latter two aiding in the formation of the thoracic and lumbar portions of the anterior and posterior spinal arteries respectively.

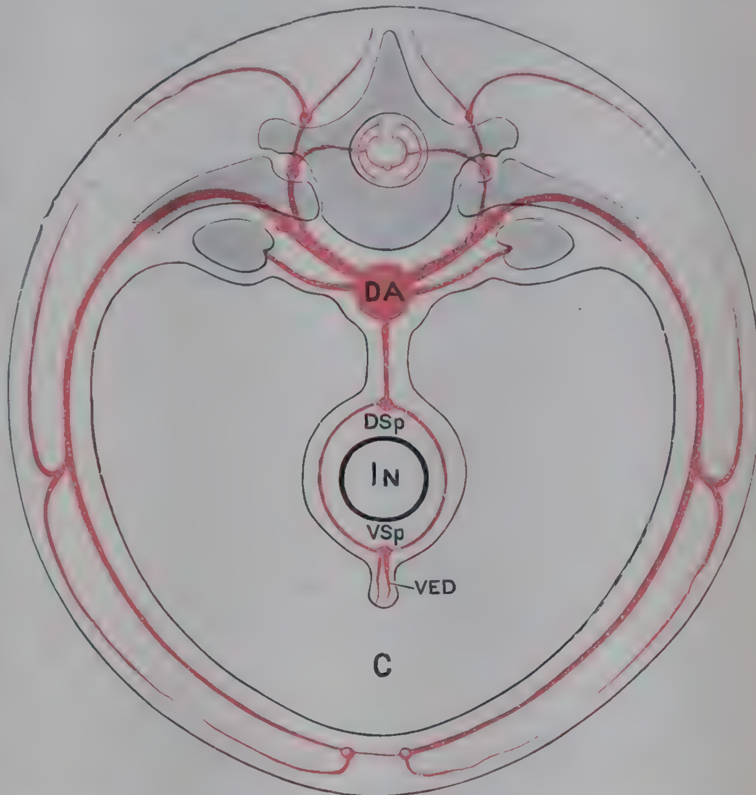

Fig. 1148.—Diagram of Segmental and Intersegmental Arteries at later Period of Development than in Fig. 1147.

C, Cœlom; DA, Dorsal aorta; DSp, Dorsal splanchnic anastomosis; In, Intestine; VED, Branch to ventral enteric diverticulum; VSp, Ventral splanchnic anastomosis.

It is in the cervical region, however, that the most interesting changes occur. The first six pairs of somatic intersegmental arteries lose their connexions with the dorsal roots of the aortic arches, *i.e.*, in other words, with the longitudinal anastomosing channels in that region. The seventh pair, however, persist in their entirety; and from them are formed, on the right side, a portion of the subclavian trunk, and, on the left side, the whole of the subclavian stem from its commencement up to the origin of the vertebral artery. On each side the ventral branch of the seventh intersegmental artery forms that portion of the subclavian artery which lies between the origins of the vertebral and internal mammary arteries, and also the trunk of the internal mammary artery as far as the upper border of the first costal cartilage. The remainder of the internal mammary artery represents the ventral longitudinal anastomoses between the ventral branches of the seventh and the following somatic intersegmental arteries. The continuation of the subclavian artery, beyond the inner margin of the first rib, is the persistent and enlarged lateral offset of the ventral branch of the seventh somatic intersegmental artery, which is continued into the upper limb, caudal or postaxial to the shoulder girdle. The thyro-cervical trunk and the superior intercostal artery, both derived from the subclavian artery, are persistent pre-costal anastomoses, and the ascending cervical artery belongs to the same series of vessels. The vertebral artery, which appears as a branch of the subclavian in the adult, is, morphologically, somewhat complex. The first part represents the dorsal branch of the seventh somatic intersegmental artery; the second part—that passing through the cervical transverse processes—consists of the persistent post-costal anastomoses bewteen the dorsal branches of the first seven intersegmental arteries; a third part, that lying on the arch of the atlas, is the

spinal branch of the first somatic intersegmental artery and its neural continuation; whilst, finally, the upper part of the vertebral artery—the part in the cranial cavity—appears to represent a prolongation of the pre-neural anastomoses, which still farther upwards are probably represented by the basilar artery. As already stated, the post-costal anastomoses below the seventh intersegmental artery occasionally persist, and in such cases the vertebral may lose its connexion with the subclavian, and spring from one or other of the posterior branches of the upper intercostal arteries.

The deep cervical artery is to be regarded as a remnant of the post-transverse longitudinal anastomoses.

The origin of the seventh somatic intersegmental artery from the dorsal longitudinal trunk is, at first, some distance caudal to the sixth aortic arch, but, simultaneously with the elongation of the neck and the retraction of the heart into the thoracic region, it is shifted headwards until it is opposite the dorsal end of the fourth aortic arch.

The median sacral artery is formed by the fusion of two vessels, each of which springs from the dorsal surface of the aorta. It is regarded as the direct continuation of the descending aorta.

The **lateral** or **intermediate visceral arteries** supply the organs developed in the region of the intermediate cell-mass. They form an irregular series of vessels in the adult, but presumably in the primitive condition there was a pair in each segment of the body; many of these disappear, however, and the series is represented in the adult only by the suprarenals, the renals, and the testicular or ovarian arteries—possibly, also, by some of the branches of the internal iliac arteries.

The **splanchnic arteries** arise in the embryo from the ventral aspects of the primitive dorsal aortæ, and are not strictly either segmental or intersegmental in arrangement. They are distributed to the walls of the alimentary canal. Each anastomoses with its immediate neighbours on both the dorsal and the ventral walls of the gut.

After the fusion of the dorsal longitudinal trunks to form the descending aorta, the roots of each pair of the splanchnic arteries fuse into a common stem, or one of the pair—right or left—disappears altogether. At a later period the majority of the splanchnic arteries lose their direct connexion with the descending aorta; those which retain their connexion are the cœliac artery and the superior and inferior mesenteric arteries.

The bronchial and œsophageal arteries are later formations. They appear to correspond morphologically with the more primitive splanchnic arteries, but the developmental history is not known.

The left gastric branch of the cœliac artery, as it passes from its origin to the lesser curvature of the stomach, represents a right splanchnic artery; the remainder of the left gastric artery and the right gastric branch of the hepatic are remnants of the ventral anastomoses between the splanchnic arteries headwards of the umbilicus.

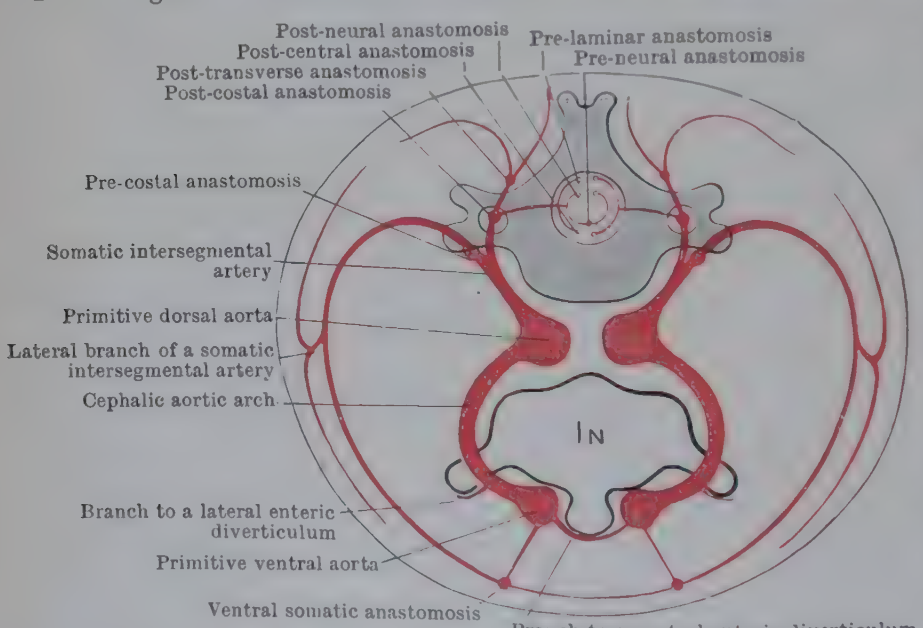

Fig. 1149.—Diagram of Arrangement and Communications of Segmental and Intersegmental Arteries in Region of Cephalic Aortic Arches.

In, Intestine.

The splenic artery is a branch given off from a splanchnic artery to an organ developed in the mesogastrium; and the hepatic is a branch from the ventral splanchnic anastomoses to the hepatic diverticulum of the duodenal portion of the fore-gut.

The superior and inferior mesenteric arteries represent at their origins splanchnic branches, and in the remainder of their extent they represent the dorsal anastomoses on the gut-wall.

Aorta, Pulmonary Trunk, and other Chief Stem-Vessels

The heart and the majority of the great arterial trunks of the body, including the aorta, the innominate, part of the right subclavian, the common, external, and greater parts of the internal carotid arteries, and the pulmonary trunk, are all modified portions either of the primitive aortæ or of the aortic arches. The developmental changes, which result in the formation of the vessels named, are described in the preceding chapter, and the morphology of these vessels is obviously the same as that of the trunks from which they are derived.

It will be sufficient, therefore, to point out that the primitive aortæ may be regarded as the greatly enlarged pre-central or pre-vertebral longitudinal anastomoses between the successive intersegmental arteries of each side; obviously, therefore, each primitive aorta, like the rest of the longitudinal anastomoses, consists chiefly of segmental elements. The origins of the intersegmental vessels enter into its formation only in so far as they connect the segmental vessels together, and so complete the longitudinal anastomoses.

The first cephalic aortic arches are simply portions of the primitive aortæ. The other aortic arches have possibly a different morphological significance, but their exact nature is not definitely settled.

The second, third, fourth, fifth, and sixth cephalic aortic arches of each side are developed in the undivided mesoderm of the head region, caudal to the first arch. They spring from the part of the primitive aorta which, after the head-fold is formed, lies on the ventral aspect of the fore-gut, and they extend, at the side of the pharyngeal part of the fore-gut, to the dorsal aorta. Thus in some respects they may be looked upon as segmental vessels. In addition to the vessels already mentioned, there are given off from the ventral aortæ and the aortic arches a series of branches which supply ventral and lateral diverticula from the alimentary canal; these are represented in the adult by the superior thyroid and the thyroidea ima arteries.

Iliac Arteries and their Branches.—The common iliac arteries are formed from the secondary roots of the umbilical arteries, and their exact morphological position is uncertain. The true morphological position of the internal iliac arteries is not yet defined. They also are parts of the secondary roots of the umbilical arteries, and they give off both somatic and splanchnic branches; therefore they do not correspond either with somatic intersegmental or with splanchnic arteries. The branches of the internal iliac artery are arranged in two groups: (1) a visceral set which supplies the walls of the hind-gut and the genital organs, and (2) a parietal set which is distributed to the body-wall and to the hind-limbs. The branches distributed to the gut probably represent the splanchnic vessels, more or less homologous with ordinary splanchnic branches of the primitive aortæ, and the parietal branches are possibly the homologues of intersegmental arteries.

Arteries of Limbs

In all probability the vessels of both the upper and the lower limbs are derived originally from several somatic intersegmental arteries, the majority of which, however, have atrophied. The upper limb is supplied in man by the lateral offset from the ventral branch of the seventh somatic intersegmental artery. It passes into the limb caudal to the shoulder girdle, courses through the upper arm, enters the cubital fossa, and is continued through the forearm, in the early stages, as the anterior interosseous artery, which ends in the deep palmar arch. At a later period, ontogenetically, a median artery appears as a branch of the parent stem, and it ends in a superficial palmar arch; still later the radial and ulnar branches are formed. The latter grow rapidly, soon exceeding in size the parent stem, and they terminate in the superficial and deep palmar arches. The interosseous and median arteries decrease, and generally lose their direct connexions with the palmar arches. The posterior interosseous artery also is a secondary branch from the parent stem, and the digital arteries are offsets from the palmar arterial arches (Fig. 1135, p. 1375).

The chief arteries of the lower limbs spring directly from the secondary roots of the umbilical arteries, and may be looked upon as being essentially intersegmental; whether they represent the whole or only parts of typical somatic intersegmental arteries, however, is not clear.

The arteries of the lower limbs certainly show no very obvious indications of division into dorsal and ventral branches, though such indications are not entirely wanting. In their comparative absence it is supposed that the dorsal branches have been either suppressed or incorporated with the common stems; that similarly the ventral branches and their lateral offsets are indistinguishably fused, and that probably both are represented in a limb-artery.

The original stem-vessel of the lower limb is the inferior gluteal artery, which is continued distally, posterior to the pelvic girdle, into the popliteal and peroneal arteries, and so to the sole of the foot, where it ends in a vascular plexus. Subsequently the external iliac artery is given off from the secondary root of the umbilical artery, dorsal to the origin of the inferior gluteal, and, passing into the limb anterior to the pelvic girdle, it becomes the greater part of the femoral artery. That vessel ultimately unites with the proximal part of the popliteal artery, and after the communication is established the distal part of the inferior gluteal atrophies and loses its connexion with the popliteal, which henceforth appears to be the direct continuation of the femoral trunk; therefore, whilst the main artery of the upper limb is formed by the prolongation of the lateral branch of one intersegmental artery, the corresponding vessel of the lower limb is developed from representatives of, probably, two somatic intersegmental arteries, the external iliac and femoral trunks being the representatives of one, whilst the popliteal and its continuation, the peroneal, are parts of another.

The first main artery of the leg, ontogenetically, is the peroneal, which is continued into the plantar arch; after a time, however, the posterior and anterior tibial branches appear. As a rule, they soon preponderate in size, and they terminate in the plantar arch, whilst the original trunk diminishes and loses its direct connexion with the arch (Fig. 1136).

The peroneal artery corresponds in position and development with the common interosseous trunk and the anterior interosseous artery in the forearm. The posterior tibial apparently corresponds with the median artery; it develops in a similar way, and has similar relations to

homologous nerves, the posterior tibial nerve representing the combined median and ulnar nerves of the upper limb.

The anterior tibial artery represents the posterior interosseous, whilst the radial and ulnar arteries of the upper limb are not represented in the lower limb (cf. Figs. 1135 and 1136).

MORPHOLOGY OF VEINS

The formation of the chief adult veins from the various longitudinal trunks which appear in the embryo has been described in the account of the development of the veins (pp. 1377-1384); and the transference of the terminations of the intersegmental veins from one position to another was noted.

In the discussion of the morphology of the arteries it was shown that the ventral branches of the intersegmental arteries are primitively connected by pre-costal and ventral anastomoses; the dorsal branches by post-costal and post-transverse anastomoses; the spinal offsets of the dorsal branches are linked together by post-central and pre-laminar anastomoses, and their neural branches by pre- and post-neural anastomoses.

Similar anastomoses are formed between the corresponding veins, but they tend in many cases to be plexiform, as in the case of the vertebral veins.

Remnants of pre-costal venous anastomoses are found in the adult as the ascending lumbar and lateral sacral veins; and ventral anastomoses are represented by the internal mammary, and the superior and inferior epigastric veins.

Post-costal anastomoses are represented by the vertebral veins, and post-transverse anastomoses by the deep cervical veins.

Pre-laminar and post-central anastomoses form the adult posterior and anterior longitudinal vertebral sinuses; and pre- and post-neural anastomoses give rise to the antero-lateral and postero-lateral veins of the spinal cord.

The morphology of the splanchnic veins corresponds closely with that of the splanchnic arteries, and does not require separate consideration.

Veins of Limbs.—The veins of the limbs, like the arteries, were probably at one time intersegmental in character, but we have no indisputable proof that this was the case. Looked at from an embryological standpoint, the most primitive limb-veins are a superficial distal arch and a post-axial trunk-vein in each limb; at a later period digital veins are connected with the distal arch, and a pre-axial trunk is formed. In the upper limb the distal arch and its tributaries remain as the dorsal venous arch and the digital veins, and the post-axial vein becomes the basilic, axillary, and subclavian veins. The pre-axial vein of the upper limb is represented in the adult by the cephalic vein; the latter vessel originally terminated in the external jugular vein, above the clavicle, the union with the axillary portion of the post-axial vessel being a secondary condition; the primary condition is, however, frequently retained in Man, and is constant in many monkeys. The anastomosis between the pre-axial and post-axial veins in the region of the elbow, and the connexion of the anastomosing channels, are brought about by newly formed vessels of secondary character.

The distal arch in the lower limb and the tributaries connected with it remain in the adult as the dorsal venous arch of the foot and the digital veins. The post-axial vein becomes the short saphenous vein, which was originally continued proximally as the popliteal and inferior gluteal veins to the internal iliac portion of the posterior cardinal vein.

The pre-axial vein of the lower limb becomes the long saphenous vein, which is continued proximally to the posterior cardinal portion of the left common iliac vein as the proximal part of the femoral and the external iliac veins.

The venæ comitantes of the arteries in both the upper and lower limbs are secondarily developed vessels which become connected with the upper portions of the pre-axial venous trunks.

VARIATIONS AND ABNORMALITIES OF VASCULAR SYSTEM

Variations are of special interest to the anatomist because of their morphological significance, and the vascular system is, perhaps more than any other, rich in such variations, many of which are of great practical importance.

With the exception of those irregularities which are directly due to the effect of morbid conditions and external influences, all variations are the result of modifications of normal developmental processes. The exceptions referred to are, however, very numerous; thus, disease and external influences may lead to the obliteration of vessels, a condition which is invariably associated with the enlargement of collateral vessels; and it is obvious that abnormalities so produced may occur in almost any situation.

Variations which are determined by, or are dependent upon, modifications of the usual developmental processes are of greater interest. In the human subject they are generally due either to the retention of conditions which, normally, are only transitory in ontogenetic development, or to the acquirement of conditions which, though not as a rule present at any time in Man, occur normally in some animals.

There are, in addition, other variations from the normal, such as the division of the axillary artery into radial and ulnar branches; the higher or lower division of the brachial artery; the

formation of "vasa aberrantia", *e.g.*, of long slender vessels that connect the axillary or brachial to the radial, ulnar, or interosseous arteries; the altered position of certain vessels, *e.g.*, the transference of the subclavian artery to the front of the scalenus anterior, or of the ulnar artery to the front of the superficial flexor muscles; all of which, though undoubtedly due to alterations of ordinary developmental processes, still do not represent any known conditions met with, either temporarily or permanently, in Man or in other animals. Their occurrence cannot at present be adequately explained, and their retention in the adult is dependent entirely upon their utility.

To the first and the last of these different groups of abnormalities it is not necessary to refer further, whilst, with regard to the rest, they have been already sufficiently indicated after the accounts of the heart and individual vessels. They cannot, however, be fully understood and explained except on the basis of a comprehensive knowledge of the development and morphology of the vascular system, to the paragraphs on which the reader is referred.

Abnormalities or variations of veins are more frequently met with than those of arteries, and they are due to similar causes. Those who require more detailed information should consult special monographs (Quain, 1844 ; Dubrueil, 1847 ; Adachi, 1928, 1933).

LYMPHATIC SYSTEM

While the arterial system is the sole distributing agent, the veins are assisted by another set of absorbent vessels—the lymph-vascular system. The fluid absorbed by it—called **lymph**—contains numerous white corpuscles and is colourless except that from the intestinal canal, which appears milky during digestion because of its fatty content.

In structure the **lymph-vessels** resemble veins, but differ in the following ways. (*a*) the capillaries are wider and more irregular in calibre; (*b*) beyond the stage corresponding with venules the vessels are smaller than veins and have their valves

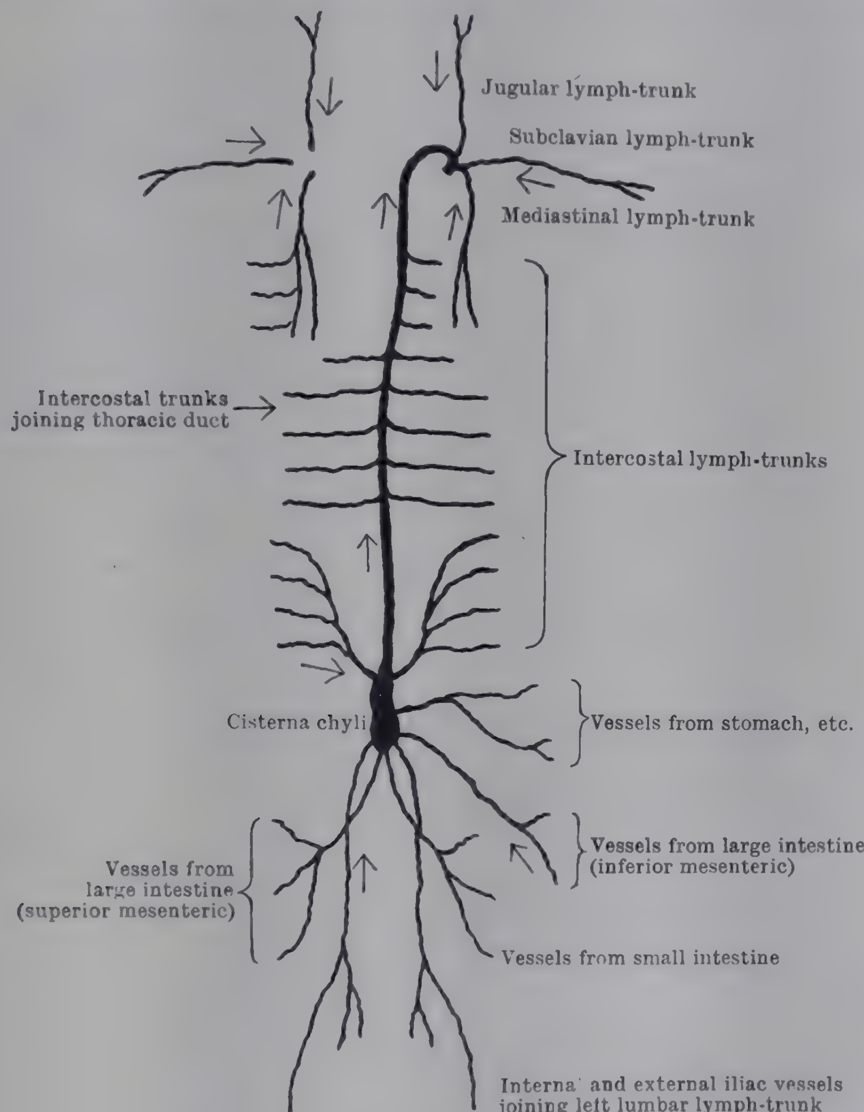

FIG. 1150.—DIAGRAM OF MAIN LYMPH-VESSELS.

so closely and regularly set that in distension they have a uniform beaded appearance—a distinguishing characteristic; (*c*) they run in streams with little tendency to form large trunks; (*d*) they are interrupted by nodular aggregations of lymphoid tissue called **lymph-glands**; (*e*) their distribution is limited, for they are absent not only from avascular tissues but also from the entire central nervous system, and possibly from muscle and bone.

The lymph-vessels merely collect and convey lymph; the lymph-glands serve in part as "filters"—arresting solid particles or bacteria which may be taken up by the lymph-vessels—and in part as the sources of origin of those lymph-corpuscles which are called **lymphocytes** and become white blood-corpuscles when they enter the blood-stream. In its course from the tissues to the blood-vessels most of the lymph passes through at least one lymph-gland, and generally more than one; direct delivery of lymph into the veins is very exceptional (see p. 1439).

The capillaries from which **lymph-vessels** arise are essentially sub-epithelial in position and are found abundantly in the skin, mucous membranes, all glands (including ductless glands), all serous membranes and synovial membranes.

The *superficial lymph-vessels* lie in the skin and subcutaneous tissues; they frequently accompany the superficial veins and, in the limbs, they join the deep vessels in definitely localized situations.

On each side of the body the cutaneous lymph-vessels converge from three large areas upon three groups of lymph-glands (Figs. 1151, 1152, 1178): (*a*) from the skin of the lower limb, perineum, external genital organs and the trunk below the level of the umbilicus—to empty into the lymph-glands in the groin; (*b*) from the skin of the upper limb and the trunk above the umbilicus to the level of the clavicle in front and halfway up the back of the neck behind—to the lymph-glands in the axilla; (*c*) from the scalp, face, and the rest of the neck—to the cervical glands.

The *deep lymph-vessels* drain the lymph from parts of the body which lie deep to the deep fascia. They tend to accompany the blood-vessels of the various parts and organs; those of the viscera, however, frequently take unexpected courses to reach the nearest lymph-glands.

The deep vessels of the limbs and trunk are relatively scanty and arise primarily in the synovial membranes of the joints. As cutaneous lymph-vessels may penetrate the deep fascia with the veins and run between muscles to join the deep stream, and as the lymph-vessels of mucous membranes have to burrow through the muscular structure of the organs from the tongue downwards, it may appear that lymph-vessels take origin in muscular tissue; but in relation to muscle they are probably mainly passengers. Lymph-capillary networks have, however, been described on tendons; and some observers believe that they occur also in the fibro-areolar tissues of muscle. Indeed, it has been stated that a capillary plexus exists around the fibres of striated muscle (Aagaard, 1913).

The **lymph-glands** also are divided into superficial and deep groups. The former lie in the superficial fascia and are comparatively few in number; they are associated more particularly with the superficial lymph-vessels of the limbs and the trunk. The deep glands of the limbs also are comparatively few in number, but those of the head, neck, and trunk are very numerous.

General Plan of Lymphatic System.—This may be set out as follows:—(1) The capillaries of origin form plexuses which underlie surface epithelia and surround the acini and ducts of glands. (2) From these networks larger vessels of the venule type pass more deeply and penetrate the subjacent tissue—whether superficial fascia, submucous and muscular coats, or stroma of a gland—in which they communicate freely in networks. (3) From these deeper networks arise the valved collecting vessels which run towards the lymph-glands. On reaching a lymph-gland the vessels, conveniently called **afferent vessels**, penetrate the capsule at numerous points. (4) The lymph-glands are stations in which the vessels are broken up into a labyrinth of active reticular tissue (p. 12) by which the fluid is treated in such a manner that a large part of it is absorbed by the venous network in the gland and only a residue is passed out by one or two lymph-vessels. (5) These are called **efferent vessels**, and they may run with afferent vessels into another gland of the same group or pass on to another group. (6) From the most central group of each chain of glands the efferent vessels unite to form **lymph-trunks** which are named: (*a*) *Lumbar*; (*b*) *Intestinal*; (*c*) *Intercostal*; (*d*) *Mediastinal*; (*e*) *Subclavian*; (*f*) *Jugular*. (7) Each trunk drains a definite territory of the body, and they all empty into great terminal vessels—the **thoracic duct** and **right lymphatic duct** (p. 1403)—which open into the great veins in the root of the neck (Fig. 1150).

By constant reduction of the stream of lymph as it passes through the chains of lymph-glands, the *lymph-trunks*, though draining large areas, are actually small vessels which easily escape notice in a dissection; and as most of the lymph absorbed from the body is thus restored to the circulation gradually, the residue, mainly derived from the intestines (*chyle*), is accommodated in the thoracic duct—no larger than a crow-quill.

Order of Description.—After the following general paragraphs on lymph-vessels and lymph-glands, the main lymph-vessels are described first, and then the position of the groups of glands and the arrangement of the vessels in each of the territories drained by the lymph-trunks, in the order given above. The student should note that these territories do *not* correspond precisely with the ordinary divisions of the body. Readers who desire a more detailed description

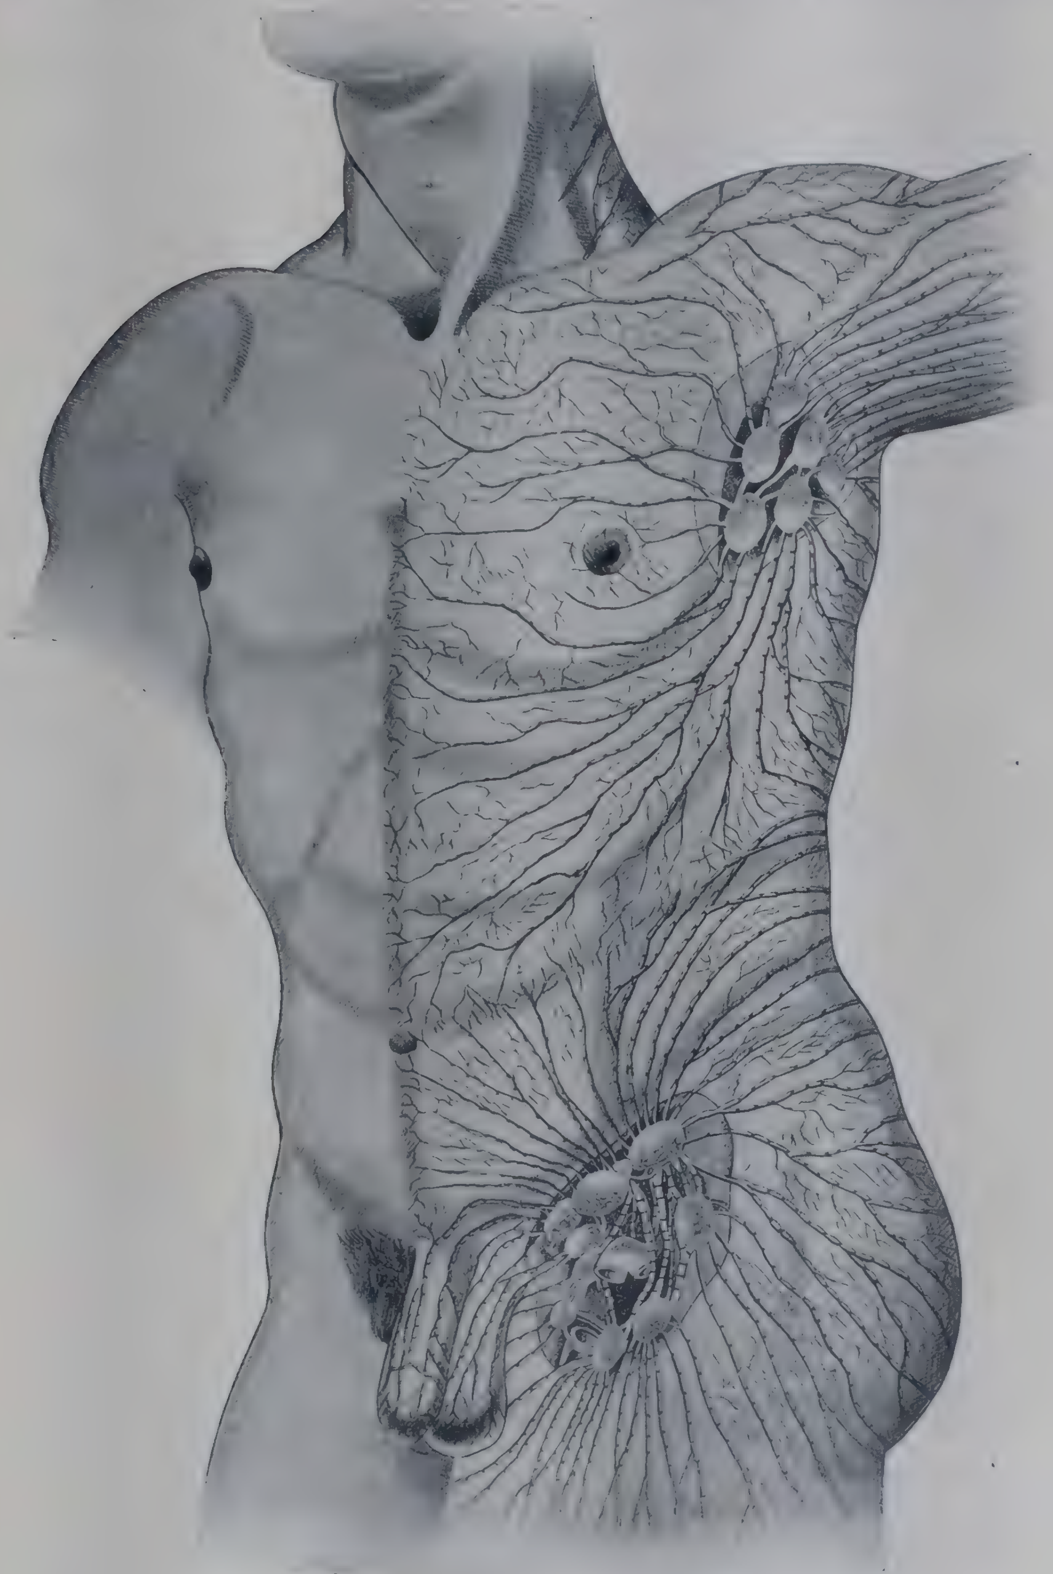

Fig. 1151.—Cutaneous Lymph-Vessels of Anterior Surface of Trunk. (After Sappey, 1874.) Note the "lymph-shed" between the vessels that pass to the axillary and to the inguinal lymph-glands.

of the topography and variations of the lymph-glands and lymph-vessels are referred to the standard works on the subject—Poirier & Cunéo (1902), or Leaf (1903); Bartels (1909); Rouvière (1932)—and to the papers quoted on special topics. For a critical account of the physiological and clinical significance of the lymphatic system in general, the monograph by Drinker & Yoffey (1941) should be consulted.

Lymph-Vessels.—The *capillaries* of origin are *closed*, having no communication with blood-vessels or with tissue-spaces. The stomata, by which they have been said

to communicate with serous cavities, are probably only patches of intercellular substance, and though fluid readily passes through serous membranes into the tissue-spaces, from which it is absorbed by the lymph-capillaries, there is no proof of a direct connexion. Lymph-capillaries are wider than blood-capillaries and more irregular in calibre ; but they have the same structure a single layer of endothelial cells through

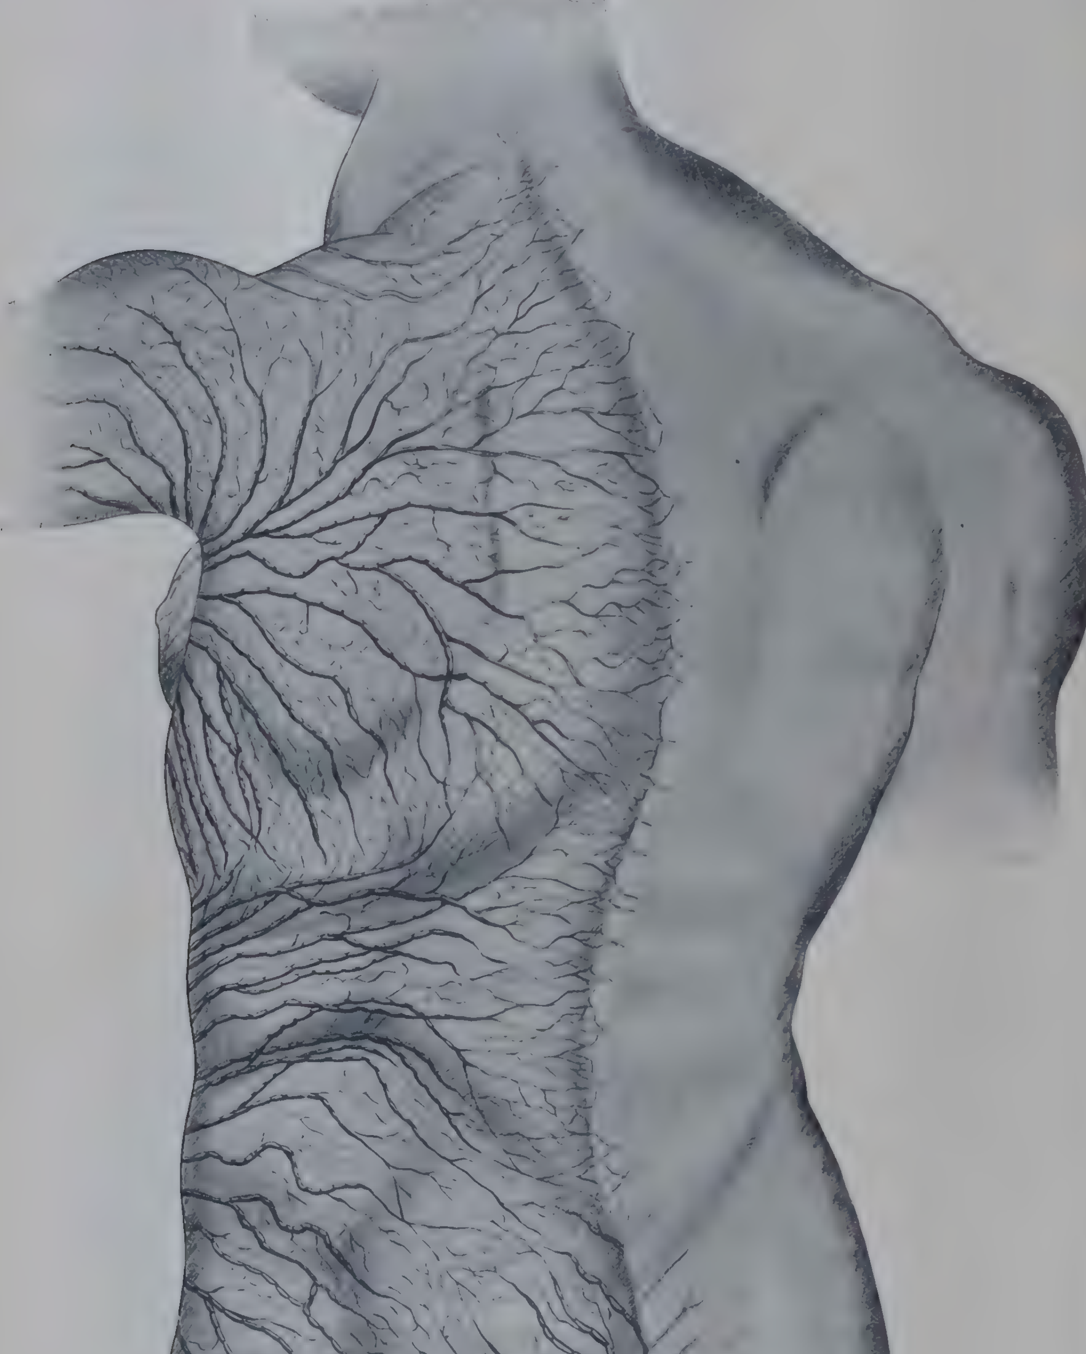

FIG. 1152.—CUTANEOUS LYMPH-VESSELS OF POSTERIOR SURFACE OF TRUNK. (After Sappey, 1874.) Note the "lymph-sheds" between the vessels that pass to the axillary and to the inguinal lymph-glands, and on the buttock between vessels that pass to the inguinal glands by lateral and by medial routes.

which lymph is absorbed from the tissue-fluid. Wandering phagocytic cells carry in solid particles (*e.g.*, carbon-dust and germs) which have entered the body through the skin or the mucous membranes.

From their subepithelial position lymph-capillaries are well placed to absorb the elements which form chalky, keratinous, and chitinous deposits and thus prevent their deposition in the

skin and in mucous, synovial, and serous membranes. There seems to be a relation between the evolution of the lymph-vascular system and the disappearance of the exoskeleton of lower forms; and nails and horns are found only in the positions which are the last to be reached by the lymph-vessels in the development of individuals.

Although the lymph-capillaries form an extensive network, it is probable that this is not continuous over large areas but arranged in more or less discrete patches from which there is selective absorption by larger vessels of the venule type. These vessels form wider-meshed networks in the skin, mucous membranes, etc., and from them vessels coalesce to form the collecting vessels.

The *collecting vessels*, as they run towards the lymph-glands, receive tributaries from a narrow area. They are small vessels, white in colour, and are distinguished by their characteristic beaded appearance due to valves of the venous type placed at close and regular intervals. They are joined by smaller, tributary vessels and frequently communicate with neighbouring collecting vessels, but, unlike the veins, they always run in streams of individual vessels rather than by confluence into larger trunks (see Fig. 1172). On reaching a gland each afferent vessel usually breaks up into smaller branches which penetrate the capsule. The issuing, efferent vessels are only slightly larger than the afferent vessels and have the same structure. Owing to the valves, the collecting lymph-vessels can be injected only by thrusting a hollow needle into the plexus of origin and pumping in metallic mercury (used by early investigators) or a colouring fluid that flows freely (Gerota, 1896; Jamieson & Dobson, 1910 *b*). Small patches only are injected from each puncture, and thus a large number of injections is required for a picture such as is given by a single injection into an artery.

As the lymph-vessels attain a larger size, their walls are strengthened by a layer of elastic fibres on the outer surface of the endothelial coat. The fibres run longitudinally, and in some cases fuse together to form a fenestrated elastic membrane.

The walls of all the largest lymph-vessels resemble those of veins and have three coats. The **inner coat** is a layer of endothelium covered externally by elastic fibres or a fenestrated elastic membrane. The **middle coat** is formed of transverse and oblique plain muscle-fibres, intermingled with elastic fibres. The **outer coat** consists of longitudinal fibrous tissue elements with which oblique and longitudinal plain muscle-fibres are intermingled; the latter feature is not met with in the blood-vascular system, except in the walls of some of the larger veins (p. 1224).

The bicuspid valves of lymph-vessels are semilunar folds of the inner coat similar to those of veins. They are extremely numerous in the collecting vessels and are present also near the entrances of the great lymph-channels into the venous system.

Lymph-Glands.—These are nodules varying in size from a pin's head to an almond; they are usually ovoid but may be globular, flattened, or irregular in shape. The larger glands show a depressed area, known as the *hilum*, through which the blood-vessels enter and the efferent lymph-vessel emerges. The consistence is firm and the colour is usually greyish pink, but the tint varies with the position, vascularity, and state of activity of the gland. The lymph-glands of the lungs are commonly blackened by deposit of carbon particles and those of the liver and spleen are often brownish; those of the mesentery are creamy or white while the chyle is passing through in quantity.

The lymph-glands lie in loose areolar tissue, generally in groups but occasionally single. As they develop, the great majority are found in association with the primitive digestive canal in the pelvis, abdomen, thorax, and neck, and in the roots of the limb-buds (axilla and groin). With the exception of the superficial inguinal glands, very few lie in the plane of the superficial fascia. A few small glands stray along the blood-vessels into the limbs, into the intercostal spaces and the intervals between the lumbar transverse processes, along the internal mammary artery behind the costal cartilages, and along the occipital, posterior auricular, and facial arteries; but all these are outposts of the main groups which lie deeply in the neck and trunk, for the most part by the sides of the great blood-vessels.

The structure of lymph-glands is such that they tend to arrest for a while the central spread of malignant, cancerous tumours, cells from which may be passing or growing along the lymph-vessels. This is the most important reason why exact knowledge of the situation of the lymph-glands to which the lymph-vessels of any region or organ may run is essential for surgical practice.

Structure of Lymph-Glands.—Lymph-glands consist essentially of: (1) masses of lymphoid tissue, supported by (2) a fibrous framework including an external capsule and internal trabeculæ separated from the lymphoid tissue by (3) spaces called lymph-sinuses. Each gland is separable also into cortex and medulla. The *cortex* lies immediately internal to the capsule, except at

the hilum, where it is absent. The *medulla* forms the internal part of the gland and reaches the surface at the hilum.

The **capsule** is formed of white fibrous tissue interspersed with elastic fibres; it contains some plain muscle-fibres which extend into the trabeculæ.

The **trabeculæ** spring from the deep surface of the capsule and radiate through the cortex into the medulla, where they are broken up to form a coarse, supporting network.

The **lymph-sinuses** lie internal to the capsule and around the trabeculæ; and they separate both from the lymphoid tissue. The afferent lymph-vessels of the gland pierce the capsule and enter the subcapsular sinus, from which branches pass inwards along the sides of the trabeculæ. The sinuses are traversed by fine fibrous tissue strands, and their channels are thus converted into a kind of sponge-work through which the lymph percolates into and through the lymphoid tissue. The lymph is ultimately collected by one or two efferent vessels which emerge from the medulla at the hilum.

The **lymphoid tissue** is continuous throughout the gland; but in the cortex it appears as rounded masses—*lymphoid nodules*—and in the medulla as branching and uniting strands known as *lymphoid cords.* Capillary-like lymph-spaces pass from the lymph-sinuses into the lymphoid tissue; and the endothelial lining becomes gradually converted into a *reticulum* of active phagocytic cells. It is through the meshes of this reticulo-endothelial tissue (p. 12) that the lymph has to pass on its way from afferent to efferent vessels, taking up *lymphocytes* from the masses of these cells with which the meshes of the reticulum are crowded.

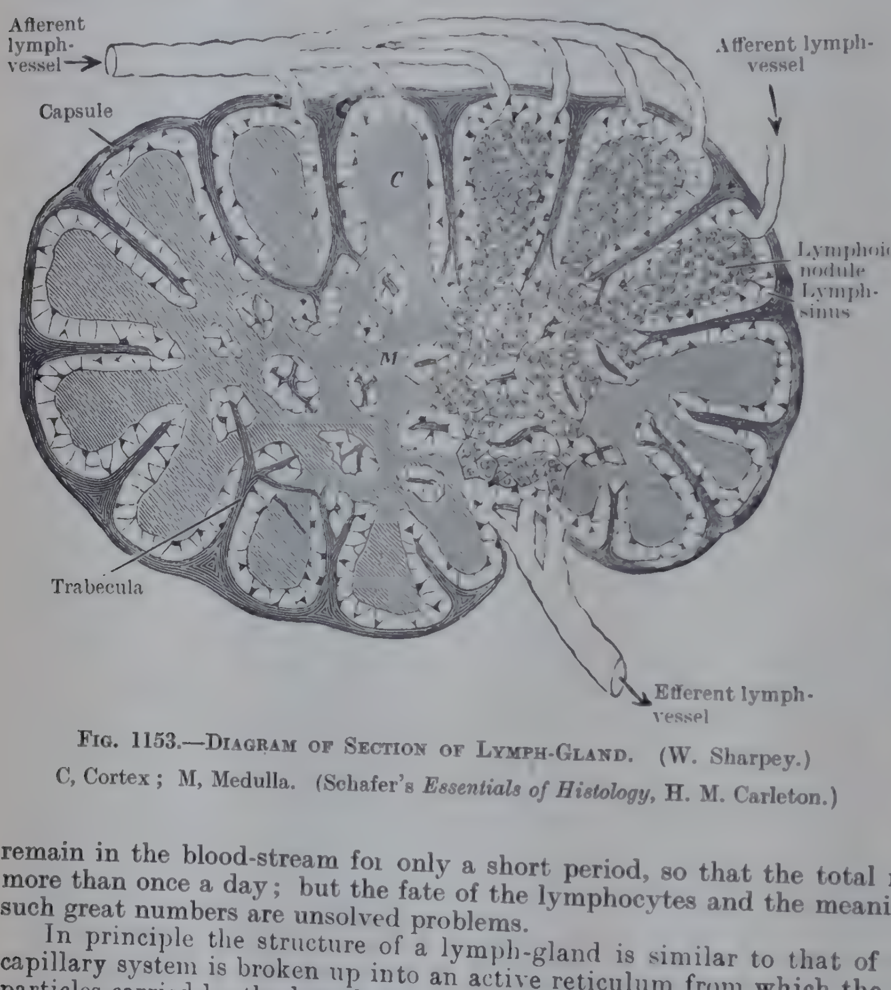

Fig. 1153.—Diagram of Section of Lymph-Gland. (W. Sharpey.)
C, Cortex; M, Medulla. (Schafer's *Essentials of Histology*, H. M. Carleton.)

One of the principal functions of the lymph-glands is the production of lymphocytes which enter the blood through the thoracic duct in prodigious numbers, to be reckoned in thousands of millions per day (Yoffey, 1933, 1936). The lymphocytes remain in the blood-stream for only a short period, so that the total number may be replaced more than once a day; but the fate of the lymphocytes and the meaning of their production in such great numbers are unsolved problems.

In principle the structure of a lymph-gland is similar to that of the spleen, in which the capillary system is broken up into an active reticulum from which the veins reform. Insoluble particles carried by the lymph to a gland are taken up by the phagocytic reticular cells, and may be permanently encapsuled in the gland.

Blood-Vessels of Lymph-Glands.—Small arteries are distributed to the capsule and through the capsule to the trabeculæ of the glands; but the main artery enters the hilum and breaks up into branches which follow the trabecular network of the medulla and enter the lymphoid nodules and cords, where they end in capillaries. The veins emerge at the hilum (Fig. 1049).

Hæmal Lymph-Glands.—In various parts of the body, but more particularly in the retro-peritoneal region, and especially along the line of the abdominal aorta, a number of glands may be found which differ from ordinary lymph-glands in that some of their sinuses contain blood (p. 1440). They are called hæmal lymph-glands; the sinuses which contain lymph are in continuity with lymph-vessels, whilst the blood-filled sinuses open into blood-vessels.

Solitary Lymphatic Nodules.—Pin-head collections of lymphoid tissue, consisting of a reticulum enmeshing lymphocytes, are found in the mucous coat of the alimentary canal. They appear to be set in the path of lymph-vessels proceeding from the capillary plexus of origin and may be deemed to be lymph-glands in miniature. These *solitary lymphatic nodules* resemble the lymphoid nodules in the cortex of lymph-glands. In the pharynx there are great aggregations of units which form tonsils; in the ileum many of the nodules

coalesce to form elongated raised patches (*aggregated lymphatic nodules*); and in the vermiform appendix they form masses which constitute the most striking feature of its structure.

Rudimentary Lymph-Glands.—In the path of lymph-vessels before they reach the regional glands there are frequently minute nodules which interrupt one or two vessels

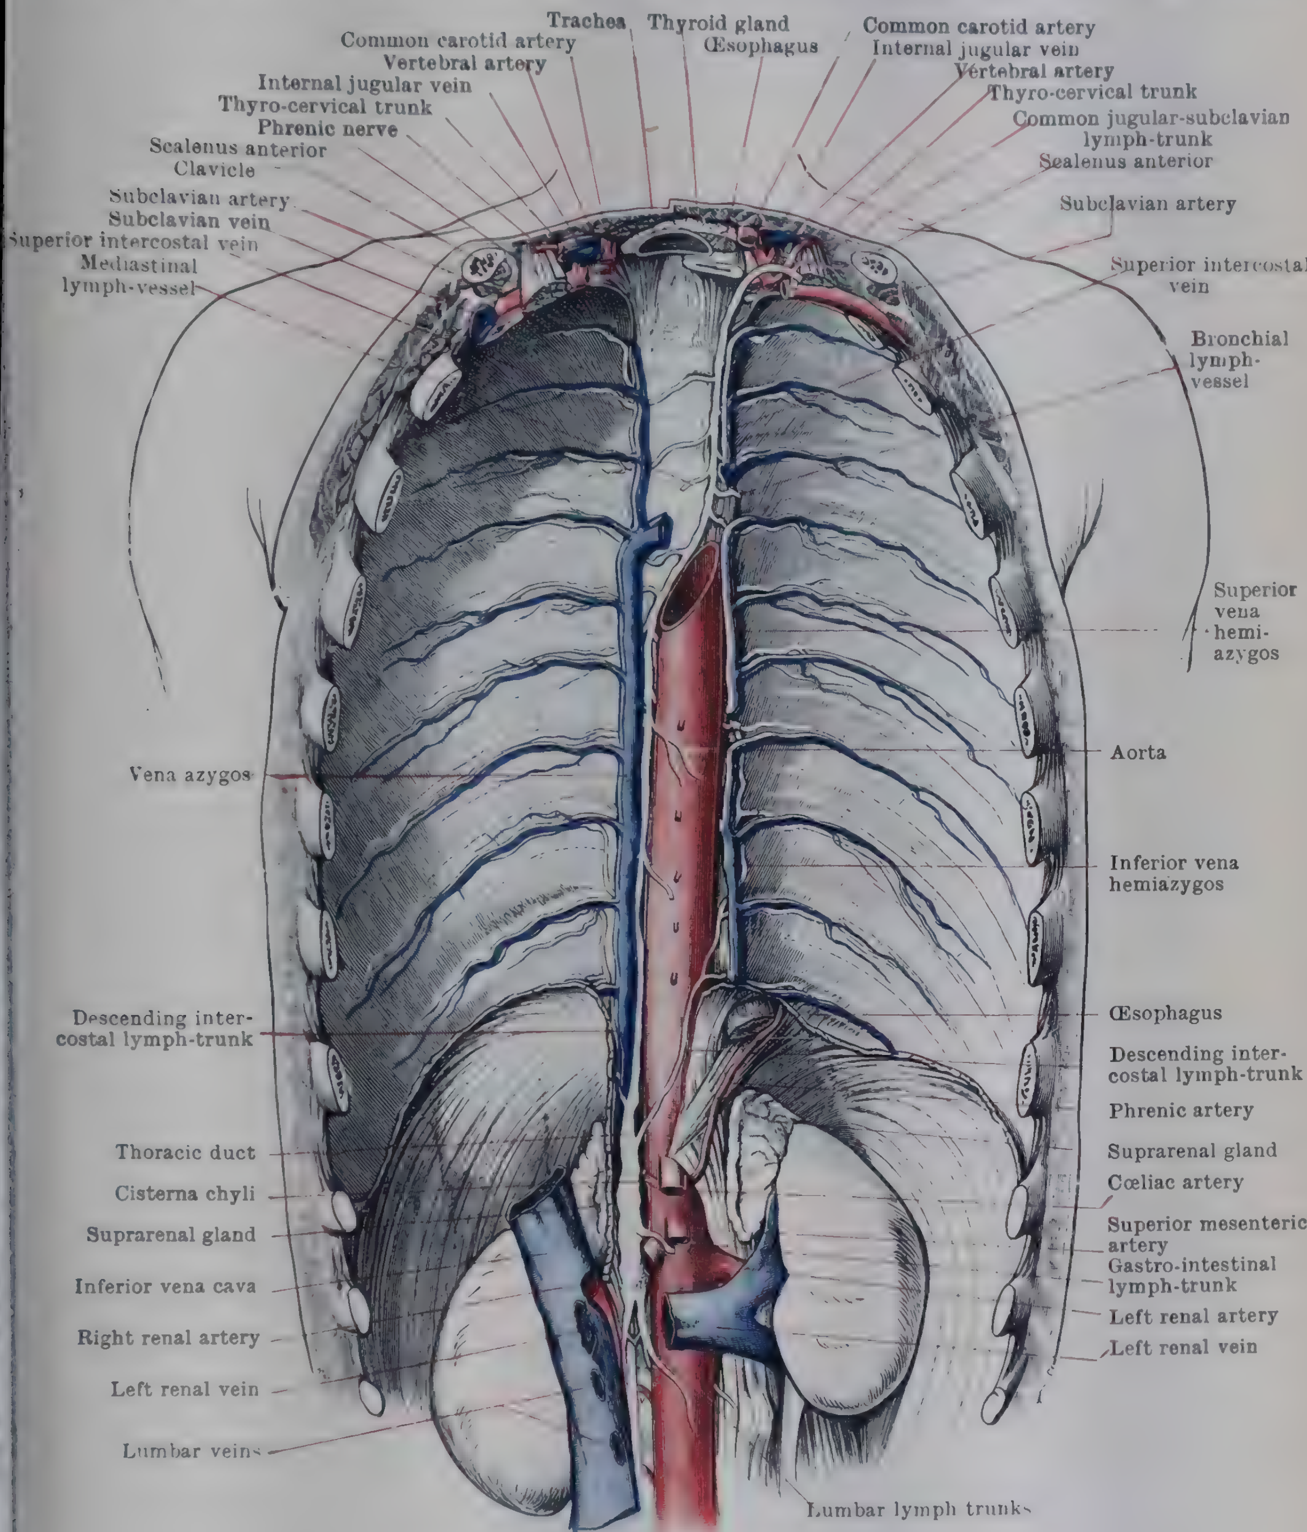

FIG. 1154.—THORACIC DUCT AND ITS TRIBUTARIES.

only. They are tiny lymph-glands in which only a few lymphoid units are involved: examples are the glands on the tibial vessels, deep vessels of forearm, tongue, etc. In some situations these minute glands become recognizable only during functional activity, *e.g.*, in the axilla during lactation.

TERMINAL LYMPH-VESSELS

The terminal lymph-vessels are the **thoracic duct** and the **right lymphatic duct** (or the vessels that represent it).

The **thoracic duct** is by far the wider and the longer of the two. It begins in the abdomen as an elongated, ovoid dilatation—the **cisterna chyli**—which measures $\frac{1}{4}$ to $\frac{1}{3}$ of an inch (6 to 8 mm.) in its broadest diameter, and from 2 to 3 inches (50 to 75 mm.) in length. The cisterna chyli lies between the aorta and the right crus of the diaphragm, and opposite the first and second lumbar vertebræ. Passing upwards from the cisterna, through the aortic opening of the diaphragm, the thoracic duct enters the posterior mediastinum, and ascends, on the front of the vertebral column, to the right of the median plane, to the level of the fifth thoracic vertebra; it then crosses from the right to the left of the median plane, and ascends through the superior mediastinum to the root of the neck, where it turns laterally behind the carotid sheath and

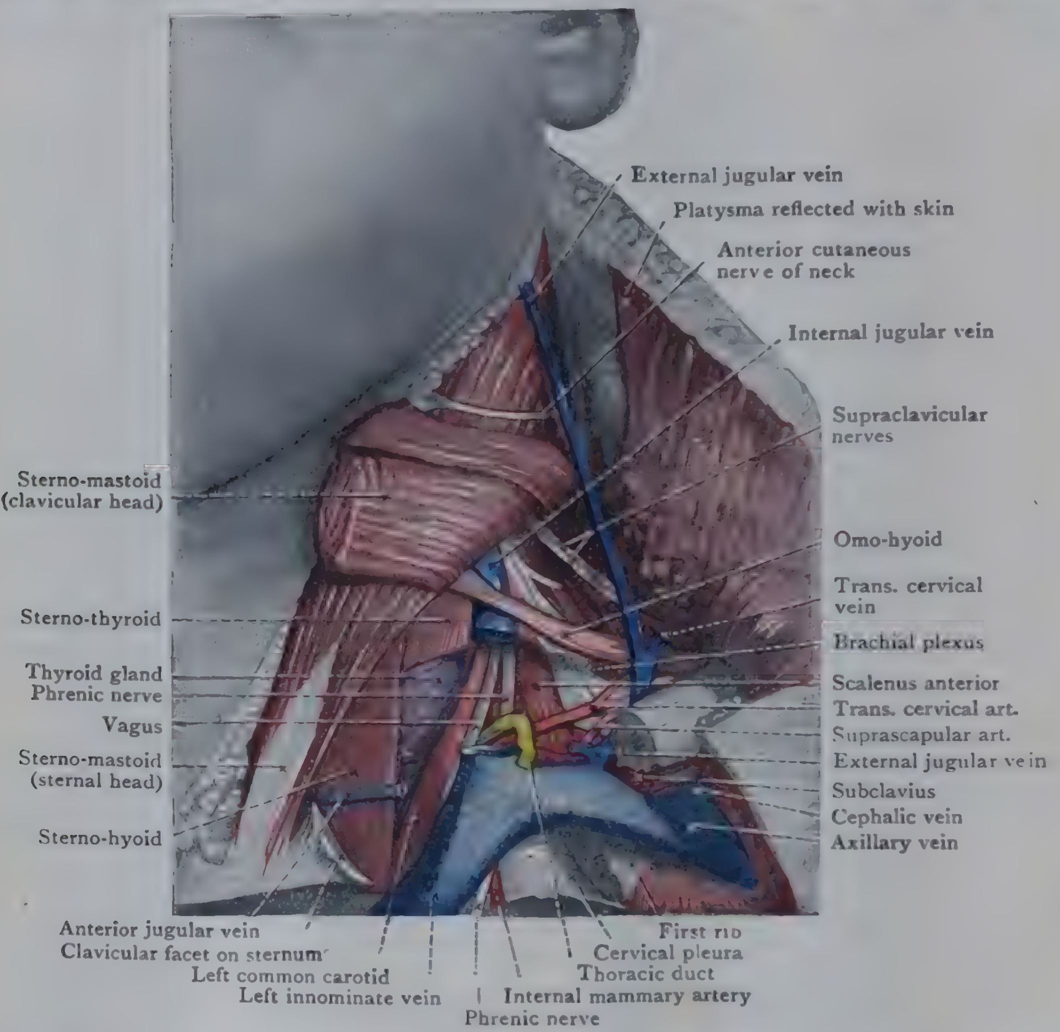

Fig. 1155.—Deep Dissection of Root of Neck on Left Side to show Cervical Pleura and Relations of Thoracic Duct.

Parts of the sterno-mastoid and the sterno-thyroid have been removed.

then descends across the subclavian artery to end at the medial border of the left scalenus anterior by joining the left innominate vein in the angle of junction of the internal jugular and the left subclavian veins.

The thoracic duct is about 18 inches (45 cm.) long, and about a line (2 mm.) in diameter, but it is rather wider at its origin from the cisterna. It may divide and reunite in its course through the thorax, and its terminal part is often broken up into a number of branches which end separately in the great veins. It is provided with numerous valves arranged in pairs, the most perfect of which is near its termination.

Relations.—*In the abdomen*, the cisterna chyli lies anterior to the upper two lumbar vertebræ and the corresponding right lumbar arteries, between the aorta on the left and the vena azygos and the right crus of the diaphragm on the right. *In the posterior mediastinum*, the thoracic duct is separated from the vertebral column and the anterior longitudinal ligament by the right posterior intercostal arteries and the transverse parts of the hemiazygos veins; it is covered, in front, in the lower part of its extent by the diaphragm and the

right pleura, and in the upper part by the œsophagus; to its right is the vena azygos, and to its left the descending aorta. *In the superior mediastinum* it passes forwards from the vertebral column and it is separated from the left longus cervicis muscle by a mass of fatty tissue; the œsophagus lies in front of it in that region, but the left margin of the duct projects beyond the œsophagus, and is in relation anteriorly, and from below upwards, with the arch of the aorta, the left subclavian artery and the pleura. As the duct enters the root of the neck it passes behind the left common carotid artery, whilst to its right and a little in front is the œsophagus, and the left pleura is still in association with its left border.

At the root of the neck it arches laterally in front of the apex of the pleura and then downwards across the first part of the left subclavian artery. It passes in front of the vertebral artery and vein, the roots of the inferior thyroid, transverse cervical, and suprascapular arteries, the medial border of the scalenus anterior and the left phrenic nerve, and behind the left carotid sheath and its contents (Fig. 1155).

Tributaries.—The cisterna chyli commonly receives five tributaries:—(1) The **intestinal trunk**, which is formed by the efferents of the superior mesenteric and cœliac groups of lymph-glands, and conveys lymph from the lower and anterior part of the liver, the spleen, the pancreas, the stomach, the small intestine and the greater part of the large intestine. (2) A pair of **lumbar trunks**, formed by the efferents of the aortic glands, carry lymph from the whole of the skin below the level of the umbilicus, from the deep portions of the lower limbs, the lower abdominal and the pelvic walls, from the rest of the large intestine and the pelvic viscera, and from the kidneys, suprarenal glands and genital glands. (3) A pair of **descending intercostal lymph-trunks**, formed by the efferent vessels from the lower intercostal glands (see p. 1423), descend to the cisterna through the aortic opening of the diaphragm. Occasionally they unite to form a single trunk, and sometimes they, or some of the tributaries from which they are usually formed, open directly into the thoracic duct (Fig. 1154).

In its course through the posterior mediastinum the thoracic duct receives efferents from the posterior mediastinal glands and such of the intercostal glands as do not send their efferents into the descending trunk; through the posterior mediastinal glands it receives lymph from the œsophagus and the back of the pericardium, and also some from the upper and posterior part of the liver.

In the superior mediastinum the efferents of the upper intercostal glands of both sides open into it; it may receive also communications from the mediastinal lymph-trunks of both sides.

At the root of the neck, immediately before its termination, it may receive: (1) the efferents from the glands of the left upper limb, which frequently unite to form a **subclavian trunk**; and (2) the **left jugular trunk**, which conveys the lymph from the left side of the head and neck; but either of those vessels or both of them may end separately in the innominate or the subclavian vein. The **left mediastinal trunk** is rarely a tributary of the thoracic duct in the neck; almost invariably it has an independent entrance into the left innominate vein. It collects lymph from the deeper parts of the anterior thoracic wall and of the upper part of the anterior abdominal wall and from the anterior part of the diaphragm on the left side, from the left half of the mediastinum, the left side of the heart and the left lung.

The **right lymphatic duct** (Fig. 1156) is not always present. Indeed, it rarely exists as such, since the three vessels which occasionally unite to form it usually open separately into the right internal jugular, subclavian, and innominate veins. These vessels are (1) the **right jugular trunk**, (2) the **right subclavian trunk**, and (3) the **right mediastinal trunk**. It is not uncommon for the jugular and subclavian trunks (conveying lymph from the right side of the head and neck and from the right upper limb respectively) to unite, as on the left side, before entering the veins at the point corresponding to that at which the thoracic duct enters on the left side; and this is the commonest form of "right lymphatic duct". The right mediastinal trunk, which collects lymph from an area corresponding to that drained by the left vessel, but including also the upper part of the right lobe of the liver, almost invariably enters the right innominate vein separately: but even in the rare event of its union with the other two trunks the resulting *right*

lymphatic duct does not correspond to the thoracic duct but only to the united tributaries which the thoracic duct also receives.

Variations.—The **cisterna chyli** may be very irregular or may be replaced by a plexus of vessels, formed by the intestinal and lumbar lymph-trunks, from which the thoracic duct takes origin by several roots.

The **thoracic duct** in its course through the thorax frequently divides into two unequal branches which may run side by side for some distance before reuniting; or it may even be broken up into a plexiform arrangement of lymph-vessels. It may end in a number of branches which enter the great veins separately; and it sometimes divides in the upper part of the thorax into two stems, of which the right joins the right jugular trunk to form one variety of the right lymphatic duct (Fig. 1156). The thoracic duct may end in either the internal jugular or the subclavian vein, or even in the vertebral vein; whilst very rarely it may open into the vena azygos.

The arrangement and mode of termination of the **three lymph-trunks—subclavian, jugular, mediastinal**—found in the root of the neck on each side are very variable indeed. They may all open separately into one or other of the great veins; or they may unite together in a variety of ways. Their number may be increased by division of one of them, or by some of their tributaries ending independently—for example, the main efferent of the internal mammary lymph-glands may fail to join the mediastinal trunk. On the left side, the mode of ending is influenced, in addition, by the presence of the thoracic duct, which, as noted, may itself break up into several divisions. The following statement may thus be taken as indicating only what are probably the commonest arrangements of the trunks.

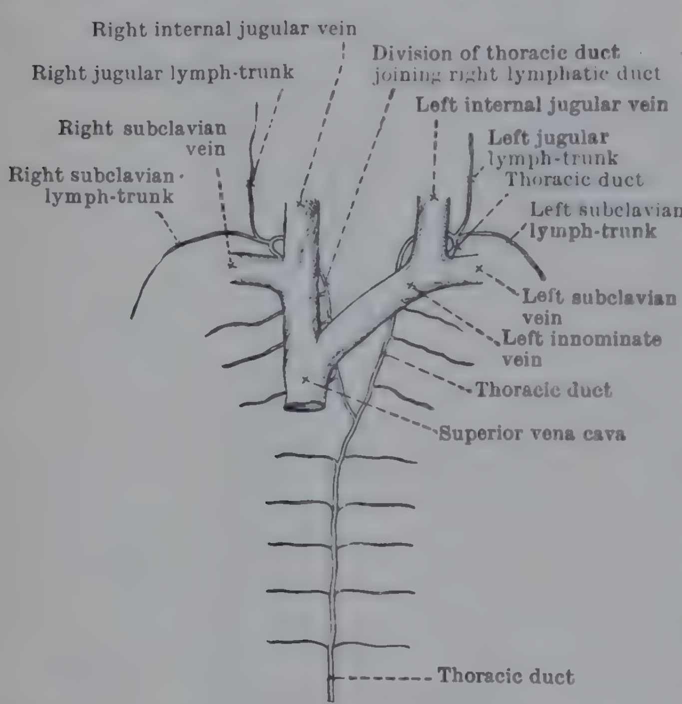

Fig. 1156.—Diagram showing Variation in Ending of Thoracic Duct.
The mediastinal lymph-trunks are not represented.

On the left side the jugular trunk ends in the thoracic duct, and the other two trunks may do so also; but the subclavian trunk often ends in the subclavian vein, and the mediastinal trunk usually ends in the innominate vein.

On the right side the subclavian, jugular, and mediastinal trunks usually have separate entrances into the subclavian, internal jugular, and innominate veins respectively. But it is not uncommon for the subclavian and jugular trunks to unite at the medial margin of the scalenus anterior above the subclavian artery. The resulting vessel is called the *right lymphatic duct*. In rare cases the mediastinal trunk also joins the duct; and its internal mammary tributary may have independent entrance into the innominate vein.

LUMBAR LYMPH-TRUNKS

The **lumbar lymph-trunks** receive the lymph from the lower limbs, the perineum and external genital organs, the abdominal wall below the level of the umbilicus, the urogenital system in the pelvis and abdomen, and the part of the digestive tract supplied by the inferior mesenteric artery. In maintaining the idea of the continuity of this great lymph-stream it is necessary to trespass over the boundaries of the usual divisions of the body, since, for example, a true picture of the drainage of the skin of the area cannot be obtained by a description of the lymph-vessels of the lower limb alone.

Superficial Lymph-Glands of Lower Limb

The **superficial inguinal lymph-glands** (Figs. 1151 1157) lie in the subcutaneous fat below the inguinal ligament, and extend downwards on each side of the long

saphenous vein for a few inches. They are arranged in a *proximal* set (5-6) below and parallel with the ligament and a *distal* set (4-5) associated with the vein. Each set may be divided into medial and lateral parts, but, as all these glands are freely interconnected, they are best considered as one T-shaped group. Their *afferents* are derived from the skin of the whole body below the level of the umbilicus and from the lining membranes of the anal canal and of the penile portion of the spongy part of the urethra, or, in the female, of the vulva and lower end of the vagina. In the female they receive also one or two vessels from the uterus which run along the round ligament through the inguinal canal. The

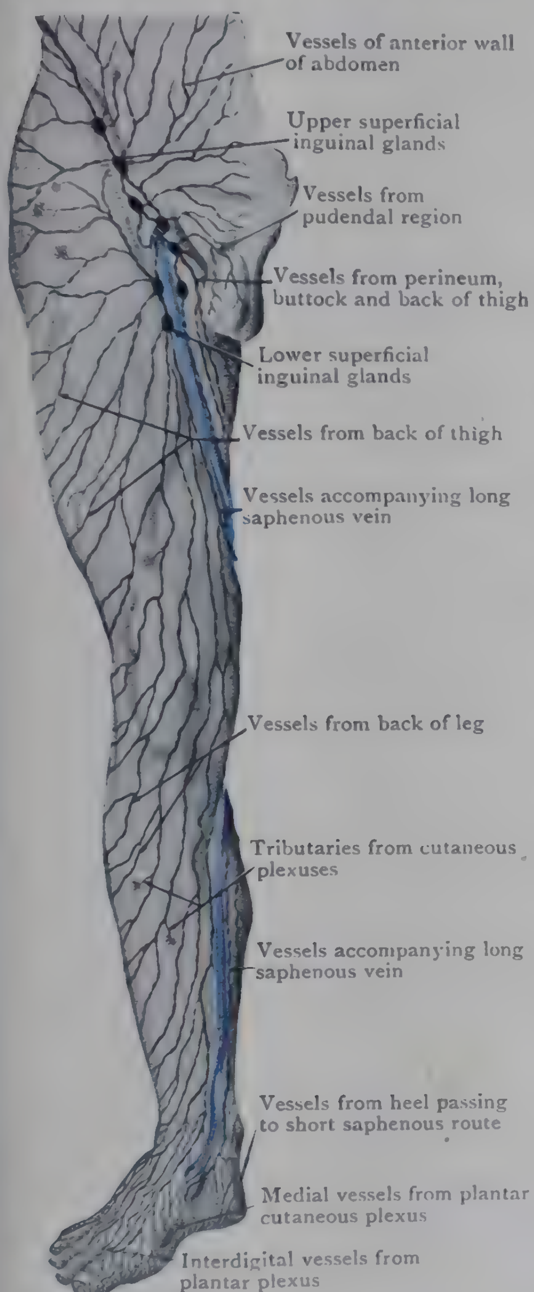

Fig. 1157.—Superficial Lymph-Vessels of Front of Lower Limb.

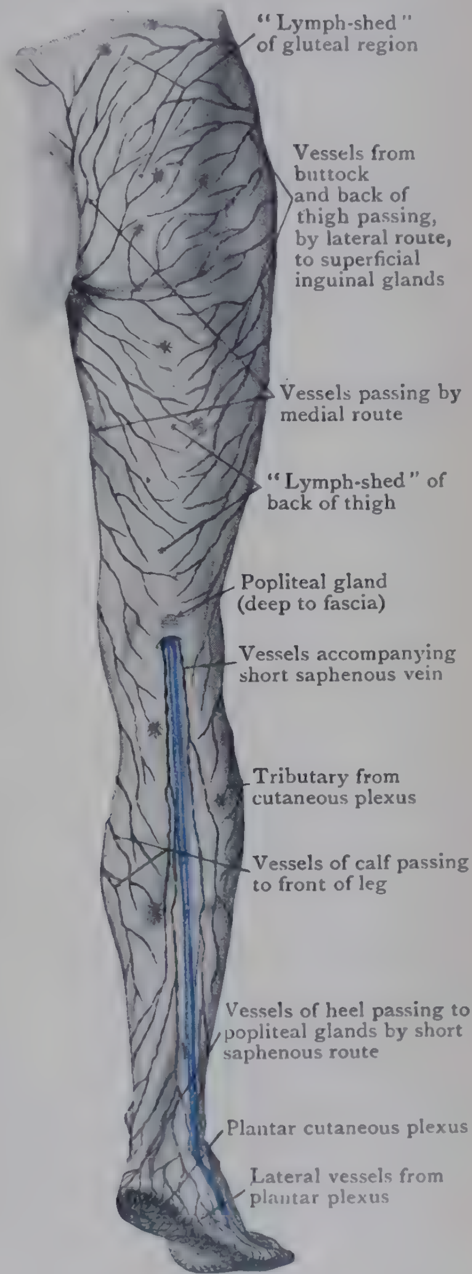

Fig. 1158.—Superficial Lymph-Vessels of Back of Lower Limb.

efferents pass deeply through the cribriform fascia and, though some enter the deep inguinal lymph-glands, most of them pass upwards through the compartments of the femoral sheath, mainly the femoral canal, to end in the glands on the external iliac artery.

Superficial Lymph-Vessels of Lower Limb and Trunk

The **superficial lymph-vessels of the territory of the lumbar trunk** arise in the capillary network of the skin, from which the collecting vessels stream from a wide area toward the groin. The main stream begins in the foot, follows the direction of the long

the lateral and medial borders of the leg and thigh from the back and sides of the limb. Towards the root of the limb the vessels run almost horizontally; the lateral vessels of the buttock sweep round below the iliac crest and are succeeded by a descending stream from the back, sides, and front of the abdominal wall below the level of the umbilicus: on the medial side a stream descends from the back of the sacrum and the natal cleft, is joined by some vessels from the medial third of the buttock, by the perineal, anal, and scrotal or vulvar lymph-vessels, and turns laterally in the superficial fascia that overlies the adductor longus: and, lastly, the lymph-vessels of the penis, including those of the penile urethra, complete the great whorl (Figs. 1151, 1152, 1157, 1158).

Certain exceptions and peculiarities must be noted: (*a*) a few lymph-vessels from the skin over the area of the short saphenous vein accompany that vessel into the popliteal glands; (*b*) at several points lymph-vessels leave the superficial stream and are conducted along the blood-vessels through the deep fascia to join the deep stream; (*c*) the lymph-vessels of the skin of the penis accompany those of the scrotum but those of the glans follow the deep dorsal vein till in contact with the pubis; there, the majority turn laterally to reach the superficial inguinal glands, but a few accompany the vein under the pubic arch into the pelvis. As the lymph-vessels of the glans run towards the pubis they receive numerous tributaries which emerge from the urethra along the ventral median line and encircle the organ. The student should note that these vessels were formed when the urethra was a groove on the surface and have been turned in by the closure of the groove; (*d*) the testis does *not* send lymph-vessels to the superficial inguinal glands.

The arrangement of the superficial lymph-vessels of the toes and the foot is very similar to that met with in the fingers and the hand (p. 1429). From plexuses on the plantar surface vessels pass to the dorsum of the foot and toes, where they unite into a number of vessels, the majority of which accompany the long saphenous vein and end in the distal group of superficial inguinal glands. Some of the lymph from the lateral part of the plantar surface and from the lateral border of the foot, and the lymph from the heel, enter vessels which accompany the short saphenous vein; these end in the popliteal glands (Fig. 1158).

Deep Lymph-Glands and Lymph-Vessels of Lower Limb

The deep lymph-glands and lymph-vessels of the lower limb are associated with the blood-vessels. The deep glands of the lower limb are few and small. The **anterior tibial lymph-gland** is a small nodule on the upper part of the interosseous membrane; usually minute or immature, it is occasionally large enough to be detected in a dissection. It interrupts the course of one of the deep lymph-vessels.

The **popliteal lymph-glands** (6 or 7) are small nodules, of the size of wheat grains, most of which lie in the popliteal fat alongside the great blood-vessels. A more superficial gland lies under the deep fascia on the upper end of the short saphenous vein and receives the cutaneous lymph-vessels which accompany it (Fig. 1158). Those alongside the popliteal blood-vessels receive the anterior and posterior tibial lymph-vessels and others which issue from the knee joint with the lateral and medial genicular blood-vessels: one gland lies on the surface of the posterior ligament of the knee joint and receives the lymph-vessels which issue along the middle genicular blood-vessels. The *efferents* of the popliteal glands pass upwards to form the deep femoral lymph-vessels which end in the deep inguinal glands.

The **deep inguinal lymph-glands** (Figs. 1160, 1162, 1163) are situated on the medial side of the femoral vein. They are small glands, one to three in number, and are difficult to demonstrate. Of these, one below the femoral canal is the most constant, one in the canal is occasional, and one in the femoral ring is frequently found. They receive all the deep vessels in the region of distribution of the femoral artery, including vessels from the front of the hip joint and a few from the glans penis and urethra which have followed the track of the deep external pudendal artery. Their *efferents* pass to the external iliac glands.

The **deep lymph-vessels** of the lower limb arise from capillary networks in the synovial membranes of joints and tendon-sheaths, and follow the main blood-vessels. They are joined by some cutaneous lymph-vessels from the limb and penis which have passed deeply along the cutaneous blood-vessels. Many of the vessels from the leg and foot end in the popliteal glands, but some pass directly to the deep inguinal glands in which also deep vessels of the more proximal parts end. The deep lymph-vessels of the gluteal region and perineum accompany branches of the internal iliac artery into the pelvis and will be noted in the next section.

Lymph-Vessels of Anterior Wall of Abdomen

The **lymph-vessels of the anterior wall of the abdomen** may be briefly reviewed at this point. Since they pass in different directions and ultimately discharge not only into the *lumbar lymph-trunk* but also into the *subclavian* and *mediastinal* lymph-trunks, their description is to be found in the sections dealing with these respective trunks.

The *superficial lymph-vessels* of the upper part of the anterior wall of the abdomen go mainly to the anterior or pectoral group of axillary glands; but some pierce the wall of the lower part of the thorax and end in the internal mammary glands. Those of the lower part of the abdominal wall end in the proximal group of superficial inguinal glands (Fig. 1151).

The *deep lymph-vessels* of the upper part of the anterior abdominal wall accompany the superior epigastric blood-vessels and end in the internal mammary glands. Those of the lower part accompany the inferior epigastric and deep circumflex iliac vessels, and end in the inferior external iliac glands (see below). Small lymph-glands are often found interrupting these deep lymph-vessels.

Lymph-Vessels of External Genital Organs

The **lymph-vessels of the scrotum** or of the **vulva** pass to the proximal superficial inguinal glands, and mostly to the medial group.

The **superficial lymph-vessels of the penis** go to the medial glands of the proximal superficial inguinal group. The **deep lymph-vessels of the penis**, including those of the penile portion of the urethra, end either in the medial glands of the proximal superficial inguinal group or in the deep inguinal glands. A few vessels follow the deep dorsal vein, and join the rich outflow of the prostate to the internal iliac glands. The **lymph-vessels of the clitoris** end like those of the penis.

Lymph-Glands of Pelvis

The lymph-glands of the pelvis may be grouped according to their position in association with blood-vessels: (1) *external iliac* in succession to the inguinal lymph-glands; (2) *internal iliac* with sub-groups associated with the branches of the artery; and (3) *common iliac*. (Figs. 1159, 1160, 1162.)

The **external iliac lymph-glands** (8-10) form three incomplete chains—lateral, intermediate, and medial—which lie along the external iliac vessels. The largest members are found on the lower end of the blood-vessels—usually one in front, one on the medial side, and one on the lateral side; each of these may be single or may be accompanied by smaller glands. A few are scattered along the blood-vessels at higher levels. They receive the efferents of the inguinal glands, superficial and deep, the deep lymph-vessels of the lower part of the anterior abdominal wall—interrupted by small outlying members of the group, *inferior epigastric glands* and *circumflex iliac glands*—and a number of afferents *direct* from the pelvic viscera. Their *efferents* pass to the common iliac glands.

The **internal iliac lymph-glands** lie along the trunk and branches of the internal iliac vessels on the pelvic wall and in the fatty tissue around the organs. They receive *afferents* from all the pelvic viscera, and also from the perineum and the gluteal region. Their *efferents* pass to the common iliac glands. On the pelvic wall some of the glands around the stem of the internal iliac artery merge into the medial external iliac chain above; others may be found on the stems of the parietal branches of the artery—*gluteal, pudendal, obturator*—and they may be so named; but only one group need be specially designated—the **sacral lymph-glands**, which lie in the hollow of the sacrum.

In the fatty tissue near the viscera there are usually a number of small outlying glands:—

(*a*) **Ano-rectal lymph-glands** (2-8) in relation with the ampulla of the rectum and the back of the bladder or the vagina; (*b*) a **middle rectal lymph-gland** on each side of the rectum about its middle; (*c*) **vesical lymph-glands**—*anterior* (occasional) in the retropubic fat, and *lateral* along the side of the bladder in relation with the obliterated umbilical artery; (*d*) in the female the **para-uterine lymph-glands** in the root of the broad ligament close to the cervix.

The **common iliac lymph-glands** (4-6) continue the internal and external iliac groups upwards; those on the lateral side and behind each common iliac artery may

two common iliac groups come together in the angle between the common iliac arteries they form a *median* group of glands.

The nominal groups of pelvic glands are in reality quite artificial. The important facts are that a number of lymph-glands are situated in the fat round the internal iliac blood-vessels and their branches—**lymph-glands of the cavity**; and that a number on the external and common iliac vessels form a collar on the brim—**lymph-glands of the brim**.

The glands of the brim (external iliac and common iliac) receive the efferent

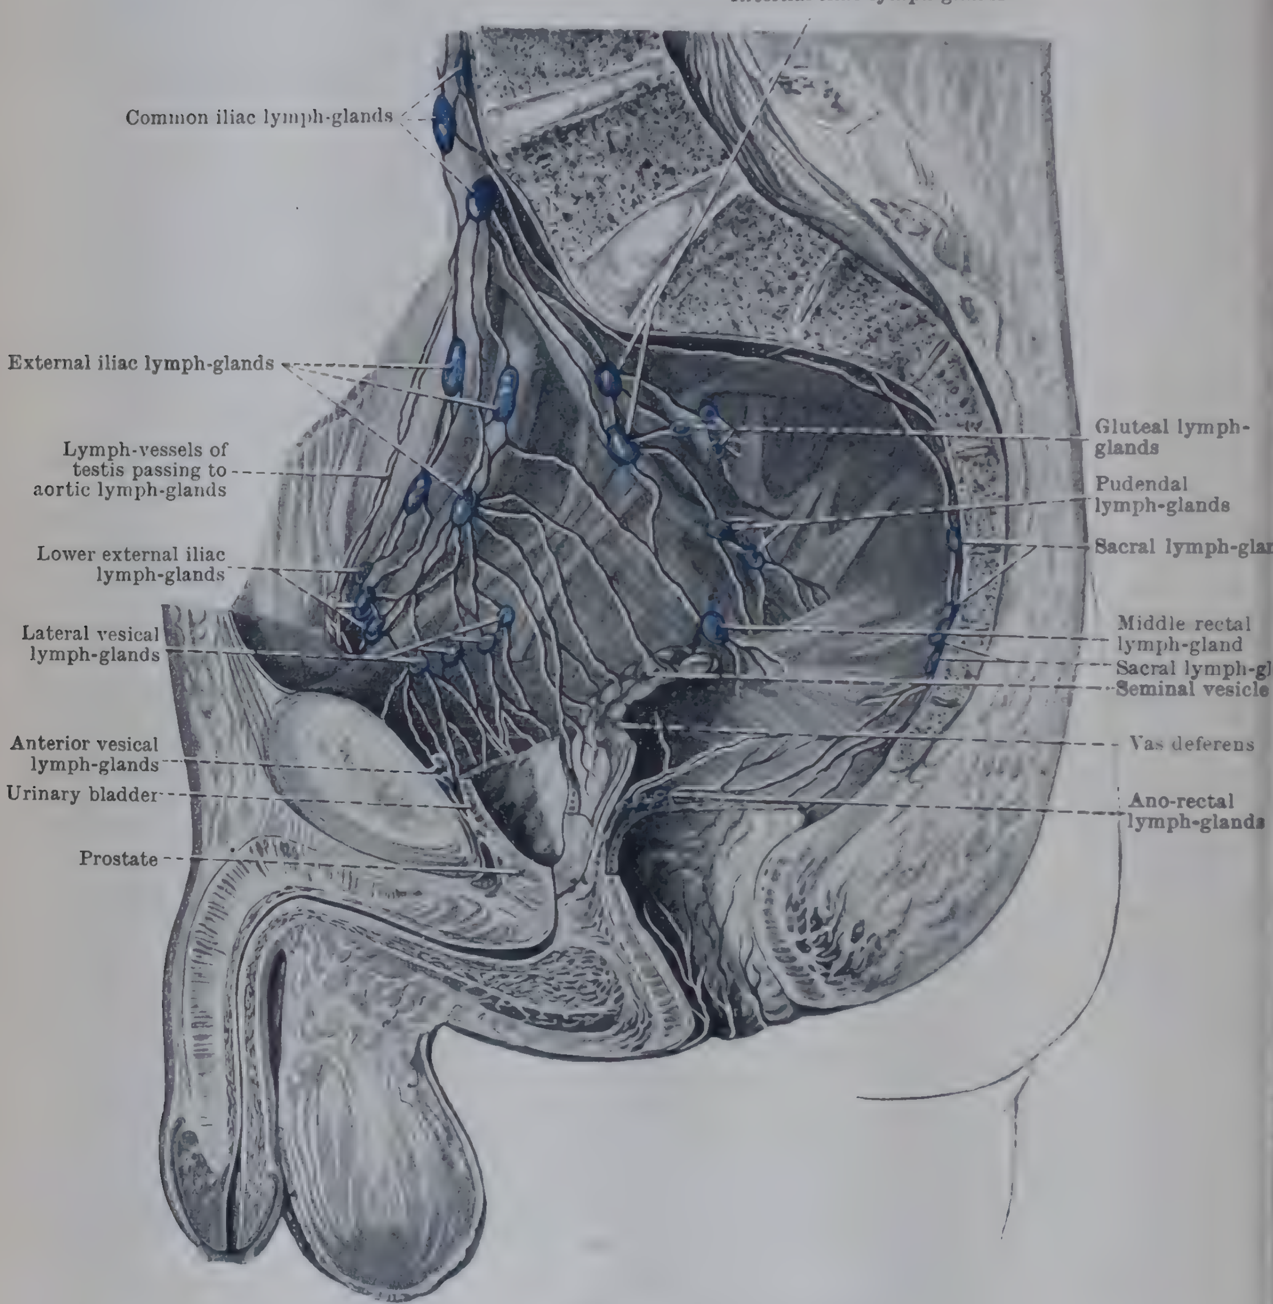

FIG. 1159.—LYMPH-GLANDS OF THE PELVIS.

vessels from the glands of the cavity (internal iliac and all sub-groups) and also numerous direct afferent vessels from *all the pelvic organs* and from the peritoneum of the lower abdominal wall. Moreover, vessels from the upper part of the rectum, from the upper part of the uterus and from the uterine tube and the ovary, escape even the glands of the brim and pass into the abdomen to end in the aortic glands.

PARIETAL AFFERENT LYMPH-VESSELS OF PELVIC GLANDS

The deep lymph-vessels from the anterior and lateral abdominal wall below the umbilicus and from the iliac fossa arise from a subperitoneal capillary network, and

follow the inferior epigastric and deep circumflex iliac arteries to the lowest external iliac glands.

Lymph-vessels that arise from the medial side of the hip joint follow the obturator artery, and from the back of the joint others pass along the gluteal vessels, with deep lymph-vessels of the gluteal region, to reach internal iliac glands situated on these branches of the main artery. Deep lymph-vessels from the perineum, arising in the bulbar and membranous parts of the urethra, from the bulbo-urethral glands (from the greater

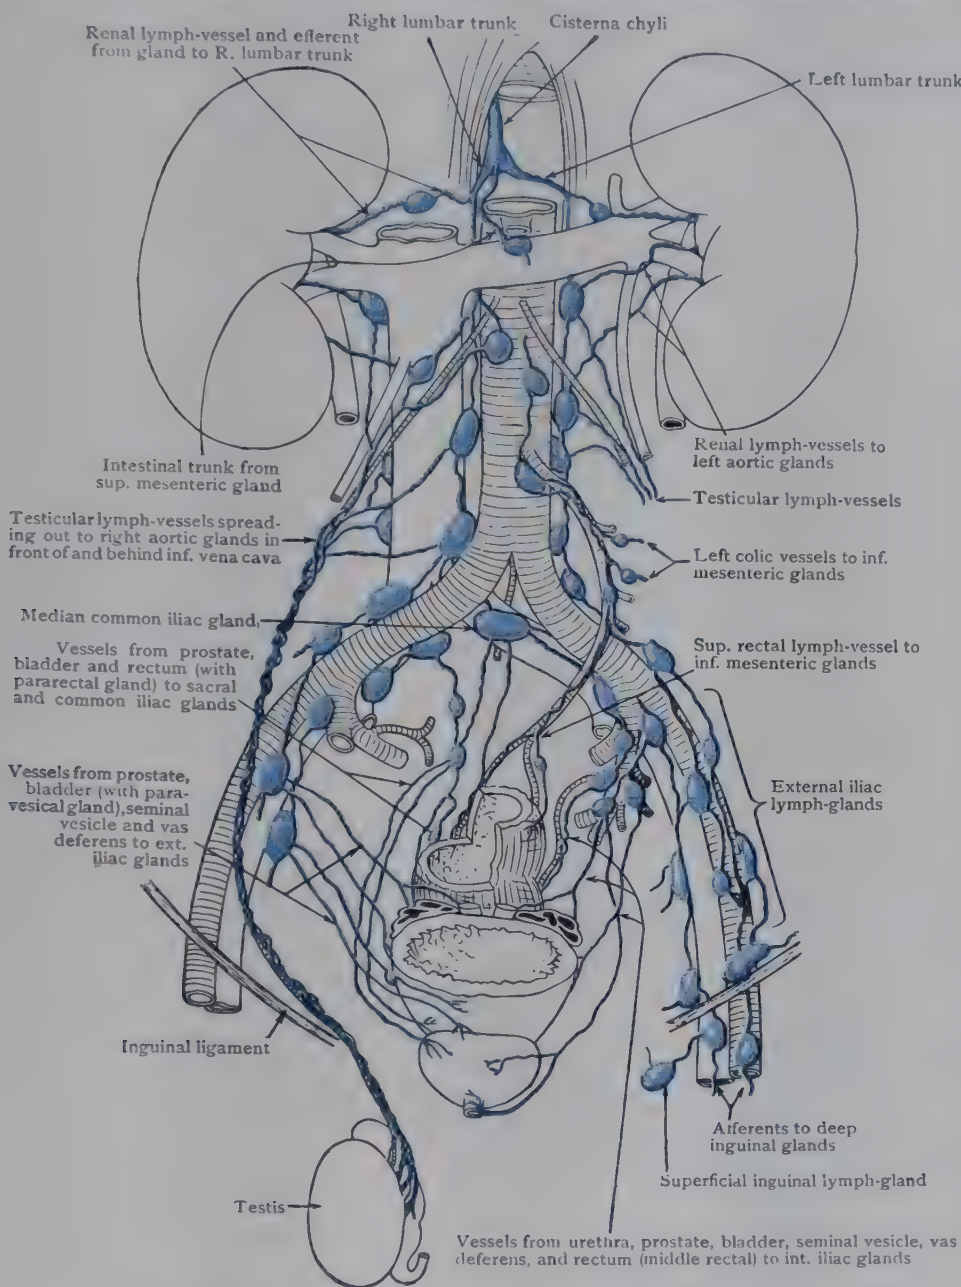

FIG. 1160.—DIAGRAM OF LYMPH-VESSELS AND LYMPH-GLANDS OF MALE PELVIS AND ABDOMEN.

vestibular glands in the female), and some from the anal canal, follow the internal pudendal artery to the internal iliac glands, and thence to the lymph-glands of the brim.

LYMPH-VESSELS OF PELVIC VISCERA

Although the lymph-glands of the pelvis are for the most part situated along the blood-vessels, it is important to note that the lymph-vessels of pelvic organs do not necessarily follow only the paths of the blood-vessels that supply them. Many of them take other paths (*e.g.*, to the external iliac glands) and the drainage of pelvic organs is therefore to some extent along unexpected lines. On the other hand the lymph-vessels of the ovary and of the upper part of the rectum do follow their blood-vessels out of the pelvis to end in glands in the abdomen.

Lymph-Vessels of Urinary Bladder.—The lymph-vessels of the urinary bladder arise from a submucous plexus, most abundant in the region of the trigone (Albarran, 1892),

and pierce the muscular coat. From the superior and infero-lateral surfaces of the bladder, the vessels, some of which are interrupted in the anterior and lateral vesical glands, pass to the external iliac lymph-glands. From the base of the bladder also vessels pass to the external iliac glands, but some end in internal iliac glands. Lymph-vessels from the neck of the bladder are associated with those from the prostate that run to the sacral and the median common iliac glands.

Lymph-Vessels of Ureter.—The lymph-vessels of the *pelvic part* of the ureter are associated with those of the urinary bladder (see also p. 1416).

Lymph-Vessels of Prostate.—The prostatic lymph-vessels mainly follow the inferior vesical artery and end in the anterior and lateral vesical glands, and in the internal iliac glands; some, however, pass backwards to the sacral glands, and others follow the vas deferens to external iliac glands; one or two may run downwards to join the vessels of the membranous part of the urethra.

Lymph-Vessels of Male Urethra.—It has been pointed out that the lymph-vessels of the greater part of the *spongy part* of the urethra pass to the superficial inguinal glands; others go with lymph-vessels of the glans penis to the deep inguinal glands. The lymph-vessels of the *bulbar* and *membranous parts* of the urethra have been mentioned under the parietal afferents of the pelvic glands, since they mainly follow the internal pudendal artery to the internal iliac glands; other vessels may pass behind the pubic symphysis to the lower medial gland of the external iliac group, and with lymph-vessels from the lower part of the anterior wall of the bladder to higher medial glands of the same group. The lymph-vessels of the *prostatic part* of the urethra unite with the other lymph-vessels of the prostate.

The **lymph-vessels of the female urethra** correspond with those of the membranous and prostatic parts of the male urethra.

Lymph-Vessels of Seminal Vesicle.—The seminal vesicle is associated in lymph-drainage with the base of the bladder, the prostate, and the ampulla of the vas deferens. Collectors pass with prostatic vessels to internal iliac glands and others end in a posterior gland of the medial external iliac group.

Lymph-Vessels of Vas Deferens.—The lymph-vessels of the pelvic part of the vas deferens are associated with those of the seminal vesicle, the prostate, and bladder, and they pass, according to their site of origin, to the external and internal iliac glands (see also p. 1416).

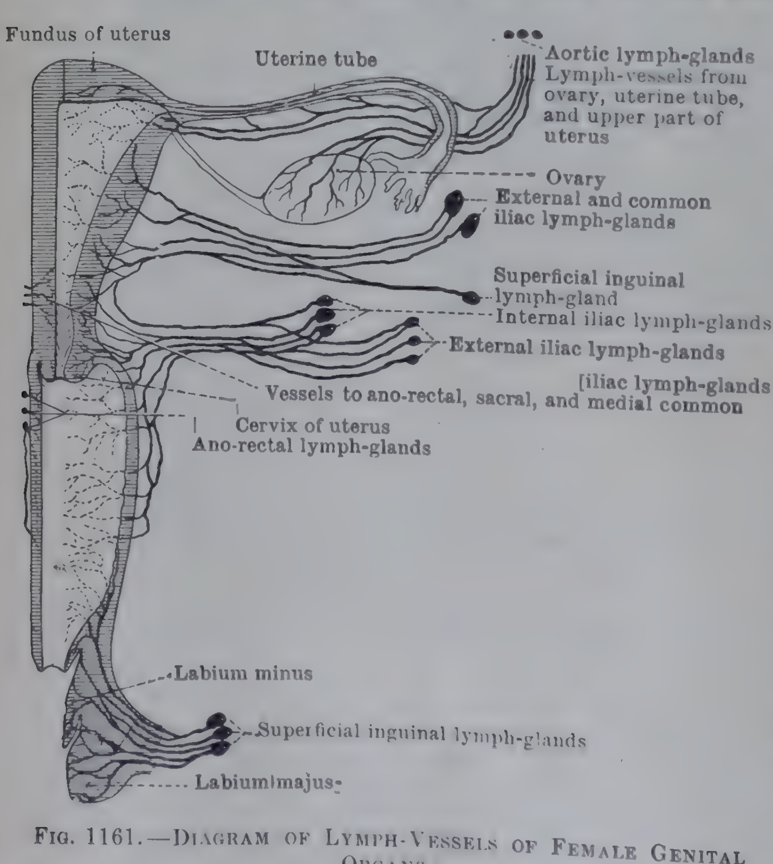

Fig. 1161.—Diagram of Lymph-Vessels of Female Genital Organs.

Lymph-Vessels of Vagina.—The lymph-vessels of the vagina scatter widely. From the lower part some go to sacral and common iliac glands, and others from the region of the hymen pass with vessels from the vulva to the superficial inguinal glands; from the middle part they accompany the vaginal blood-vessels to internal iliac glands; from the upper part they accompany lymph-vessels from the cervix of the uterus to external and internal iliac glands (Figs. 1161, 1162). Some of the vessels from the lower part of the posterior wall of the vagina may be interrupted in the small ano-rectal glands.

Lymph-Vessels of Uterus.—The capillary plexus in the mucous coat of the uterus communicates with a voluminous subserous plexus from which the collecting vessels arise. They run to widely separated groups of lymph-glands—superficial inguinal, external and internal iliac, sacral and common iliac, and aortic (Figs. 1161, 1162).

From the *cervix*, vessels pass to both external and internal iliac glands, and also to the sacral and median common iliac glands. From the *lower part of the body* some may pass with vessels from the cervix to internal iliac glands, but most of them go to external iliac glands. From the *upper part of the body* and the *fundus* the most important outflow is with the vessels of the uterine tube and ovary upwards over the pelvic brim to aortic lymph-glands (see p. 1416). The aortic glands that receive lymph-vessels from the uterus are situated near the origin of the inferior vena cava on the right side and of the inferior mesenteric artery on the left. In addition, one or two vessels from the fundus and the body run along the round ligament of the uterus to the superficial inguinal lymph-glands. Some of the uterine lymph-vessels are interrupted in the para-uterine glands.

Lymph-Vessels of Uterine Tube.—The main lymph-drainage of the uterine tube is with the lymph-vessels of the fundus of the uterus and of the ovary to aortic lymph-glands (see p. 1416); but a vessel may occasionally pass to an external iliac or even to an internal iliac gland.

Lymph-Vessels of Ovary.—The lymph-vessels of the ovary pass entirely out of the pelvis to aortic lymph-glands (see p. 1416).

Lymph-Vessels of Rectum and Anal Canal.—Like those of the uterus and vagina, the lymph-vessels of the anal canal and rectum end in widely separated groups of glands. They arise mainly from a plexus in the mucous coat continuous through the plexus of the anal canal with the cutaneous plexus of the perineum. Most of the collecting vessels end in pelvic glands—sacral, internal iliac, and common iliac—but from the lower end of the anal canal some pass with cutaneous vessels to superficial inguinal glands, and, from the upper part of the rectum, the lymph-drainage is continuous with that of the pelvic colon, and the vessels pass upwards out of the pelvis to the inferior mesenteric glands.

From the lower end of the anal canal vessels run, with those of the skin around the anus, forwards in the perineum and ascend to the superficial inguinal glands. From the greater part of the anal canal the lymph-vessels run either across the ischio-rectal fossa or upwards with those of the lower part of the rectum along the middle rectal blood-vessels to internal iliac glands. Other vessels from the rectum end in the sacral and median common iliac glands; and a very important group ascends along the superior rectal blood-vessels to reach glands about the stem of the inferior mesenteric artery. Vessels from the anal canal and lower part of the rectum may be interrupted in the small ano-rectal lymph-glands; and others from the middle and upper parts of the rectum pass through para-rectal glands.

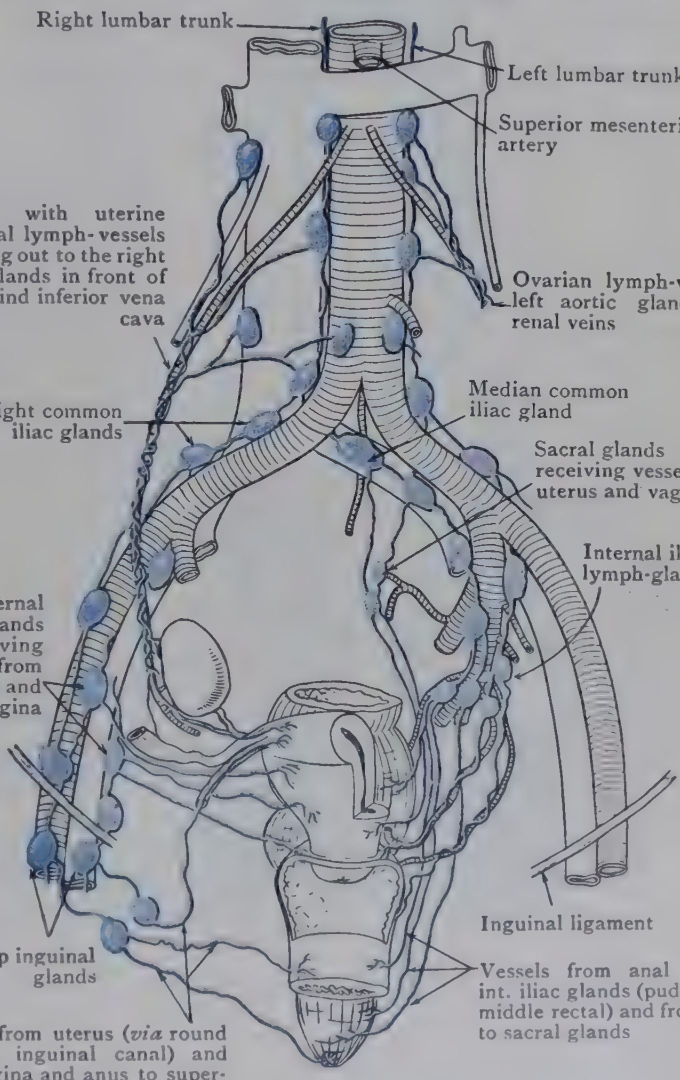

Fig. 1162.—Diagram of Lymph-Vessels and Lymph-Glands of Female Pelvis and Abdomen.

Aortic and Inferior Mesenteric Lymph-Glands

The **aortic lymph-glands** (Figs. 1160, 1163) are arranged in a number of chains which lie in the loose tissue around the aorta and inferior vena cava. Below they are in continuity with the common iliac glands; and from the upper members of the aortic group behind the pancreas the right and left lumbar lymph-trunks emerge. The lymph-glands lie at the sides of the great vessels, between them, in front of and behind them: they have, therefore, been subdivided into *right lateral* (pre-venous, retro-venous), *left lateral*, *pre-aortic*, and *retro-aortic*; but these names, which have

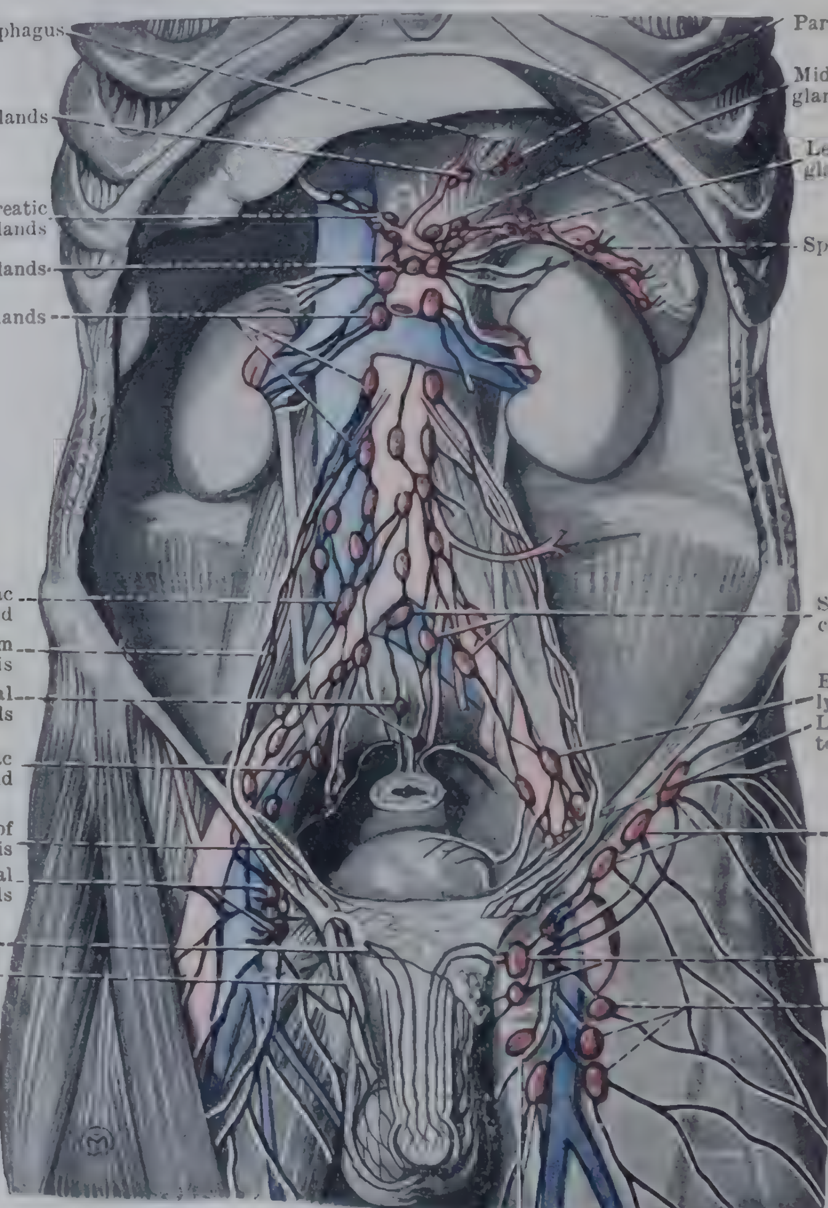

Fig. 1163.—Semi-Diagrammatic view of Lymph-Glands and Lymph-Vessels of Inguinal Region, Pelvis and Posterior Wall of Abdomen.

an occasional value, should not be allowed to obscure the fact that the aortic glands are all freely interconnected. They are most numerous on the left side of the aorta, where they are tightly packed from the common iliac artery up to the renal artery. Their concentration in this situation may be explained, first by the fact that the corresponding members on the right side have to be disposed around the vena cava, and secondly by the fact that the upper end of the inferior mesenteric chain is not separated from the aortic glands. Above the level of the renal vessels the aortic group is represented by a few small glands not easily distinguished from the cœliac and superior mesenteric groups. In the process of development a large number of glands are formed in the primitive mesentery. Those at the root of the mesentery drain the body-wall and the abdominal organs developed in the region of the inter-

mediate cell-mass—suprarenal, kidney, and testis or ovary—and receive the efferents from lower limbs and pelvis. Those in the primitive mesentery are associated with the three great visceral vessels—cœliac, superior mesenteric, and inferior mesenteric arteries—and drain the abdominal part of the fore-gut, the mid-gut, and the hind-gut. Each of these great groups may be regarded as offshoots of the aortic glands, but while the inferior mesenteric group does not dissociate itself from the lumbar trunks, the efferent lymph-vessels of the cœliac and superior mesenteric groups open separately into the cisterna chyli by the intestinal trunk.

Some outlying small members of the aortic group of glands are separated from the main body by the psoas and lie in the intervals between the lumbar transverse processes; they are in series with the sacral glands below and the intercostal glands above; they may be called the *lateral lumbar lymph-glands.*

The *afferent* vessels of these lateral glands are derived from the lumbar synovial joints, the dura mater of the vertebral canal and some cutaneous vessels from the lumbar region which have followed the posterior branches of the lumbar arteries; their *efferents* pass along the lumbar blood-vessels to the aortic glands. The main aortic glands receive: (*a*) the efferents of the common iliac glands (lymph of whole lower limb, abdominal wall below umbilical level, perineum, external genital organs and pelvis); (*b*) efferents of the lateral lumbar glands; (*c*) efferents of the inferior mesenteric chain; (*d*) afferents from the testis and epididymis (ovary, uterine tube, and upper part of uterus in the female); and (*e*) afferents from the abdominal part of the ureter, the kidneys and suprarenal glands, and from the under surface of the diaphragm. The territory of drainage corresponds to the distribution of the paired branches of the aorta, with that of the inferior mesenteric artery added.

The **inferior mesenteric system of lymph-glands** is an extension of the aortic group of glands along the inferior mesenteric artery and its branches. The main **inferior mesenteric lymph-glands** lie along the stem of the artery. They receive lymph from the outlying glands of the system that are scattered along the branches of the artery as far as the wall of the intestine. The outlying glands are known as the lymph-glands of the colon, and are arranged in subsidiary groups. The same arrangement of lymph-glands is found along the branches of the *superior mesenteric artery* that supply part of the large intestine (see p. 1419).

The **lymph-glands of the colon** (Fig. 1166) may be considered as forming four groups—epicolic, paracolic, intermediate and main colic (Jamieson & Dobson, 1909).

(*a*) The **epicolic glands** are small nodules which lie in the appendices epiploicæ and in relation with the wall of the gut. (*b*) The **paracolic glands** lie along the medial borders of the ascending and descending parts of the colon, along the upper border of the transverse colon, and on the mesenteric border of the pelvic colon. (*c*) The **intermediate colic glands** lie along the branches of the colic arteries. (*d*) The **main colic glands** are situated around the stems from which the colic arteries arise.

The lymph gathered by the lymph-plexuses in the walls of the gut passes through one or more of these subsidiary groups of glands before it reaches the lymph-glands situated on the stems of the main blood-vessels. In addition to the drainage of the rectum by lymph-vessels that pass upwards out of the pelvis with the superior rectal artery, *afferents* of the main inferior mesenteric glands convey lymph from the descending and pelvic parts of the colon; their *efferents* pass to the aortic lymph-glands which drain mainly into the left lumbar lymph-trunk.

Afferent Lymph-Vessels of Aortic Glands

Lymph-Vessels of Testis and Epididymis.—A rich capillary network surrounds the tubules in the testis and gives origin to collecting vessels which traverse the mediastinum testis to emerge through the back of the organ; they are joined by the vessels of the epididymis and a superficial set from the serous covering. These vessels (6-8) ascend in the spermatic cord, pass through the deep inguinal ring and then follow

curve medially and spread out like a fountain spray to end in the lower aortic lymph glands, from the bifurcation of the aorta to the level of the renal veins (Fig. 1160). On vessel (probably from the tunica vaginalis) usually diverges into an external iliac glan (Jamieson & Dobson, 1910 *a*). The student should note that the lymph-vessels of th testis were developed while the organ lay on the posterior abdominal wall, and that th scrotum is merely a diverticulum of the lower abdominal wall: hence the difference i the destination of the lymph-vessels of the scrotum (inguinal glands) and of the testi and epididymis (aortic glands).

Lymph-Vessels of Vas Deferens.—As far as the brim of the pelvis, these joi the testicular lymph-vessels: from the pelvic portion (as already noted, p. 1412 they pass upwards to the external iliac glands and backwards to the internal ilia glands.

Lymph-Vessels of Ovary.—Like the lymph-vessels of the testis those of the ovar end in aortic lymph-glands; their destination also depends on the development of th organ in the abdomen. They emerge through the hilum of the ovary, are joined b lymph-vessels from the fundus of the uterus and the uterine tube and ascend over th pelvic brim with the ovarian blood-vessels. On the posterior wall of the abdomen the spread out to end in aortic glands from the bifurcation of the aorta to the level of th renal veins (Fig. 1162).

Lymph-Vessels of Ureter.—The vessels of the ureter are believed to arise from a scanty plexus in the mucous coat. The collecting vessels are not numerous. From th pelvic part of the ureter, vessels pass to the internal, external, and common iliac glands from the middle part to the aortic glands; and from the upper end, including the pelvi and calyces, they run with the renal lymph-vessels.

Lymph-Vessels of Kidney.—These vessels are injected with difficulty and, like those o the bladder and ureter, appear to be scanty.

In addition to the subserous plexus on the parts of the kidney covered wit peritoneum, there is a plexus of lymph-vessels in the renal fat from which collector pass to aortic glands. In the fibrous capsule of the kidney there is another plexu which receives communications from the vessels in the cortex of the organ and give origin to collecting vessels which pass medially to join those emerging from th hilum.

The lymph-vessels of the cortical and medullary parts of the substance of the kidne unite in the region of the bases of the pyramids and traverse the renal columns to appea in the sinus. They emerge from the hilum both in front of and behind the blood-vessel and run medially to end in aortic glands at and below the level of the hilum. On th right side some of the glands in which they end are situated behind the inferior ven cava.

From the back of the upper end of the kidney a few vessels may pass with some from the suprarenal glands through the diaphragm (with the communications between th renal and suprarenal veins and the azygos veins) into the lowest lymph-glands in th posterior mediastinum.

Lymph-Vessels of Suprarenal Gland.—Lymph-vessels emerge from the surface of th suprarenal gland with the arteries and through the hilum with the vein. These vessel drain the cortex and the medulla respectively, but they arise from a continuous capillar plexus. They end mainly in cœliac and upper aortic lymph-glands; but some of then have been noted above as passing through the diaphragm into the posterior mediastina glands.

Lymph-Vessels of Peritoneum.—The lymph-vessels of the serous coats of the viscer are described with the lymph-drainage of each organ. Those from the parietal peri toneum arise from a subserous network—specially rich on the diaphragm—and tend t converge on the blood-vessels which run in the extraperitoneal tissue in the differen regions. In the pelvis they pass to the nearest glands in the cavity or on the brim On the anterior abdominal wall and in the iliac fossa they accompany the superior an inferior epigastric and the deep circumflex iliac blood-vessels. On the posterior wall o the abdomen in the lower part they join the vessels that run from the ascending an descending colon and are thus conveyed to the groups of glands on the superior and inferio mesenteric arteries. Laterally they accompany the lumbar blood-vessels to the latera aortic glands. Higher up they join the vessels from the kidneys. Above, the diaphrag matic lymph-vessels mainly pierce the diaphragm to join the rich subpleural plexus o its upper surface; the stream which accompanies the phrenic blood-vessels to reach th uppermost aortic glands is therefore small.

INTESTINAL LYMPH-TRUNK

The **intestinal lymph-trunk** enters the cisterna chyli and is formed by the union of the efferents of the proximal members of great groups of lymph-glands situated on the cœliac and superior mesenteric arteries and their branches. The efferents of the proximal lymph-glands of the group associated with the inferior mesenteric artery empty into the aortic glands on the left side of the aorta, and so mainly into the left lumbar lymph-trunk. These three sets of glands are developed in the parts of the primitive mesentery associated with the fore-gut, mid-gut, and hind-gut respectively.

The student will note that the term "aortic glands" is applied to those which lie on the great vessels at the root of the primitive mesentery, and the terms "cœliac", "superior mesenteric", and "inferior mesenteric" to those originally *in* that mesentery. Above the level of the renal vessels, where the superior mesenteric and cœliac glands merge and communicate with the upper aortic glands, it is impossible to distinguish clearly between the two sets. The distinctions in that region are rather artificially made to facilitate description.

Cœliac and Superior Mesenteric Lymph-Glands

The **cœliac system of lymph-glands** presents descriptive difficulties. The main group extends along the upper border of the pancreas in association with the cœliac artery and its hepatic and splenic branches. For convenience of appellation and because they found all the glands on the hepatic and splenic arteries to be stations for the lymph-vessels of the stomach and less importantly associated with the liver and spleen, Jamieson & Dobson (1907*a*) subdivided and named them the *right, middle, and left suprapancreatic glands*; to each set certain lymph-streams converge from well-defined territories. The term "gastric" glands for any particular group is apt to be misleading, as *all* the groups in the cœliac system receive lymph-vessels from the stomach. The following table indicates the relation of the different groups of glands in the cœliac system:—

CŒLIAC LYMPH-GLANDS

Right Suprapancreatic	—	Middle Suprapancreatic	—	Left Suprapancreatic
Biliary Glands	Suprapyloric	Subpyloric	Left Gastric	Splenic
Cystic Gland		Right Gastro-epiploic		Left Gastro-epiploic

The **splenic lymph-glands** are a few small glands situated above the tail of the pancreas at the hilum of the spleen. They receive the lymph-vessels of the spleen and also vessels which accompany the left gastro-epiploic artery from the lower border of the stomach; in the course of some of these, one or two small **left gastro-epiploic lymph-glands** may be found in the gastro-splenic ligament near the spleen.

The **left suprapancreatic lymph-glands** lie on the stem of the splenic artery. They receive the efferents of the splenic glands, lymph-vessels from the body of the pancreas, and an abundant stream from the fundus and body of the stomach with the short gastric arteries.

The **left gastric lymph-glands** form a long chain. The most distal members—lower left gastric—lie on the lesser curvature of the stomach to the left of the angular notch. Above this, the cardiac end of the stomach is surrounded by the glands like a string of beads round the neck of the organ (*paracardial lymph-glands*). Beyond that the chain lies around the trunk of the left gastric artery—upper left gastric glands. Finally the chain merges with the middle suprapancreatic group. The left gastric glands receive the lymph-vessels from an area of the stomach, front and back, between the lesser curvature and a line from the summit of the fundus downwards

canal. From any part of this surface some of the vessels skirt past the lower and paracardial glands and reach the upper group. This behaviour is characteristic of the lymph-vessels of the alimentary canal (see Figs. 1166, 1167).

The **middle suprapancreatic lymph-glands** surround the stem of the cœliac artery and receive the efferents of the left gastric glands, of the left and right suprapancreatic glands, and some efferents of the subpyloric glands (see below).

The **right suprapancreatic lymph-glands** lie along the horizontal part of the stem of the hepatic artery and are continuous in various directions with the following subgroups.

The **hepatic** and **biliary lymph-glands** form a continuous chain which runs along the ascending part of the stem of the artery as far as the porta hepatis and downwards behind the duodenum and the head of the pancreas with the bile-duct;

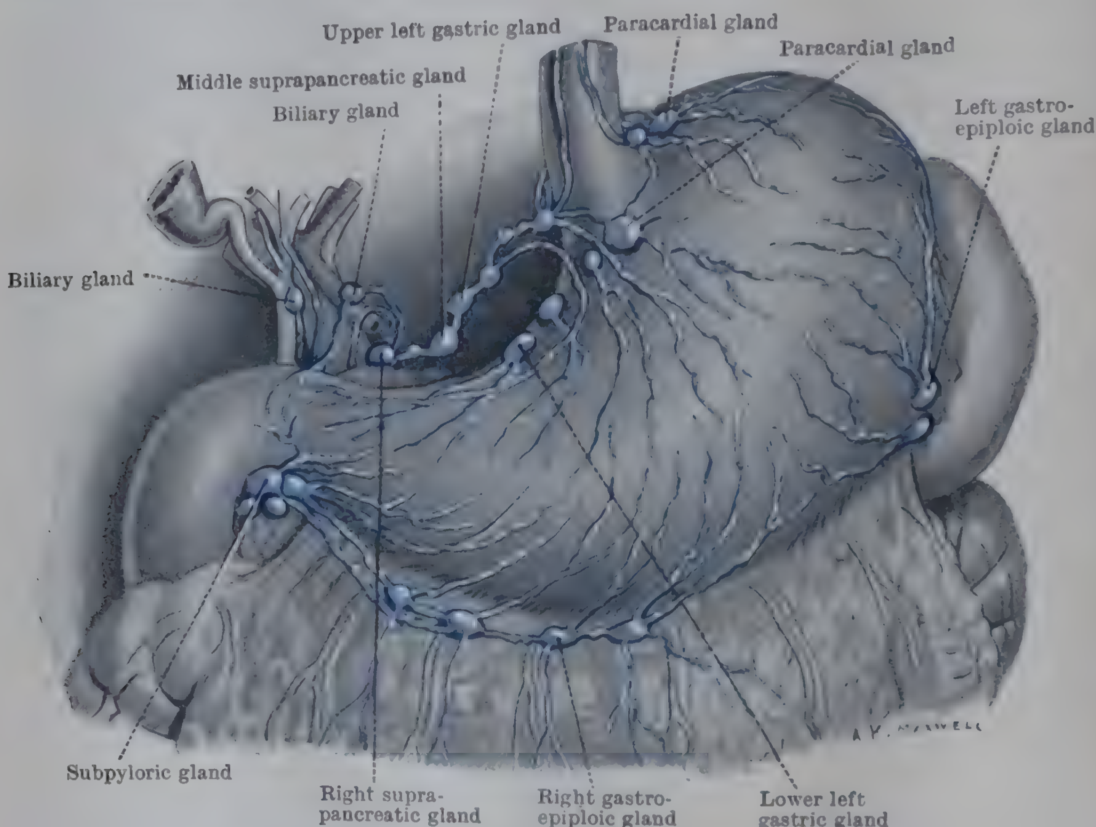

FIG. 1164.—LYMPH-VESSELS AND LYMPH-GLANDS OF STOMACH.
(Jamieson & Dobson, 1907 *a*, redrawn.)

a constant member of this group lies in the curve of the neck of the gall-bladder—the **cystic lymph-gland**. The lower end of this chain receives *afferents* from the head of pancreas, the back of the duodenum, and a few from the pyloric end of the stomach; the upper members of the chain (hepatic glands) receive numerous afferent vessels from the liver (lower margin of the parietal surface and the whole of the visceral surface), and from the gall-bladder and the bile-ducts. The *efferents* end in the right suprapancreatic group.

The **subpyloric lymph-glands** form an important group which lies on the head of the pancreas below the beginning of the duodenum, and after a short interval is continued as a chain of single glands in the course of the right gastro-epiploic artery between the layers of the great omentum—**right gastro-epiploic lymph-glands.** These glands together drain the lower part of the pyloric portion of the stomach, and the subpyloric *efferents* run in various directions, some to the nearest main group—the superior mesenteric root glands, some obliquely over the pancreas to the middle suprapancreatic group, and some to the right suprapancreatic glands (Fig. 1165).

The **suprapyloric lymph-glands** are a small group found in the lesser omentum along the right gastric artery; they interrupt a few vessels from the pyloric canal, and send *efferents* to the right suprapancreatic group.

The *efferent* vessels of the middle and right suprapancreatic glands combine

with the superior mesenteric ultimate efferents to form the single or multiple *intestinal trunk*. Some efferent vessels pass to communicate with glands in the superior mesenteric and aortic groups.

The **superior mesenteric system of lymph-glands** extends into the primitive mesentery of the mid-gut, and the glands that belong to it are scattered along the stem of the artery and all its branches as far as the intestinal wall. They

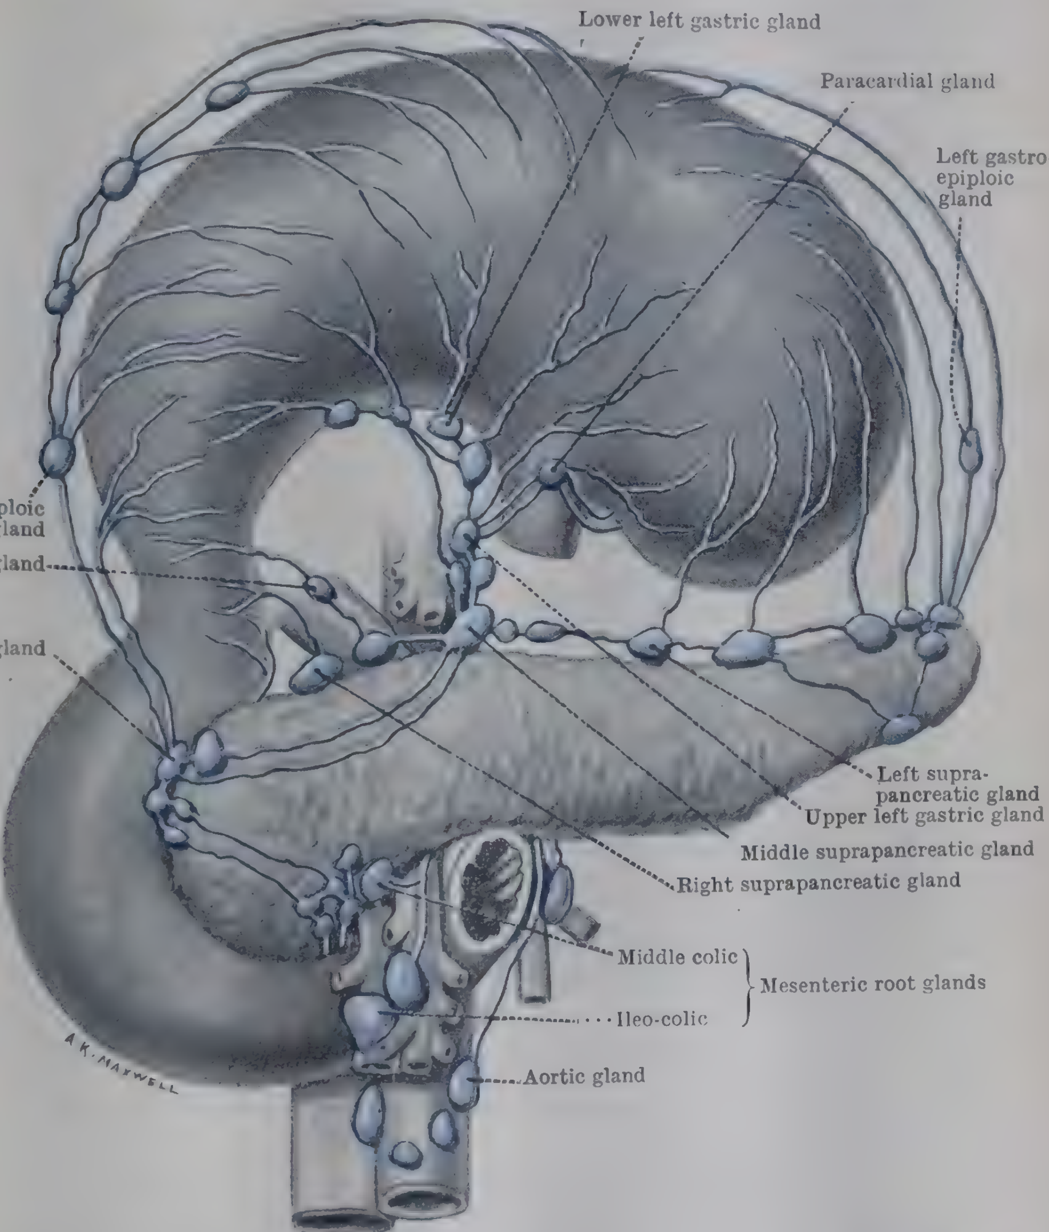

FIG. 1165.—LYMPH-VESSELS AND LYMPH-GLANDS OF POSTERIOR SURFACE OF STOMACH. The stomach has been turned upwards to show the suprapancreatic and other groups of glands.
(Jamieson & Dobson, 1907 *a*, redrawn.)

form one great group, but it is customary, for convenience of topographical reference, to indicate the following subdivisions: (*a*) mesenteric root glands; (*b*) subsidiary chains with the branches of the artery—(1) the glands of the mesentery, (2) ileo-colic, (3) right colic, (4) middle colic.

(*a*) The **mesenteric root glands** are large and numerous, clustered around the stems of the main blood-vessels as they lie in front of the duodenum and the head of the pancreas. They receive the ultimate efferents of all the subsidiary groups as well as some efferents from the subpyloric glands and direct afferents from the head of the pancreas and the duodenum, and also some efferents from the upper left colic group (see p. 1420).

(*b*) In the subsidiary groups related to the drainage of the large intestine the

vessels (*paracolic*) and some form irregular chains along the colic vessels and tend to group themselves into *intermediate* and *main* sets. There is no such regular order in the lymph-glands of the mesentery.

(1) The **lymph-glands of the mesentery** (100-200 in number) are scattered in the fatty tissue of the mesentery without order: they receive the *afferent* vessels from the jejunum and the ileum (excepting the lowest few inches); the *efferents* pass from gland to gland and the ultimate efferents enter the mesenteric root glands.

(2) The epicolic and paracolic members of the group of **ileo-colic lymph-glands** are represented by a cluster in the ileo-colic angle from which a few outlying glands descend with the anterior and posterior cæcal vessels in front of and behind the ileo-colic junction—**cæcal lymph-glands**. One **appendicular gland** may be found in the mesentery of the appendix. The intermediate group is a clump half-way up the stem of the ileo-colic artery, and the main group is situated on the artery at its origin from the superior mesenteric, and may lie on the front of the third part of the duodenum. The vessels of the lower end of the ileum, of the appendix, cæcum, and lower end of the ascending colon form the *afferent* vessels of the group, and all parts of the chain receive direct vessels from the intestine as well as the efferent vessels of the distal glands. The ultimate *efferents* pass into the mesenteric root glands.

(3) The **right colic lymph-glands** form a variable group according with the variations of the artery. When distinct, it may be described in the same manner as the ileo-colic group.

(4) The **middle colic lymph-glands** form a chain consisting of numerous epicolic and paracolic glands disposed along the transverse colon from the right flexure as far as the junction of its middle and left thirds, an intermediate group about the point of bifurcation of the middle colic artery, and a main group on the stem of the artery as it enters the mesocolon. The chain drains the right flexure and the proximal two-thirds of the transverse colon; and the ultimate *efferents* enter the mesenteric root glands.

Inferior Mesenteric Lymph-Glands.—As already noted, the inferior mesenteric chain of glands is blended with the aortic glands, and its vessels contribute to the lumbar lymph-trunks; but as it is convenient to describe together all the lymph-vessels of the digestive system in the abdomen, the description of the course of the inferior mesenteric lymph-vessels has been deferred to the next section.

LYMPH-VESSELS OF DIGESTIVE SYSTEM IN ABDOMEN

The lymph-vessels of the abdominal part of the alimentary canal arise from a capillary plexus in the mucous membrane under the lining epithelium and around the gastric and intestinal glands. In the small intestine they also have a very important origin in the central lacteal vessels of the villi (Fig. 533, p. 626). Many vessels appear to arise from labyrinthic networks in the solitary lymphatic nodules, but it is probable that these vessels have come from the plexus of origin and are broken up in the solitary nodules—which are thus lymph-glands in miniature. The lymph-vessels from the mucous membrane perforate the muscular coats, between which they communicate freely, and on emerging are joined by the tributaries from the subserous network: they then pass away with the blood-vessels. In the small intestine they may run longitudinally on the surface for some inches before turning into the mesentery. The vessels are not all trapped by the glands nearest the wall of the alimentary canal; from all parts of the canal many run directly to glands at any point along the course of the blood-vessels.

Lymph-Vessels of Large Intestine.—In the area of distribution of the inferior mesenteric artery, the lymph-vessels of the large intestine pass to the epicolic, paracolic, and intermediate and main groups of glands associated with the branches of the artery. Those which follow the inferior left colic arteries from the **descending** and **pelvic colon** are joined by the stream which passes upwards from the rectum on the superior rectal artery (p. 1413). The lymph-drainage from the *left third* of the **transverse colon** and the **left flexure** must be specially mentioned because the stream divides at the intermediate glands (Fig. 1166) to follow two paths—one leading along the superior left colic artery to the inferior mesenteric main group on the left side of the aorta, the other along the curve of the inferior mesenteric vein to the superior mesenteric root

glands. Some small peritoneal lymph-vessels from the flexure run up in the greater omentum and thence through the gastro splenic ligament to the glands at the hilum of the spleen. The vessels from the *right two-thirds* of the **transverse colon** and from the *right flexure* run to the middle colic group; from the upper and middle parts of the **ascending colon** to the right colic group; from the lower part of the ascending colon, **cæcum, appendix** and **end of the ileum** to the ileo-colic group. The course of the lymph-vessels from the cæcum and appendix is shown from the front in Fig. 1166, and is specially illustrated from behind in Fig. 1167. Many collecting vessels leave the appendix and enter its mesentery where they unite to form four or five main lymph-vessels. These follow the

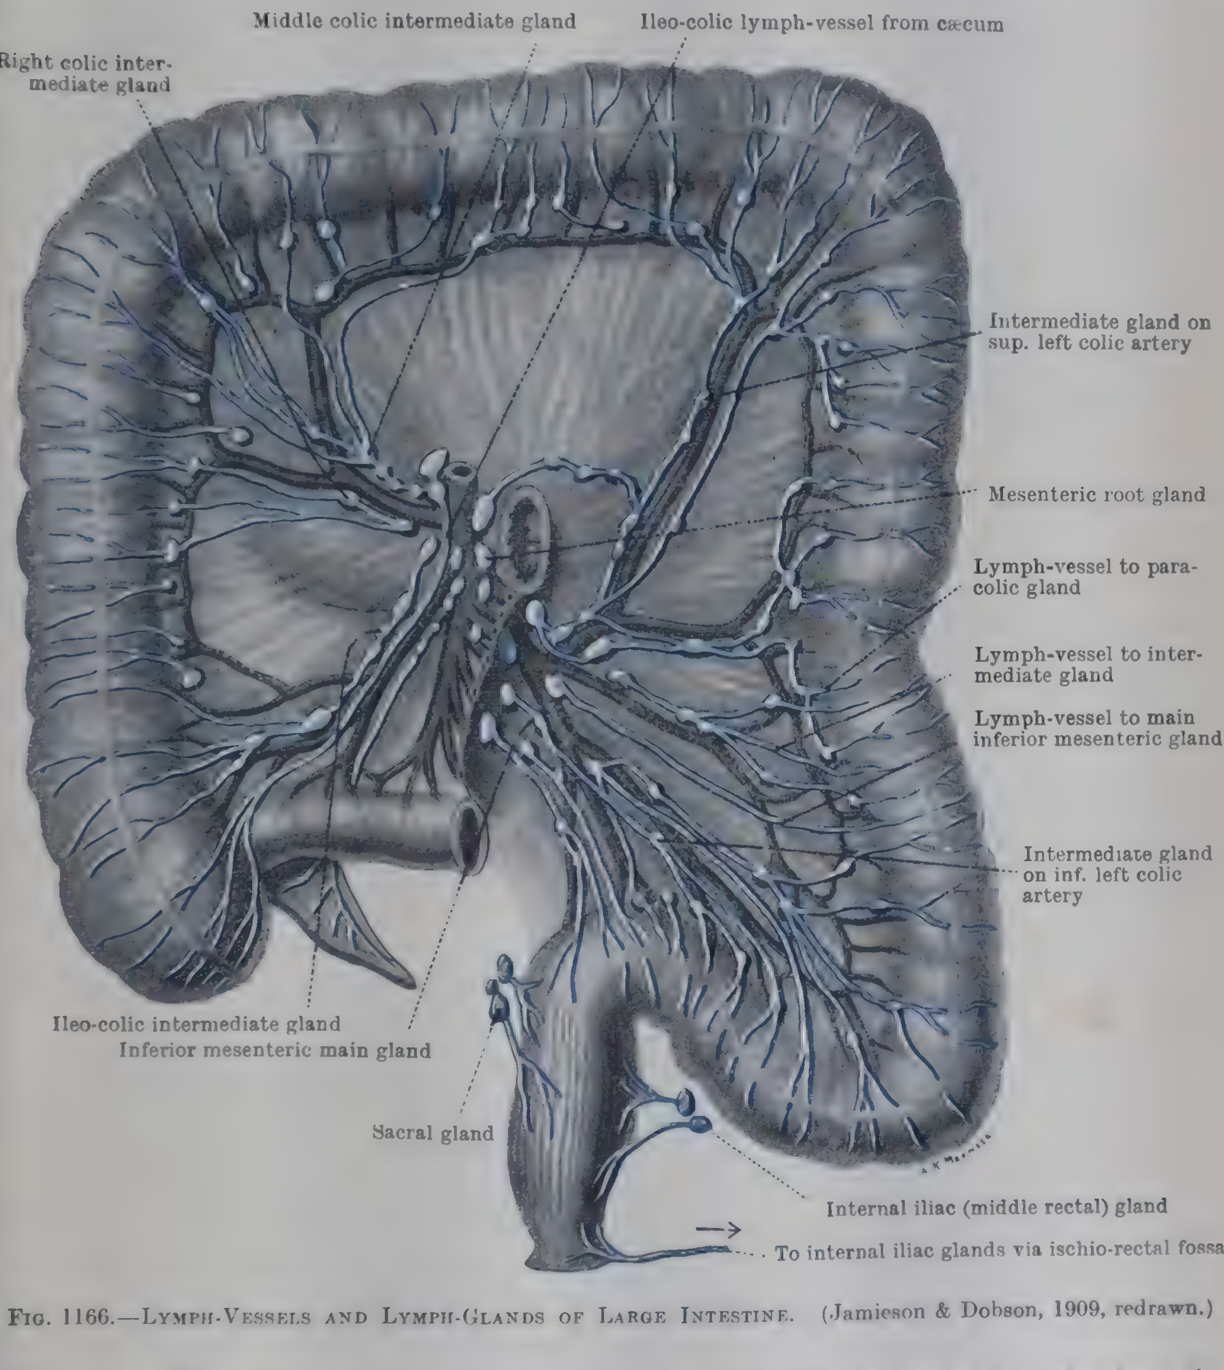

Fig. 1166.—Lymph-Vessels and Lymph-Glands of Large Intestine. (Jamieson & Dobson, 1909, redrawn.)

appendicular blood-vessels behind the lower end of the ileum and end in glands along the whole length of the ileo-colic chain.

Lymph-Vessels of Small Intestine.—From the lower end of the ileum to the duodeno-jejunal flexure—**ileum** and **jejunum**—the lymph-vessels run to the glands of the mesentery. From the lower half of the **duodenum** the vessels run directly to the mesenteric root glands, from the upper half to the subpyloric glands in front and to the biliary glands behind.

Lymph-Vessels of Stomach.—These run in three streams: (*a*) from the front and back of the fundus and body over an area indicated by a line (nearer the greater than the lesser curvature) from the fundus to the pyloric canal, to the left gastric glands;

epiploic and subpyloric glands, and upwards in the right end of the lesser omentum to the suprapyloric glands, lower members of the biliary chain and the right suprapancreatic glands (Figs. 1164, 1165).

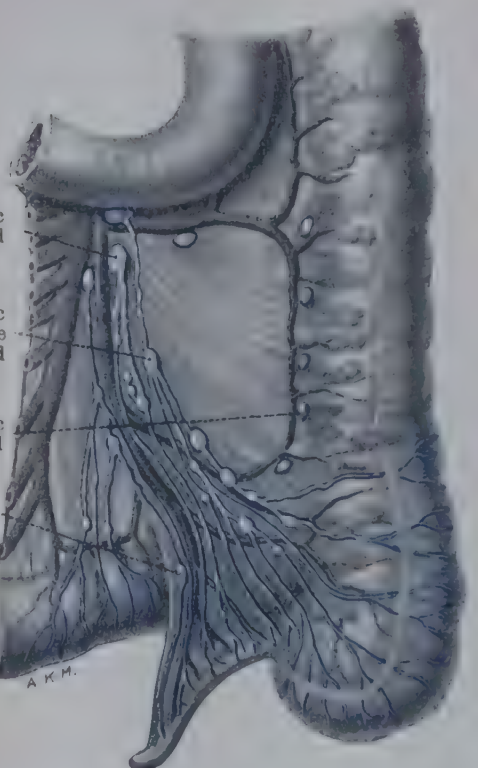

Fig. 1167.—Lymph-Vessels and Lymph-Glands of Cæcum and Appendix from behind. (Jamieson & Dobson, 1907 *b*, redrawn.)

Lymph-Vessels of Pancreas. — The pancreas is drained by vessels which enter the suprapancreatic glands above, the superior mesenteric root glands below, and the aortic glands behind.

Lymph-Vessels of Liver. — Interlobular collecting vessels are formed from capillaries in the lobules of the liver. They mostly come to the surface at innumerable points and form the peritoneal lymph-vessels. From the greater part of the right, superior, and anterior surfaces they run in large numbers to the falciform ligament, which they traverse and then turn upwards to pass along the superior epigastric blood-vessels into the retrosternal glands (see p. 1423). Those from the lower inch or so of the right and anterior surfaces turn round the lower edge of the liver and sweep towards the porta hepatis, where they pick up the vessels of the visceral surface and the **gall-bladder**, and a deep stream of vessels from the interior of the liver, some of which end in the hepatic glands of the porta. They pass into the lesser omentum and descend in it to end in the biliary chain of glands, but many pass to the left to reach the left gastric glands. Other vessels emerge from the back of the liver and follow the right phrenic vessels to the cœliac

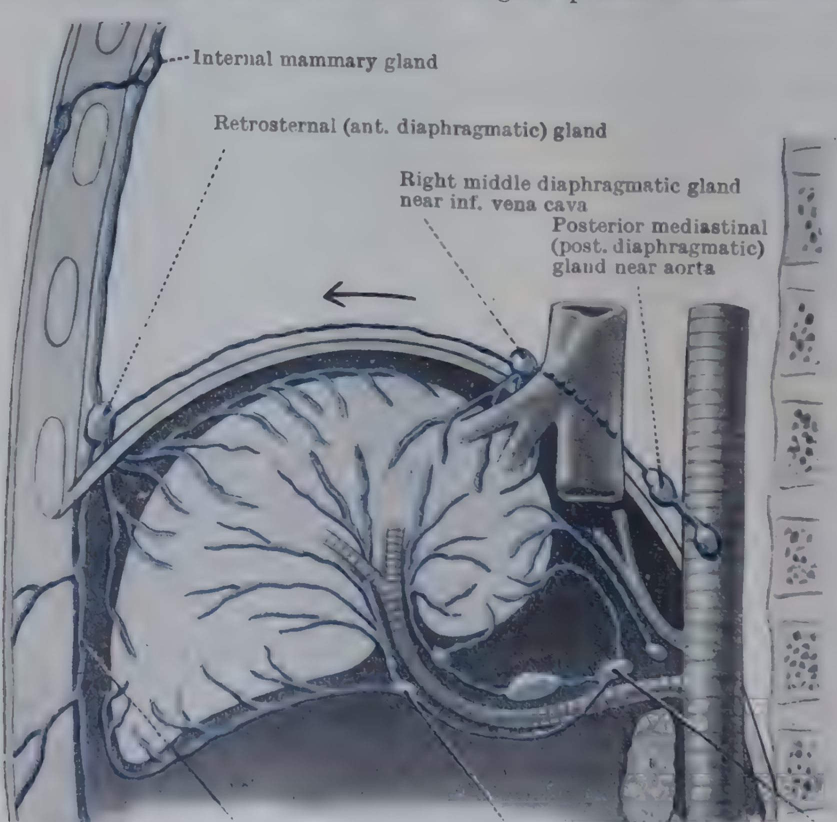

Fig. 1168.—Diagrammatic Sagittal Section showing Lymph-Drainage of Liver.

glands. Deep vessels, from the interior of the liver in the region of the main hepatic veins, emerge with these veins and pass up with the inferior vena cava to middle

diaphragmatic glands in the thorax (see below). It will be noted that there are two main currents of lymph from the liver—one ultimately passing into the cisterna, the other via the internal mammary route to the mediastinal trunks of both sides (Fig. 1168).

Lymph-Vessels of Spleen.—The vessels of the spleen pass to the splenic lymph-glands, which lie near the hilum of the spleen, and to the left suprapancreatic glands.

INTERCOSTAL AND MEDIASTINAL LYMPH-TRUNKS

There are numerous lymph-trunks in the thorax. A large **mediastinal lymph-trunk** is the chief pathway of both the parietal and visceral lymph-vessels; it receives the efferents of the glands associated with the internal mammary artery as well as those situated in the mediastinum. It may unite in various ways with other trunks in the root of the neck (see pp. 1405, 1406), but usually opens separately into the innominate vein.

In addition to the *descending intercostal lymph-trunks*, a number of independent **intercostal lymph-trunks** join the thoracic duct directly (see below and p. 1405). The thoracic duct receives directly a number of efferent vessels from posterior mediastinal lymph-glands also.

Lymph-Glands of Thorax

The groups of lymph-glands in the thorax are (*a*) intercostal, (*b*) diaphragmatic, (*c*) posterior mediastinal, (*d*) internal mammary, (*e*) innominate, and (*f*) tracheo-bronchial.

The **intercostal lymph-glands** are small nodules (1 or 2) situated in the vertebral end of each intercostal space in series with the lateral lumbar glands. They receive *afferents* from (*a*) the parietal pleura of the posterior thoracic wall; (*b*) vessels which accompany the intercostal arteries, mainly derived from the costo-vertebral and intervertebral synovial joints, and from the skin by a few vessels that penetrate deeply with the posterior and lateral cutaneous blood-vessels.

The *efferents* of the glands of the upper six or seven spaces of both sides run independently to the thoracic duct. Those of the glands of the lower four or five spaces join on each side to form a **descending intercostal trunk** which, after receiving the efferents of the glands in the lowest part of the posterior mediastinum, passes through the aortic opening to enter the upper part of the cisterna chyli.

The **posterior mediastinal lymph-glands**, few and variable, lie around the lower thoracic part of the œsophagus. They receive *afferents* from the œsophagus, the back of the pericardium and the back of diaphragm, on which their lowest members rest. Their *efferents* pass directly to the thoracic duct and to the descending intercostal lymph-trunks; and they are connected above with the paratracheal glands.

The **diaphragmatic lymph-glands** (Figs. 1168, 1169) may be subdivided into: (1) a *posterior* group, better considered as the lowest members of the posterior mediastinal group; (2) an *anterior* group better considered under the name "retrosternal" as part of the internal mammary chain; (3) a *middle* group, which on the left side is found as a small cluster around the phrenic nerve as it enters the diaphragm. The middle diaphragmatic glands receive *afferents* from the lateral portion of the diaphragm, and send *efferents* forwards to the retrosternal and backwards to the lower posterior mediastinal glands. On the right side the group is larger, lies in near relation to the inferior vena cava, and receives in addition a certain number of afferents from the liver which issue with the hepatic venous trunks (p. 1422).

The **retrosternal lymph-glands** (Fig. 1169) are the lowest members of the internal mammary chain and consist of a number (3-6) of relatively large glands situated on the sternal and costal origins of the diaphragm behind the base of the xiphoid

anterior part of the diaphragm, and those which accompany the superior epigastric blood-vessels. The last of these streams is the most important and is derived not only from the perforating lymph-vessels of the anterior abdominal wall (few) but from numerous vessels which pass from the upper and anterior surfaces of the liver through the falciform ligament and account for the number and size of the retrosternal group of glands. The *efferents* pass up to the next group.

The **internal mammary lymph-glands** (Fig. 1169) form a chain consisting of one or two glands in each of the upper four intercostal spaces close to the sternum (Stibbe, 1918): they receive the efferents of the retrosternal glands and the lymph-

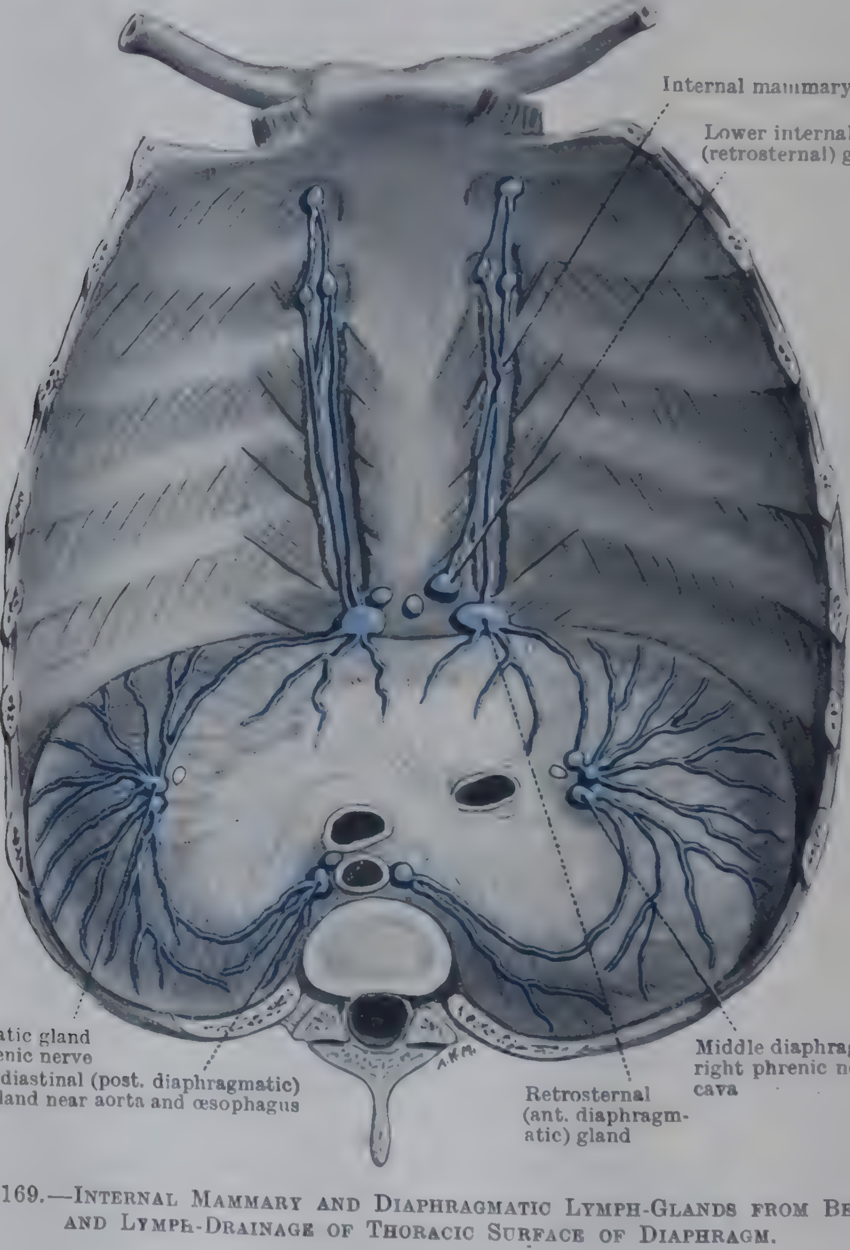

Fig. 1169.—Internal Mammary and Diaphragmatic Lymph-Glands from Behind, and Lymph-Drainage of Thoracic Surface of Diaphragm.

vessels which accompany the intercostal and perforating branches of the internal mammary artery. These vessels require special mention: the anterior intercostal afferents of the internal mammary chain drain the parietal pleura almost as far back as the angles of the ribs; and along the perforating arteries some cutaneous lymph-vessels come from the skin of the mamma and from the stroma of the medial part of the mammary gland. Hence the great surgical importance of the internal mammary chain.

The *efferents* of the internal mammary glands usually join to form a single vessel which unites with the efferents of the tracheo-bronchial and innominate glands to form the mediastinal lymph-trunk. An *internal mammary trunk* may also open independently into the veins (see p. 1406).

The lymph-glands associated with the pulmonary system and the heart lie

in the superior and middle mediastina. A rather irregular arrangement may be reduced for descriptive purposes to the following scheme: (1) glands of the roots of the lungs—(*a*) broncho-pulmonary, (*b*) inferior tracheo-bronchial, (*c*) superior tracheo-bronchial; (2) paratracheal glands; (3) innominate glands.

The **broncho-pulmonary lymph-glands** are embedded in the hilum of the lung and in the intervals between the pulmonary vessels and the bronchus as they enter the root. Small outlying *pulmonary glands* may be found on the larger bronchi in the substance of the lung.

The **inferior tracheo-bronchial lymph-glands** are situated in the angle of bifurcation of the trachea, and unite the other groups of glands of the two sides.

The **superior tracheo-bronchial lymph-glands** are continuous with the upper broncho-pulmonary glands in the angle between the trachea and the bronchus on each side.

The **glands of the root** of the lung receive the lymph-vessels of the lung (including the visceral pleura), and from the bronchi and lower end of the trachea; and vessels from the left side of the heart end in the inferior tracheo-bronchial group. Their *efferents* pass upwards on the trachea.

The **paratracheal lymph-glands** extend upwards along each side of the trachea into the neck. They drain the trachea and the corresponding part of the œsophagus.

The **innominate lymph-glands** are a few small glands scattered in the superior mediastinum in the vicinity of the innominate veins and the aortic arch. They receive lymph-vessels from the thymus and the upper part of the pericardium, and also from the right side of the heart.

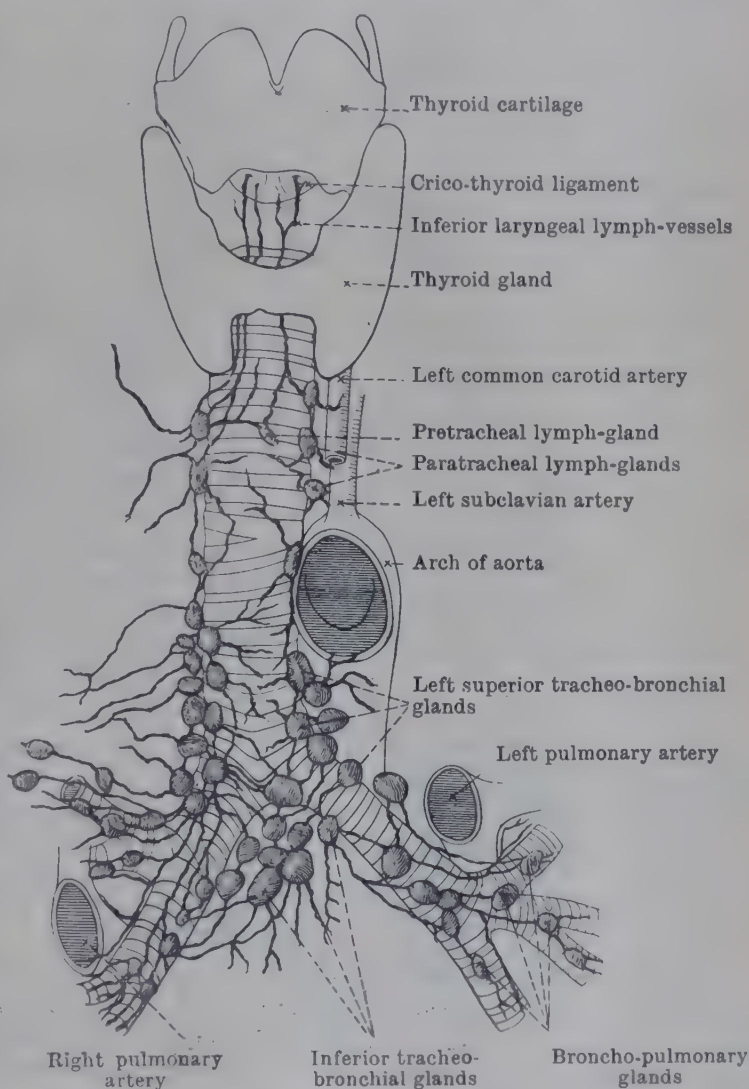

FIG. 1170.—LYMPH-GLANDS IN RELATION TO TRACHEA AND MAIN BRONCHI.

The ultimate *efferents* of all these lymph-glands unite to form a single vessel on each side of the trachea which usually joins the single efferent of the internal mammary glands to form the **mediastinal lymph-trunk**. This trunk usually enters the front of the junction of the subclavian and internal jugular veins, but the left trunk may join the thoracic duct and the right may join the jugular or the subclavian lymph-trunk or unite with them to form a right lymphatic duct (see pp. 1405, 1406).

LYMPH-VESSELS OF DIAPHRAGM AND THORAX

Lymph-Vessels of Diaphragm (Fig. 1169).—An extensive lymph-plexus is present on each surface—abdominal and thoracic—of the diaphragm. The subserous parts of the plexuses (beneath the parts of the diaphragm covered with peritoneum and pleura) are

surface also pierce the diaphragm to join with vessels from the thoracic surface on their way to the retrosternal (anterior diaphragmatic) lymph-glands. From the lateral and posterior parts of the abdominal surface, vessels may take a similar course through the diaphragm to reach the middle diaphragmatic glands, and a comparatively small number follow the course of the phrenic arteries to end in upper aortic glands on the crura of the diaphragm.

Lymph-vessels from the thoracic surface of the diaphragm run in three directions to glands situated within the thorax: (1) from the anterior part to the retrosternal lymph-glands; (2) from the lateral part to the middle diaphragmatic glands; and (3) from the posterior part of the surface to the posterior mediastinal (posterior diaphragmatic) glands. Some vessels of the posterior part of the thoracic surface may pierce the diaphragm and run with vessels of the abdominal surface to aortic glands.

The lymph-vessels that pass from the abdominal surface of the diaphragm to the middle and anterior (retrosternal) diaphragmatic glands are in communication with lymph-vessels of the liver.

Lymph-Vessels of Parietal Pleura.—The parietal pleura is drained by vessels which issue from its outer surface and form larger collecting vessels in the extrapleural areolar tissue. The collecting vessels from the **costal pleura** in general run in two directions—backwards with the intercostal blood-vessels to the intercostal glands, and forwards to the retrosternal and internal mammary glands. But vessels from the pleural lining of the axillary parts of the second and third intercostal spaces usually—and from the fourth and fifth spaces sometimes—pierce the intercostal muscles and emerge with the lateral cutaneous branches of the intercostal nerves to end in axillary lymph-glands (Rouvière, 1932). Vessels from the costal pleura of the first space run upwards through the thoracic inlet and end with those of the **cervical pleura** in lower deep cervical glands. One of them may cross the first rib with the subclavian vein and end in an apical axillary gland. Vessels from the **mediastinal pleura** pass to the tracheo-bronchial and mediastinal glands; and those from the **diaphragmatic pleura** run with the vessels of the corresponding parts of the diaphragm.

Lymph-Vessels of Lungs and Pulmonary Pleura.—Each lung possesses a plexus of vessels on the bronchial tree as far as the smallest bronchioles: there are no lymph-vessels on the alveoli. The vessels of the pulmonary (visceral) pleura penetrate the lung to join the bronchial lymph-vessels, and all emerge at the hilum and end in the glands of the root (for details see p. 720).

Lymph-Vessels of Bronchi and Trachea.—The bronchi and the intrathoracic part of the trachea drain into the lymph-glands that lie around them in the roots of the lungs and the mediastinum—broncho-pulmonary, tracheo-bronchial, and paratracheal.

Lymph-Vessels of Pericardium.—The pericardium drains into the nearest glands in front of and behind it—posterior mediastinal, retrosternal, innominate.

Lymph-Vessels of Heart.—A wide-meshed plexus of minute vessels under the endocardium—not to be confused with the injected sheath of the Purkinje network, see p. 1237 and Fig. 1068—gives rise to efferents which pierce the myocardium to join others from the richer plexus under the epicardium. The subepicardial plexus of the ventricles is easily injected, but on the atria the plexus is relatively scanty and not easily demonstrated. In consequence, the destination of the lymph-vessels of the **atria** is not well known; only a few seem to pass into the atrio-ventricular groove and join the vessels of the ventricles; it is probable that the chief drainage is from the upper parts of the atria to tracheo-bronchial glands. The collecting vessels from the **ventricles** pass into the atrio-ventricular groove and follow the coronary arteries towards their origin. Those associated with the right coronary artery usually form a single trunk which passes upwards in front of the ascending aorta to the innominate glands; those associated with the left coronary artery (draining a part of the right ventricle, as well as the whole of the left) also usually end in a single vessel which passes on the left of and behind the pulmonary trunk to one or other of the tracheo-bronchial glands—usually a member of the right superior group (Shore, 1929). (Consult also the monograph by Aagaard, 1924, and Patek, 1939.)

Lymph-Vessels of Œsophagus.—The œsophagus is drained into different groups of lymph-glands according to the situation of its parts. Its lymph-vessels run (*a*) from the *abdominal part* to the left gastric glands, (*b*) from the *lower thoracic part* to the posterior mediastinal glands, and (*c*) from the *upper thoracic* and *cervical parts* to the paratracheal glands with the vessels of the trachea.

Lymph-Vessels of Thymus.—The thymus sends vessels to the innominate glands and to the internal mammary glands of both sides.

SUBCLAVIAN LYMPH-TRUNKS

The area of drainage of the **subclavian lymph-trunk** comprises the upper limb and a cutaneous area of the trunk extending from the umbilical plane to the level of the clavicle in front and half-way up the neck behind; the vessels of the mammary gland also are included. The subclavian trunk ends in a variety of ways (see p. 1406), but very often it enters the corresponding subclavian vein directly.

Superficial and Deep Lymph-Glands of Upper Limb

The glands in the territory of the subclavian lymph-trunk comprise a few superficial glands and a greater number of deep glands including the important axillary group.

The **superficial glands** are (*a*) supratrochlear, (*b*) infraclavicular (including delto-pectoral and interpectoral): the **deep glands** are (*a*) small and inconstant nodules in the cubital fossa and on the upper parts of the arteries of the forearm, (*b*) brachial, (*c*) axillary.

Superficial Lymph-Glands of Upper Limb.—The **supratrochlear lymph-glands** are found on the medial side of the basilic vein a little above the medial epicondyle of the humerus: they receive *afferents* from the fingers and hand on the medial side of the mid-finger line and from a strip on the ulnar side of the forearm: their *efferents* join the deep stream along the basilic vein.

The **infraclavicular lymph-glands** (1-2) lie in the infraclavicular fossa on the upper end of the cephalic vein and drain some vessels from the skin of the "vaccination area" and of the shoulder, and from the upper part of the mammary gland: their *efferents* perforate the clavi-pectoral fascia to join the apical axillary glands. Outlying members of this group are found in two situations. A **delto-pectoral lymph-gland** is occasionally found in the groove between the deltoid and the pectoralis major muscles. It receives *afferents* from the skin of the lateral part of the upper arm and of the shoulder, and gives *efferents* to the infraclavicular glands and to the subclavian trunk. Small, more deeply placed, **interpectoral lymph-glands** are sometimes found between the great and small pectoral muscles. They lie in the path of the lymph-vessels which pass from the upper part of the mammary gland to the infraclavicular glands or direct to the apical glands of the axilla (Fig. 1171).

Deep Lymph-Glands of Upper Limb.—The **deep lymph-glands of the forearm** are small, inconstant, immature nodules on the radial, ulnar, and interosseous arteries and in the cubital fossa; they interrupt a few of the deep lymph-vessels. The **brachial lymph-glands** are merely outlying members of the axillary glands found occasionally along the upper part of the brachial artery. The *efferents* of all these glands pass to the lateral axillary group.

The **axillary lymph-glands** are very numerous and widely distributed in the axillary fatty tissue. They may be divided into groups below and above the pectoralis minor tendon. The lower group is subdivided into (*a*) lateral, (*b*) pectoral, (*c*) subscapular, (*d*) central. The upper group is called (*e*) apical.

The **lateral axillary glands** lie in the fatty tissue along the axillary vein. From this group the **anterior** or **pectoral** and the **posterior** or **subscapular glands** radiate along the lower border of the pectoralis minor on the chest wall with the lateral thoracic artery, and along the lateral border of the scapula with the subscapular artery. The **central group** is composed of loose members of the former three groups; they lie under the axillary fascia, and one of them frequently projects through an opening in that fascia.

The *afferents* of the lower axillary glands are (*a*) the deep vessels of the whole limb, (*b*) the cutaneous vessels of the limb and trunk above the umbilical plane, (*c*) the vessels of the mammary gland. It must be noted that all the groups

the lateral lower deep cervical glands (see p. 1433), so that some of the lymph from the axilla may go through these glands to the jugular lymph-trunk but their *efferents* go mainly to form the **subclavian lymph-trunk**, which enters

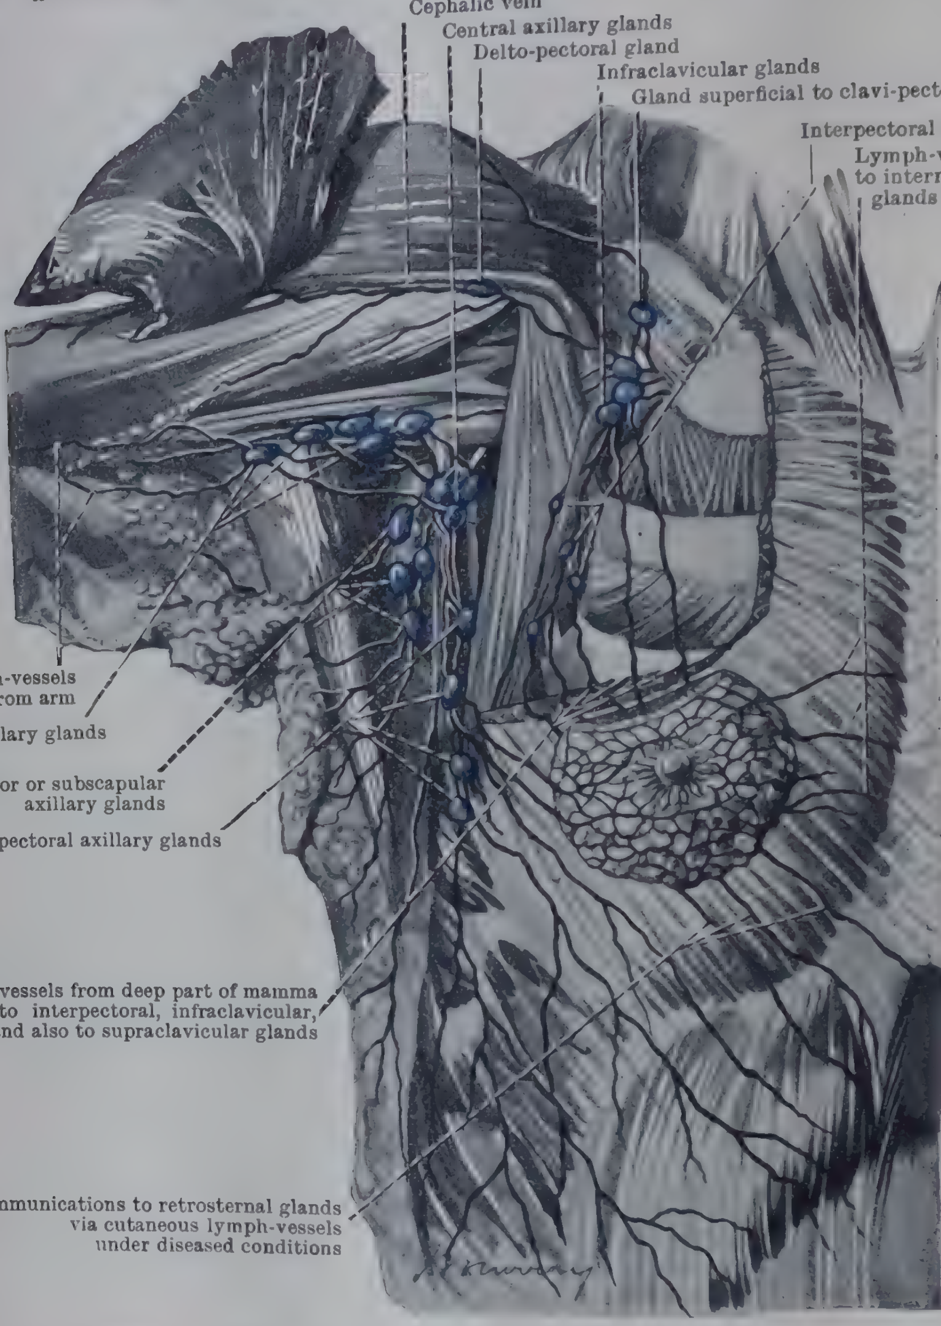

FIG. 1171.—DISSECTION OF AXILLA AND ANTERIOR PART OF THORACIC WALL, SHOWING LYMPH-GLANDS AND LYMPH-VESSELS. (Semi-diagrammatic, with only a portion of the mamma represented.)

independently into the junction of the great veins or may join the thoracic duct on the left side or unite with either the jugular or the mediastinal trunk or with both on the right side.

SUPERFICIAL LYMPH-VESSELS OF UPPER LIMB AND TRUNK

The **superficial lymph-vessels of the subclavian-trunk territory** must be considered as a whole, those of the upper limb being taken with those of the trunk above the umbilicus (including the mammary gland).

The **superficial lymph-vessels of the upper limb** begin in a rich cutaneous plexus from which vessels stream upwards irrespective of the veins. On the front of the forearm they run almost parallel to one another but with an inclination towards the axilla, and they are reinforced by vessels that slope upwards and forwards from the back of the limb round its margins. As they ascend into the upper arm some vessels on the medial side are interrupted by the supratrochlear glands, and some pass through the deep fascia with the basilic vein to join the deep stream ; but nearly all run to the axilla before they

pierce the deep fascia. The vessels from the front and back of the upper arm become more and more horizontal as they join the main stream, and some take a descending course from the front and back of the shoulder region (Figs. 1172, 1173). On the back

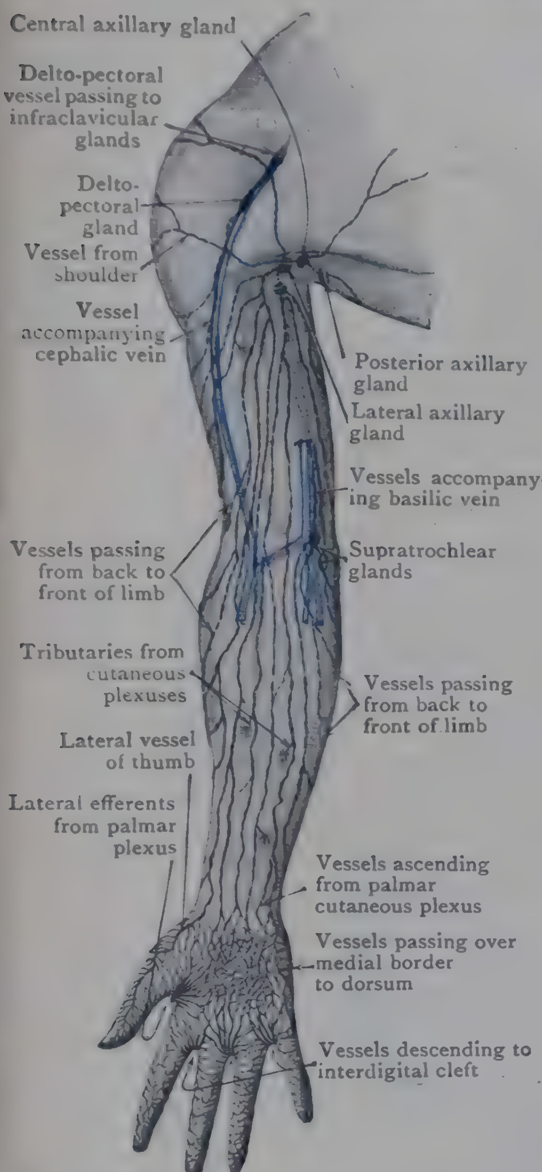

Fig. 1172.—Superficial Lymph-Vessels and Lymph-Glands of Front of Upper Limb.

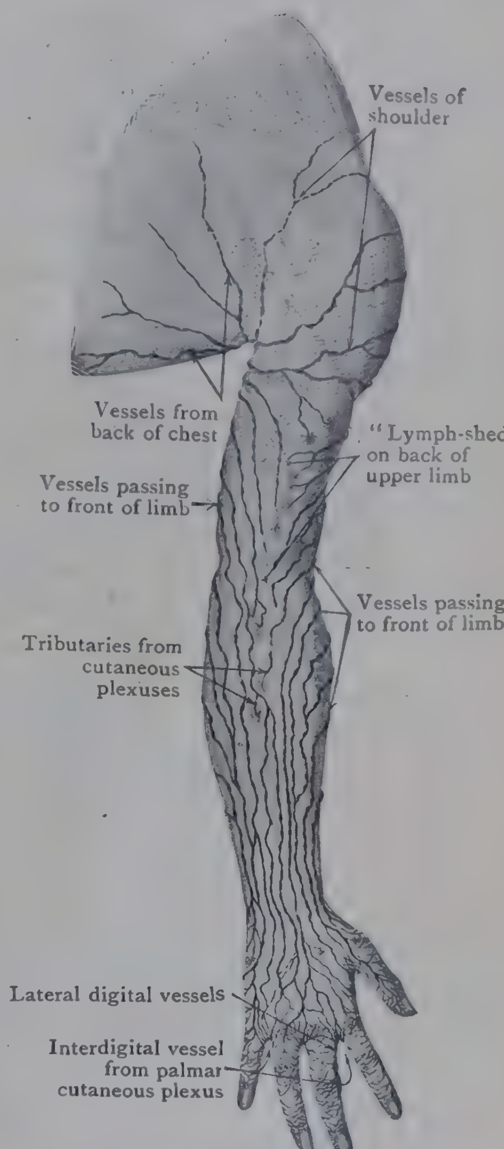

Fig. 1173.—Superficial Lymph-Vessels of Back of Upper Limb.

of the upper arm and of the elbow there is a "lymph-shed" from which vessels pass round the lateral and medial margins to the front. A few vessels from the skin over the upper part of the cephalic vein follow that vein to the infraclavicular glands, and may be interrupted in delto-pectoral glands.

The cutaneous plexuses are finest and most dense on the palmar surfaces of the fingers and hand. The efferents from the palmar digital plexus of each finger pass to the dorsum of the digit. There they form dorsal digital vessels, 2-4, which run to the dorsum of the hand, where they unite together to form new vessels.

The efferents from the palmar plexus of the hand run upwards, downwards, and to the lateral and medial margins of the hand. The lateral efferents, as they turn round the lateral border of the hand, join the efferents of the thumb. The medial efferents turn round the medial border of the hand, and join the efferents of the little finger. The efferents which run upwards are few and variable; when they are present they lie along the line of the median vein of the forearm. The efferents which run downwards pass to the interdigital clefts, where they turn backwards and join the vessels on the dorsum of the hand (Figs. 1172, 1173).

The **superficial lymph-vessels of the trunk** are arranged in a great whorl which begins at the shoulder. Behind, the vessels run downwards from the lower part of the neck, horizontally from the scapular region, and upwards from the back above the iliac crest (Fig. 1152), to converge round the posterior fold of the axilla. The vessels from the side of the trunk ascend vertically, whilst those in front gradually incline more and more horizontally until the whorl is completed by the vessels over the upper part of the

pectoral region as they descend to curve round the anterior axillary fold (Fig. 1151). The plexus of origin is continuous over the median line, and many of the vessels of one side begin on the other side. There are also several vagrant vessels which penetrate deeply along the cutaneous branches of the intercostal arteries behind and laterally, and with the perforating branches of the internal mammary and cutaneous branches of the superior epigastric in front, and thus reach the intercostal, retrosternal, and internal mammary glands. Others run with the cutaneous branches of the acromio-thoracic artery to end in the axillary and infraclavicular glands, and a few ascend over the clavicle with small blood-vessels to reach the lower deep cervical glands.

Lymph-Vessels of Mamma.—The mammary gland is a modified skin-gland; its lymph-vessels therefore run to the axillary glands like other cutaneous lymph-vessels of the region. In the infant there is already present beneath the areola of the mamma a specially developed part of the general cutaneous plexus; to this *subareolar plexus* (Sappey, 1874) the lymph-vessels of the rudimentary gland converge, and from it two or more special collecting vessels pass to the axilla. These vessels continue to be the principal route of lymph-drainage from the gland. As the gland grows, its rudimentary acini

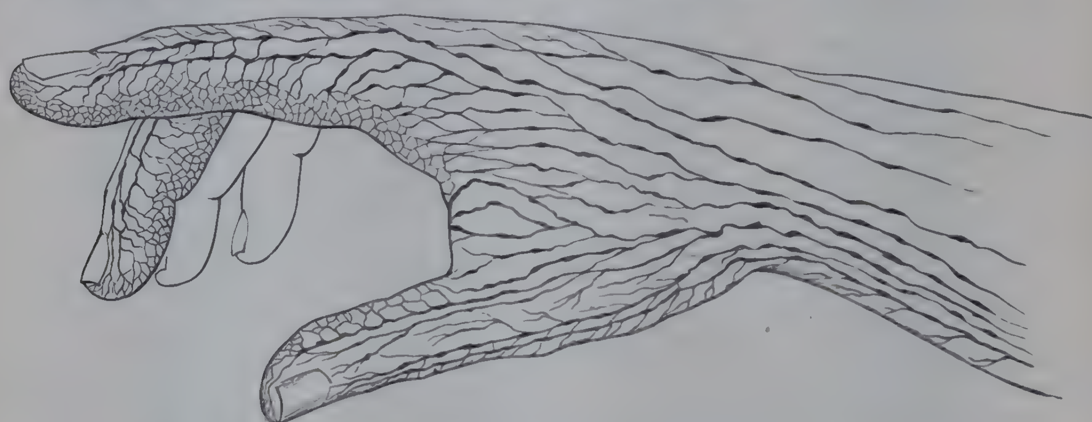

FIG. 1174.—SUPERFICIAL LYMPH-VESSELS OF THUMB AND FOREFINGER.

develop and thrust themselves radially into the subcutaneous fat to form the lobules. The glandular lymph-vessels develop *pari passu* with the lobules; perilobular plexuses are formed from which vessels pass to the surface along the lactiferous ducts; and the subareolar plexus continues to receive them.

From the subareolar plexus two main vessels (Fig. 1171) run round the axillary fold and follow the lower border of the pectoralis minor to the upper members of the anterior (pectoral) group of axillary glands situated along the lateral thoracic vein. The greater part of the mammary gland is drained by this route, but from the peripheral lobules other vessels pass in different directions to other groups of lymph-glands. From the lower part of the gland some follow the route taken by the principal vessels to the axilla. They end also in the anterior group of lymph-glands; but it should be noted again that all the groups of axillary lymph-glands are interconnected, and that lymph-vessels from the mamma may pass *directly* to any group, even to the lateral group along the axillary vein. From the upper part of the gland and from its deep surface, vessels run over or through the pectoral muscles to the apical axillary lymph-glands, either directly or via the infraclavicular group; some of these vessels are interrupted in the small interpectoral lymph-glands (see p. 1427). From the medial part of the mammary gland a few vessels pierce the pectoralis major and pass through the anterior ends of the intercostal spaces to reach the internal mammary chain of lymph-glands.

The cutaneous vessels must be remembered as an important part of the lymph-drainage of the mamma. These are included in the account already given of the superficial lymph-vessels of the trunk: and it should be noted that some of them pass deeply between the lobules of the gland. They may thus appear to issue from its substance and give the impression that the direct drainage from the periphery of the gland is more extensive than it really is. These cutaneous vessels pass to the axillary, infraclavicular, and internal mammary lymph-glands, and a few ascend from the skin of the upper part of the mamma to the lower deep cervical glands. From the skin of the medial part of the mamma, vessels may pass across the median plane to internal mammary and axillary lymph-glands of the opposite side. No path has been found from the mamma via the superior epigastric vessels to the retrosternal glands in health;

but when diseased conditions have spread into the cutaneous plexus below the gland, these lymph-glands may be affected (Fig. 1171).

Deep Lymph-Vessels of Upper Limb

The **deep lymph-vessels of the upper limb** accompany the deeper blood-vessels. Some of the deep lymph-vessels of the hand and forearm may be interrupted in the deep glands which are occasionally present in the forearm, but most of them either end in the cubital or brachial glands, or pass directly to the lateral group of axillary glands.

JUGULAR LYMPH-TRUNKS

The area of drainage of the **jugular lymph-trunk** comprises the head and neck—except the skin of the lower part of the back of the neck—and the parts drained by such deep lymph-vessels as may accompany the transverse cervical artery. The trunk is formed by the union of the efferents of the superior and inferior deep cervical lymph-glands; the right trunk enters the angle of union of the internal jugular and subclavian veins, and the left trunk joins the thoracic duct.

Lymph-Glands of Head and Neck

The arrangement of lymph-glands and vessels in the head and neck is less simple than in other parts of the body, and there is some added difficulty of description from the facts that the apical group of axillary glands merges with

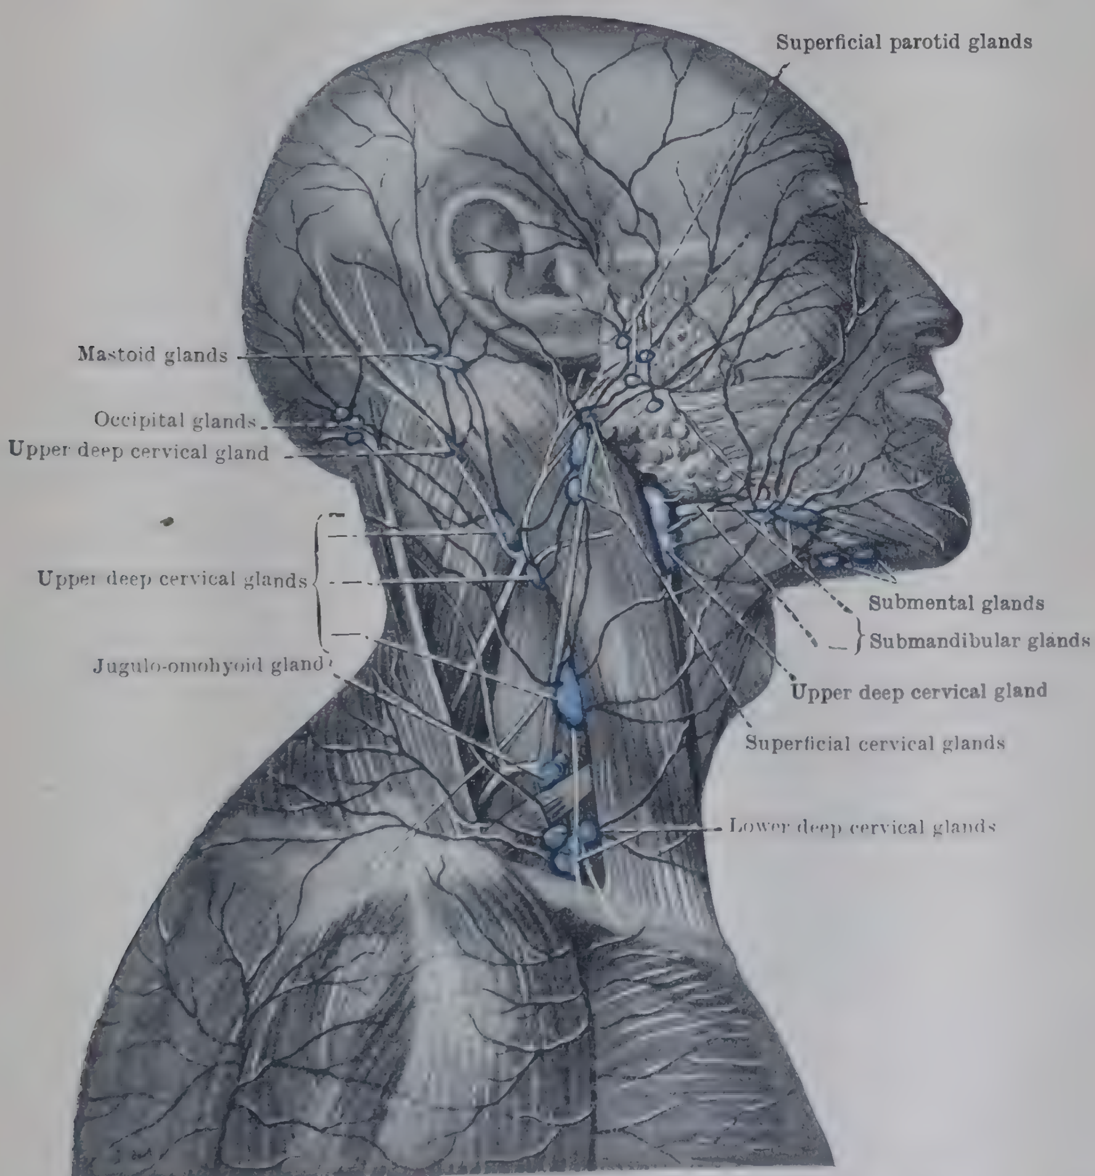

Fig. 1175.—Lymph-Glands of Head and Neck as seen with Sterno-Mastoid in Position. The occipital, mastoid, and superficial parotid glands are inserted in accordance with descriptions. The other glands were present in one or other of the two bodies from which the drawing was made. Compare Fig. 1177.

the glands in the root of the neck, and that the paratracheal group extends upwards from the thorax into the neck, and sends its upper efferents to join the jugular lymph-trunk. Further, the lymph-glands of the neck in reality form one continuous group with numerous offshoots. It is convenient, however, in order that a bird's-eye view of the whole system may be obtained, to describe a main chain of glands along the great vessels of the neck and subsidiary groups along the course of the branches of the external carotid artery and on the inferior thyroid artery.

The glands thus arranged are:—

(1) Deep cervical glands (jugular chain).

(2) Glands associated with the scalp and face, forming a "collar-chain" between the head and the neck: (*a*) occipital; (*b*) mastoid; (*c*) parotid and superficial cervical; (*d*) submandibular, with facial glands; (*e*) submental.

(3) Anterior cervical glands: (*a*) infrahyoid; (*b*) prelaryngeal; (*c*) pretracheal; (*d*) paratracheal.

Deep Cervical Lymph-Glands.—The deep cervical lymph-glands extend from the base of the skull to the root of the neck, along the path of the great vessels

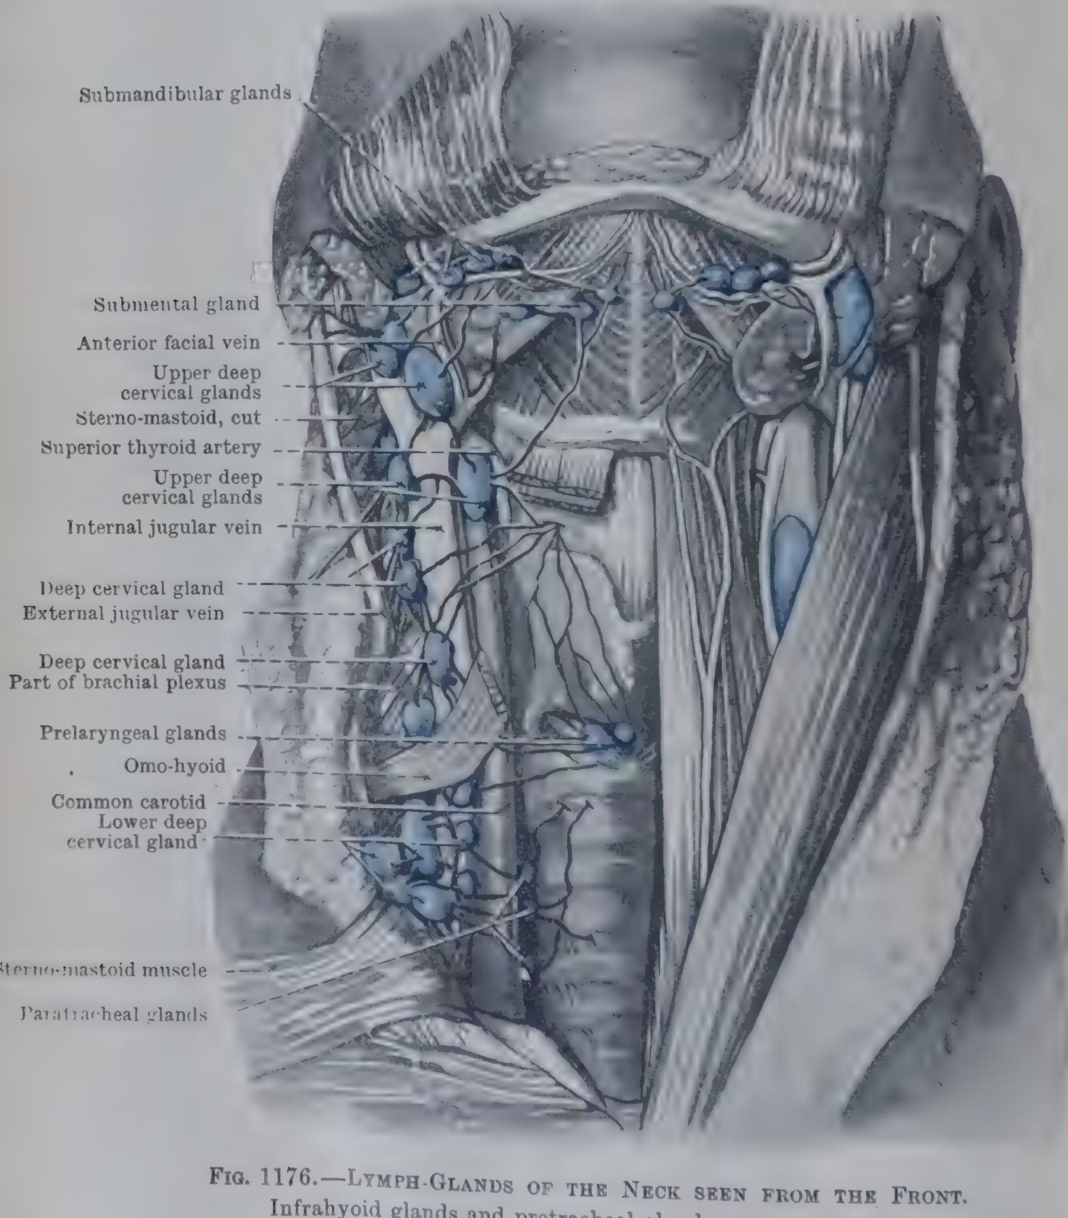

FIG. 1176.—LYMPH-GLANDS OF THE NECK SEEN FROM THE FRONT.
Infrahyoid glands and pretracheal glands were not present.

on each side of the pharynx and gullet. Most of them are concealed by the sterno-mastoid, but the oblique direction of the muscle leaves uncovered the lower end of the chain, which thus invades the lower part of the posterior triangle of the neck. Numerous members also project at the posterior border of the

sterno-mastoid and stray backwards into the posterior triangle. When enlarged by disease the row of bulging glands forms an obvious swelling along the posterior border of the sterno-mastoid. It is customary to divide the chain into superior and inferior parts, but only for the same reason as in the axilla—the fact that a muscle (omo-hyoid) crosses the chain. Nevertheless, the chain is continuous: its division into groups is a topographical convenience only. It is likewise convenient to subdivide each part of the chain into medial and lateral groups.

Superior Deep Cervical Lymph-Glands.—(1) The *medial group* of upper deep cervical lymph-glands lies on the superficial surface of the internal jugular vein and in the carotid triangle of the neck. The highest members of the group are slightly separated from the rest; they are known as **retropharyngeal glands**, and lie behind the lateral border of the naso-pharynx on the prevertebral fascia in front of the rectus capitis anterior. They receive *afferents* from the naso-pharynx, the pharyngo-tympanic tube and the atlanto-occipital and atlanto-axial joints. Below these a few, small **deep parotid lymph-glands** are embedded in the deep surface of the parotid salivary gland and even in its substance (see p. 1434). Below the parotid the chain becomes exuberant; its numerous members are mainly associated with the internal jugular vein under the sterno-mastoid; but they stray forwards so as to appear in the anterior triangle of the neck—notably one group, the largest member of which is frequently palpable below the angle of the jaw. This gland lies under the common facial vein in the interval between the digastric muscle and the internal jugular vein, and hence it has been named the *jugulo-digastric lymph-gland* (Leaf, 1898) (Fig. 1177); it is specially associated with the lymph-drainage of the tongue and of the tonsil. The lowest gland of the group projects beyond the posterior border of the sterno-mastoid immediately above the tendon of the omo-hyoid muscle—the *jugulo-omohyoid gland* (Jamieson & Dobson, 1920) (Fig. 1175); it receives efferents from the submental glands and also lymph-vessels from the tongue, including one direct from the tip. (2) The members of the *lateral group* of upper deep cervical lymph-glands lie under cover of the posterior part of the upper portion of the sterno-mastoid and in the upper part of the posterior triangle of the neck. They are embedded in the fat-laden fascia which covers the roots of the cervical plexus and the upper part of the brachial plexus, and the levator scapulæ and the scalene muscles, and several of them are in close relation with the accessory nerve (Figs. 1175, 1177).

The upper deep cervical glands receive *afferent* vessels from various subsidiary groups of glands (see pp. 1434, 1435). They receive lymph, directly or indirectly, from the skin of the head and neck, from the nose, the mouth, the tongue, the pharynx and larynx, the tonsil, the upper part of the thyroid gland, the submandibular, sublingual, and parotid salivary glands. Their *efferents* pass partly to the lower deep cervical glands and partly to the jugular lymph-trunk.

Inferior Deep Cervical Lymph-Glands (Figs. 1176, 1177).—These glands are situated below the level of the omo-hyoid muscle. They are mainly under cover of the sterno-mastoid, the trapezius and the clavicle, but some of them appear in the lower part of the posterior triangle of the neck. (1) The members of the *medial group* lie in relation with the lower part of the internal jugular vein, opposite the interval between the sternal and clavicular heads of the sterno-mastoid. They receive *afferents* from some of the upper deep cervical glands and from the pretracheal and the paratracheal glands. Their *efferents* unite with some of the efferents of the upper medial group and pass with them to the jugular lymph-trunk.

(2) The members of the *lateral group* of lower deep cervical glands lie in the fatty tissue superficial to the brachial plexus and the third part of the subclavian artery, and they extend beneath the trapezius along the transverse cervical blood-vessels. They receive lymph from the skin of the back of the neck and a few vessels which ascend over the clavicle from the skin of the pectoral region, including the upper part of the mamma, and they are in communication with the apical group of axillary glands. Their *efferents* join the jugular lymph-trunk.

The subsidiary offshoots of the deep cervical glands are found in the track of the smaller arteries.

The **anterior cervical lymph-glands** are in small outlying groups—

(1) With the superior thyroid artery: (*a*) the *infra-hyoid glands* on the thyro-hyoid membrane; (*b*) *prelaryngeal glands* on the crico-thyroid ligament.

(2) With the inferior thyroid artery: (*a*) *pretracheal glands* at the lower end of the thyroid gland; (*b*) the upper *paratracheal glands* in the groove between trachea and œsophagus. These glands receive lymph from the larynx, the trachea and œsophagus in the neck and the thyroid gland; and they transmit it to the lower deep cervical glands.

(3) With the lingual artery in relation to the hyo-glossus, a few small occasional

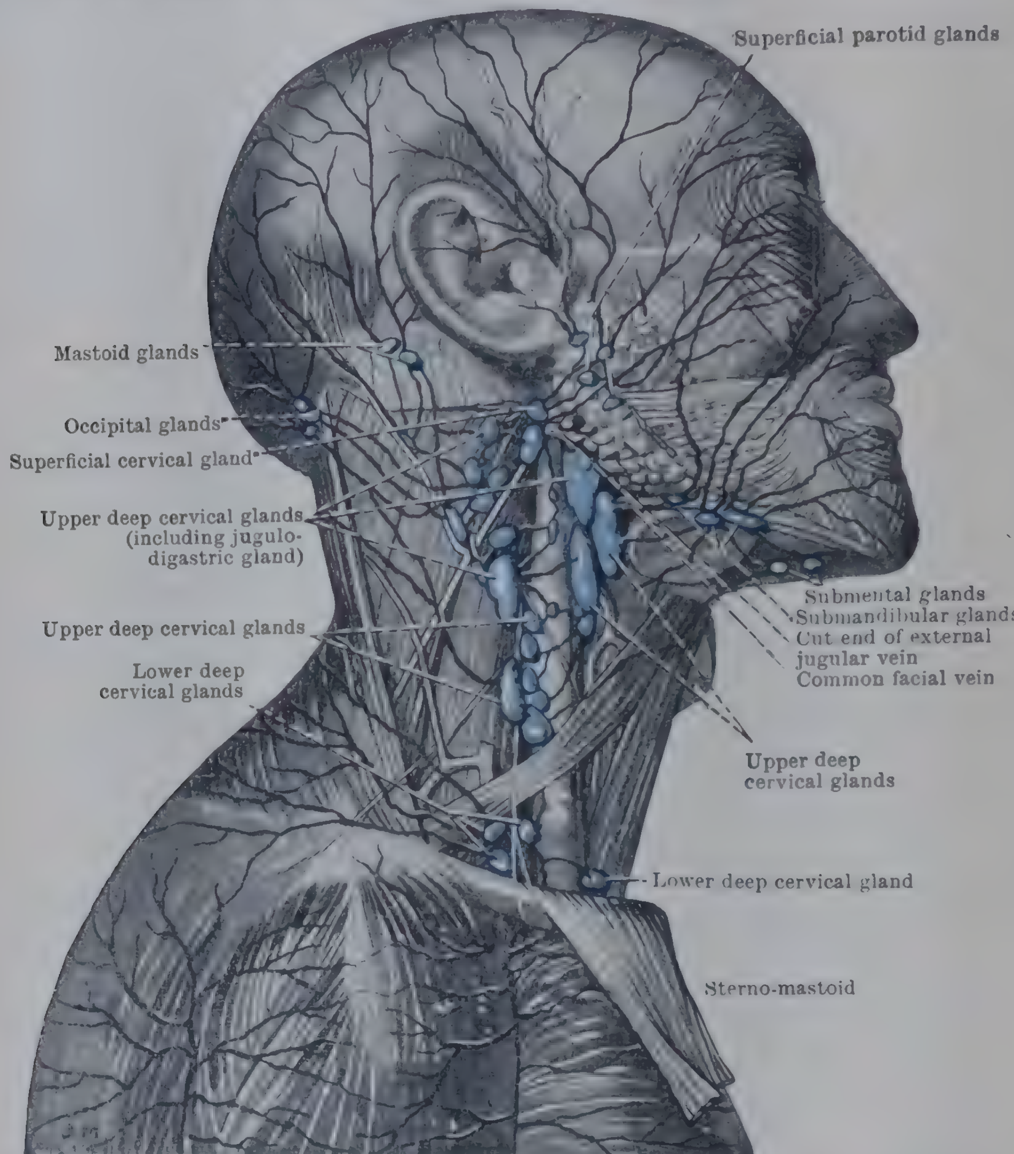

FIG. 1177.—LYMPH-GLANDS OF HEAD AND NECK AS SEEN AFTER REMOVAL OF STERNO-MASTOID MUSCLE. The occipital, mastoid, and superficial parotid glands are inserted in accordance with descriptions. The other glands were present in one or both of the bodies from which the figure was made. Compare Fig. 1175.

lingual glands on the course of some of the lymph-vessels of the tongue; and with the maxillary artery, occasional small glands in the infratemporal region.

The "collar" glands in the course of the facial, superficial temporal, posterior auricular and occipital blood-vessels require particular description.

The **occipital lymph-glands** (1-2) are situated on the occipital vessels as they emerge through the trapezius; their *afferents* come from the scalp, and their *efferents* pierce the deep fascia to join the deep cervical glands.

The **mastoid lymph-glands** (2-3) lie on the mastoid process; the largest is a flat coin-like gland frequently palpable. Their *afferents* come from the scalp and the back of the auricle, and the *efferents* run round the edge of the sterno-mastoid muscle or through it to the deep glands.

The **parotid lymph-glands** are embedded partly in the superficial surface of the

parotid salivary gland under the deep fascia and partly in its substance. The more superficial (pre-auricular) glands receive numerous afferents from the front of the auricle and from the scalp, forehead, eyebrow, eyelids and cheek; and their *efferents* pass to the deeper glands and to the upper deep cervical glands (jugulo-digastric). The deeper parotid lymph-glands receive *afferents* from the external auditory meatus, the pharyngo-tympanic tube and the tympanum, the soft palate, the posterior part of the nasal cavity and the deeper portions of the cheek. Their *efferents* pass to the upper deep cervical glands.

The **superficial cervical lymph-glands** (Fig. 1175) are merely the lower end of the superficial parotid group and may stray some distance down along the external jugular vein; they are small and become conspicuous only when diseased.

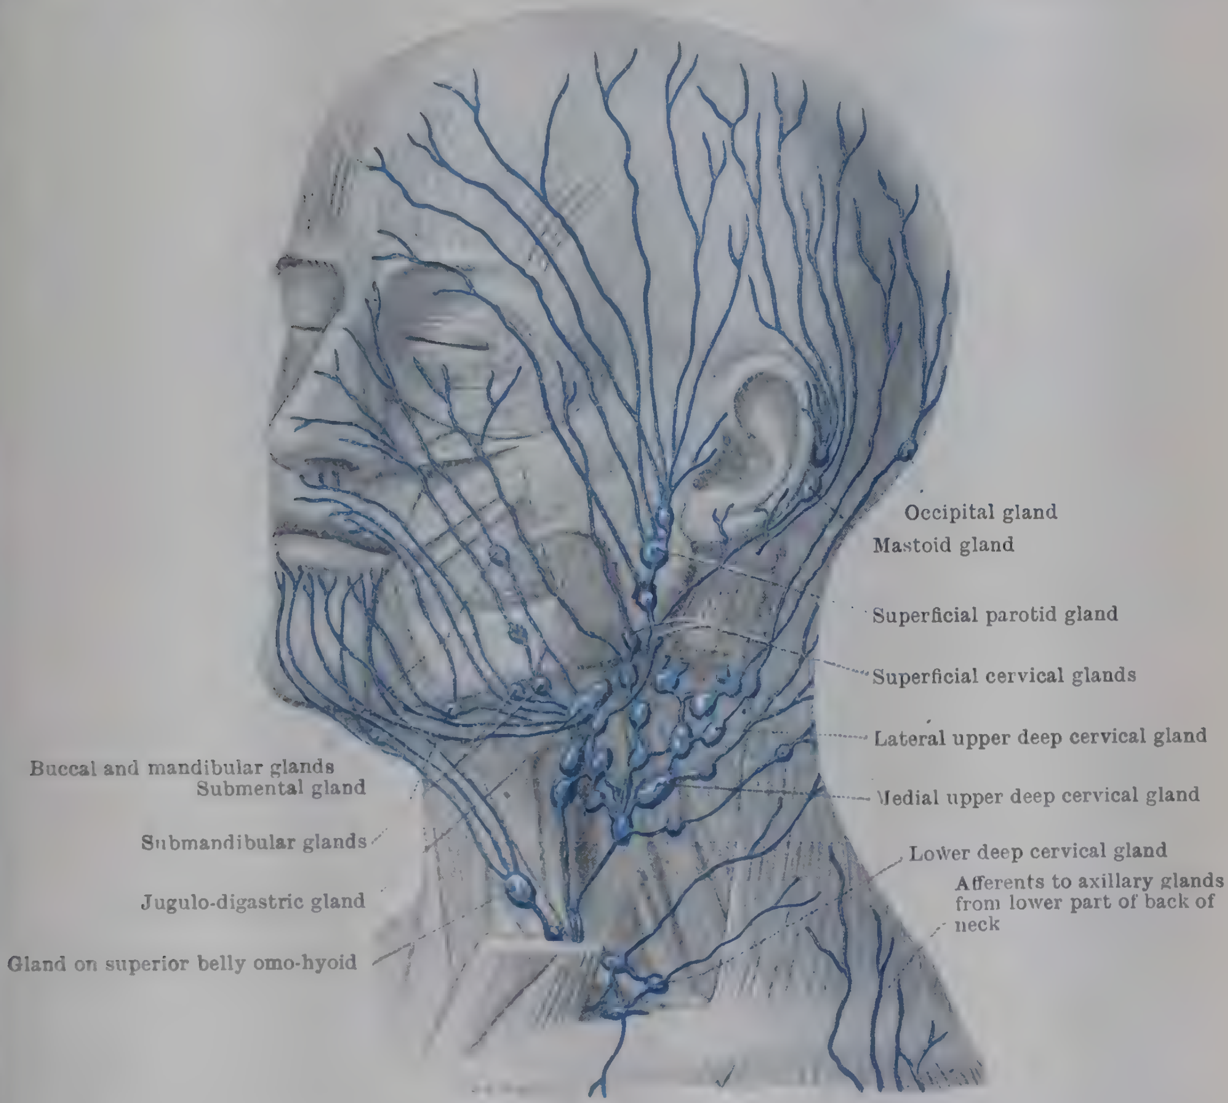

Fig. 1178.—Superficial Lymph-Vessels of Scalp and Face, and Superficial ("Collar") Lymph-Glands between Head and Neck

The **submandibular lymph-glands** (4-6) lie in the chink between the jaw and the submandibular salivary gland; the larger members are in contact with the facial vessels, and one may be placed between the salivary gland and the digastric. They receive the cutaneous vessels of the face below the eye, and many of the vessels of the tongue; the *efferents* run to the deep cervical glands, notably the jugulo-digastric and jugulo-omohyoid.

Minute glands are not infrequently found on the course of the vessels of the face, and may be named *infra-orbital*, *buccal*, and *mandibular* according to their position (Fig. 1178).

The **submental lymph-glands** (1-4) of the two sides form a composite group that lies on the mylo-hyoid muscles midway between the symphysis and the hyoid bone; their *afferents* are derived from the lower lip and chin, mingled with those passing to the submandibular lymph-glands, and from the tip of the tongue; their *efferents* run to the deep cervical glands as far down as the jugulo-omohyoid gland.

Lymph-Vessels of Head and Neck

The **superficial lymph-vessels** of the **scalp** and **forehead** run on the general lines of the occipital, posterior auricular, and superficial temporal blood-vessels to the *occipital, mastoid,* and *parotid* lymph-glands; from the **eyelids** and **cheeks** they pass to the *parotid* and *submandibular* lymph-glands; from the **nose, lips,** and **chin** to the *submandibular* and *submental* glands (Figs. 1175, 1178). These glands constitute the "collar chain" of glands; but it is important to note that it is not a complete barrier; many vessels from all parts of the scalp and face slip past these glands and run into the deep cervical chain (Fig. 1178). The superficial vessels of the **neck** perforate the deep fascia at numerous points to enter the deep cervical glands; a few on the upper part of the back of the neck

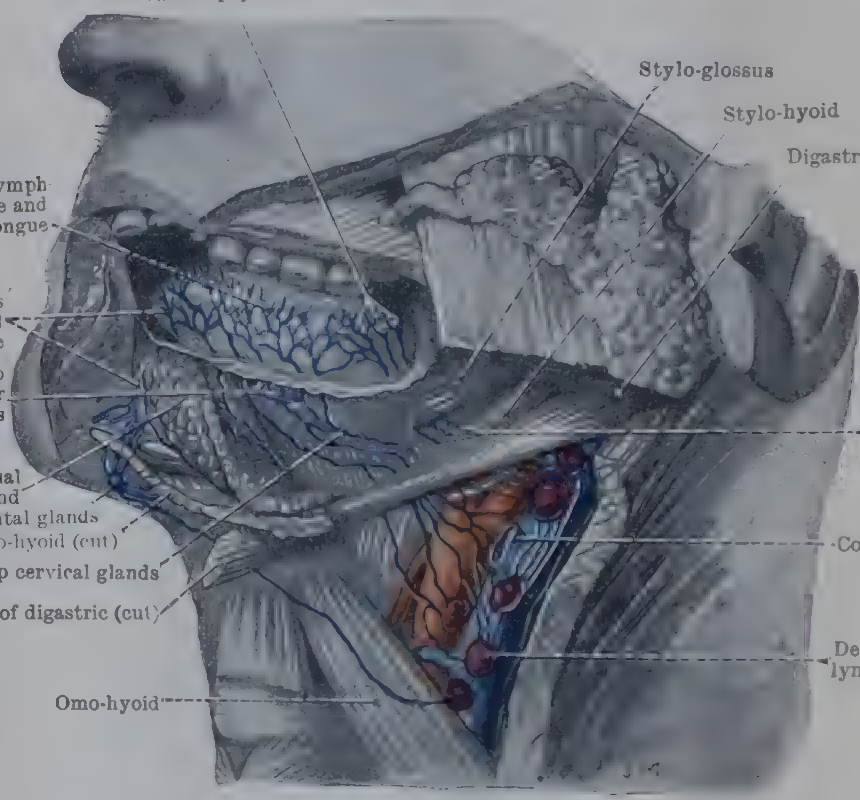

Fig. 1179.—Lymph-Vessels of Tongue.

are interrupted first by a few minute nodules that lie on the trapezius; and those from the lower part of the back of the neck join the stream which runs to the axillary glands around the posterior fold of the axilla.

Lymph-Vessels of Eyelids and Conjunctiva.—These vessels arise from cutaneous and sub-conjunctival plexuses, and form two groups, a medial and a lateral; some run superficial to the orbicularis oculi, and others deep to it. (*a*) The *medial vessels* drain a very small part of the skin only of the upper eyelid, and about one half of the skin and conjunctiva of the lower eyelid; they follow the course of the anterior facial vein to the submandibular lymph-glands, and some of them may be interrupted in the infra-orbital and buccal glands. (*b*) The *lateral vessels* (6-7) drain the greater part of the skin of the upper eyelid and the whole of its conjunctiva, and about one half of the skin and conjunctiva of the lower eyelid. They pass backwards, more or less along the line of the transverse facial vessels, and end in the parotid and superficial cervical lymph-glands. (See also p. 1175 and Burch, 1939.)

Lymph-Vessels of Orbit.—It is doubtful if any true lymph-vessels exist in the **eyeball**. Lymph-spaces have been described in the coats of the eyeball, and lymph-vessels are stated to exist in the choroid coat, but their existence is uncertain.

The lymph-vessels of the **lacrimal gland** run with the lateral palpebral lymph-vessels to the parotid lymph-glands (Orts, 1929). Those of the **lacrimal sac** separate, one running laterally beneath the conjunctiva to pass to a parotid lymph-gland, others joining medial palpebral vessels to reach the submandibular lymph-glands.

Lymph-Vessels of Ear.—The lymph-vessels from the anterior portion of the lateral surface of the upper part of the **auricle** end in the parotid lymph-glands. Those from the lower part of the auricle go to the superficial cervical glands. Those from the medial surface and from the posterior portion of the upper part of the lateral surface of the

auricle end in the mastoid glands, but some of them may establish direct communication with the upper deep cervical glands. The lymph-vessels of the **external auditory meatus** are associated with those of the auricle and end in the parotid and mastoid glands.

The lymph-vessels of the **middle ear** pass in two directions. Those from the lateral wall of the cavity join the vessels of the **tympanic membrane** and of the external auditory meatus and end in the parotid glands. The lymph-vessels which drain the medial wall and the **pharyngo-tympanic tube** end in the retropharyngeal and upper deep cervical glands.

It is doubtful if any lymph-vessels exist in the **internal ear**. It is possible that the perilymph drains into the subarachnoid space of the posterior fossa of the skull along the line of the ductus endolymphaticus, and that the endolymph reaches the subarachnoid space along the fibres of the auditory nerve.

Lymph-Vessels of Nose.—The lymph-vessels from the **external nose** pass mainly to the submandibular lymph-glands, but a vessel from the root of the nose may pass with those of the upper eyelid to a parotid gland. The vessels of the **nasal cavity** arise from a plexus in the muco-periosteum. Those from the anterior part of the cavity accompany the vessels of the lower portion of the external nose and end in the submandibular glands. Those from the posterior part end partly in the medial upper deep cervical glands and partly in the retropharyngeal glands.

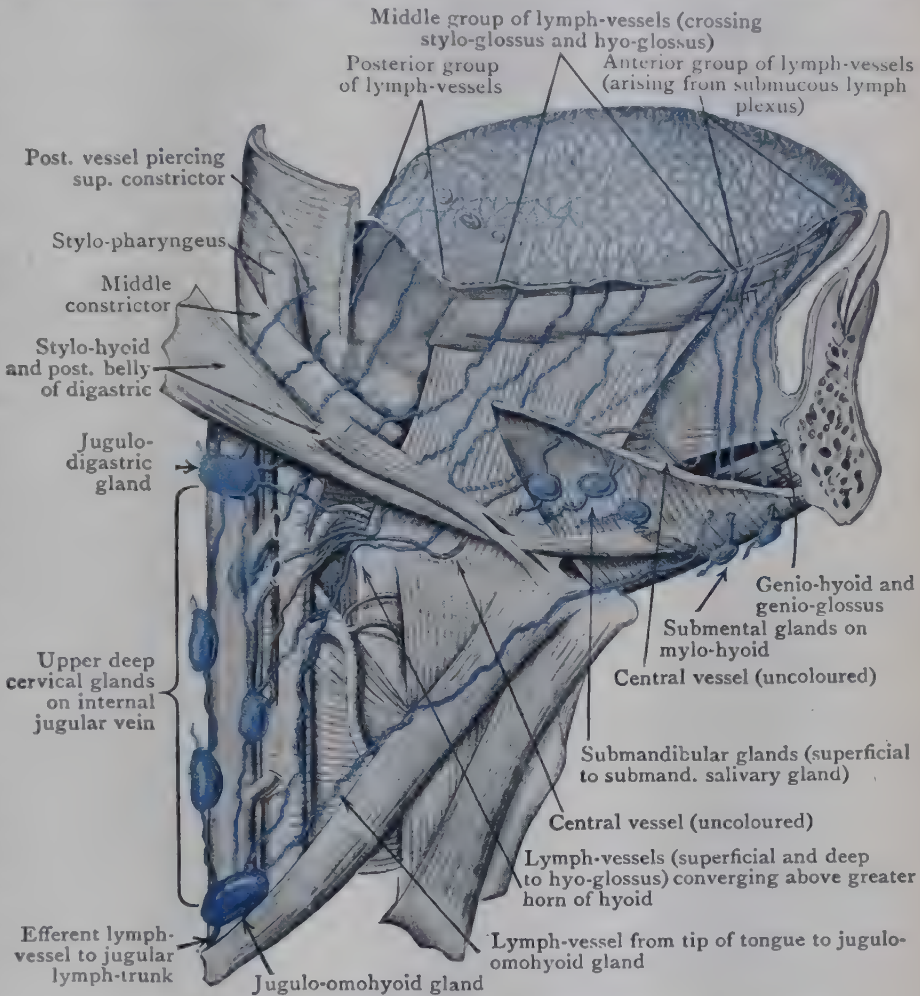

Fig. 1180.—Diagram of Course of Lymph-Vessels of Tongue.

Only one central vessel is shown (uncoloured). Central vessels and one or more of the posterior group may cross the median plane and end in deep cervical glands of the opposite side.

It has been shown by experiment that dyes applied to the nasal mucous membrane appear very rapidly in the cervical glands (Yoffey & Drinker, 1938).

There is little definite knowledge regarding the lymph-vessels of the **paranasal sinuses**, but it is probable that they follow the vessels of the nasal cavities and end in the same glands. Spaces of lymphatic character accompany the olfactory nerves into the cranium.

Lymph-Vessels of Lips.—The lymph-vessels of the lips arise from cutaneous and mucous plexuses. Those from the skin of the medial part of the lower lip pass to the submental glands and often cross the median plane. The cutaneous vessels from the lateral part of the lower lip unite with those from the upper lip and end in the submandibular glands, but some from the upper lip may end in the superficial cervical glands.

The lymph-vessels from the mucous membrane of the lips take the same course and end in the same glands as those of the skin; but they tend to spread more widely. Those of the upper lip, though ending mainly in the submandibular glands, may reach parotid and submental glands; and those from the medial part of the lower lip pass to submandibular as well as to submental lymph-glands.

Lymph-Vessels of Cheeks.—Most of the superficial and deep lymph-vessels of the cheeks pass to the submandibular lymph-glands, but some of them may reach the superficial cervical or the upper deep cervical glands. They may be interrupted in the buccal glands.

Lymph-Vessels of Gums.—The vessels from the outer parts of both mandibular and maxillary gums end in the submandibular glands. Occasionally a vessel from the anterior part of the mandibular gum ends in a submental gland. The vessels from the inner part of the mandibular gum end in the submandibular and upper deep cervical glands; those of the inner part of the maxillary gum run with the vessels of the hard and the soft palate, and end mainly in the upper deep cervical glands.

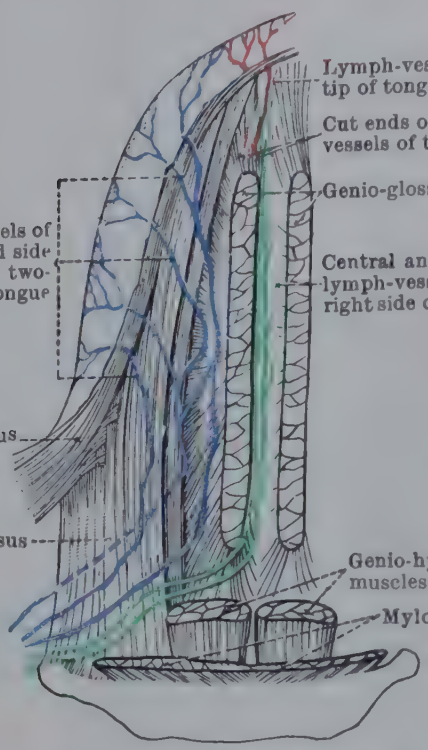

Fig. 1181.—Diagram of Lymph-Vessels of Anterior two-thirds of Tongue, seen from below. (After Poirier & Cunéo, 1902, modified.) Anterior vessels, *red*; middle vessels, *blue*; central vessels, *green*.

Lymph-Vessels of Teeth.—Lymph-vessels have been injected in the pulp of the teeth (Schweitzer, 1907; Noyes & Dewey, 1918). Those of the lower teeth run in the mandibular canal and end in the submandibular or the upper deep cervical glands. Those of the upper teeth emerge from the infra-orbital foramen and pass with vessels of the face to the submandibular glands.

Lymph-Vessels of Palate.—These vessels run backwards to join those of the inner parts of the maxillary gums and end mainly in upper deep cervical glands. But vessels from the palate may occasionally continue backwards to reach the retropharyngeal glands or pass downwards in the cheek to the submandibular glands.

Lymph-Vessels of Tongue.—The lymph-vessels of the tongue arise from a rich capillary plexus in the mucous membrane; and they end in the submental, submandibular and upper deep cervical lymph-glands. The vessels are arranged in four groups—anterior, middle, posterior, and central (Jamieson & Dobson, 1920).

The *anterior vessels* drain the tip and the inferior (free) surface. They pierce the mylo-hyoid muscle and end in the submental lymph-glands—all except one vessel which passes the submental glands, crosses the hyoid bone and ends in the jugulo-omohyoid gland.

The *middle vessels* drain the anterior two-thirds of the dorsum and margins (except the tip). They pass downwards, at different depths, to end in the submandibular and upper deep cervical glands. Those that end in the submandibular glands pass superficial to the sublingual salivary gland and pierce the mylo-hyoid muscle. Others run in a deeper plane, over both surfaces of the hyo-glossus, and end in any of the deep cervical glands between the digastric muscle and the omo-hyoid.

The *posterior vessels*—larger than the others—drain the posterior third of the dorsum. They first run backwards beneath the mucous membrane, and then turn laterally to pierce the wall of the pharynx below the tonsil; they also end in the deep cervical chain—principally in the jugulo-digastric gland.

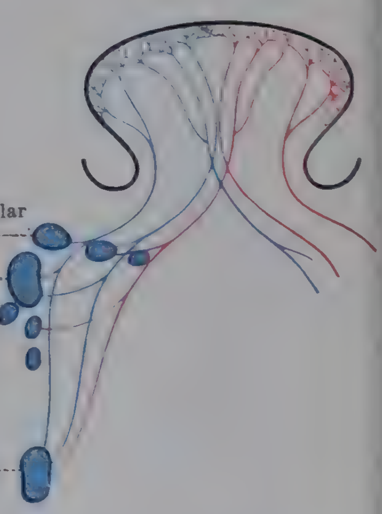

Fig. 1182.—Diagram of course of Central Lymph-Vessels of Tongue to show Crossing of Median Plane. (Jamieson & Dobson, 1920.)

The *central vessels* arise in the dorsal plexus near the median plane. They descend between the genio-glossi, and are joined by vessels from the deep parts of the tongue. They then run laterally and backwards, with the veins of the tongue, and end in upper deep cervical glands below the digastric muscle (Fig. 1181).

It is important to note that any of the upper deep cervical glands below the digastric may receive lymph-vessels direct from the tongue; and that, in general, the farther forward the origin of the vessel the lower down is the gland in which it ends. Note also that some

members of the anterior, posterior, and central groups cross the median plane to end in glands of the opposite side (Fig. 1182).

Lymph-Vessels of Floor of Mouth.—The capillary plexus of the mucous membrane of the tongue is continuous across the floor of the mouth with the plexus of the mandibular gum. The lymph-vessels that arise from that part of the mucous membrane of the mouth run with the anterior, middle and posterior vessels of the tongue to the same lymph-glands —submental, submandibular, and upper deep cervical.

Lymph-Vessels of Salivary Glands.—The lymph-vessels of the **parotid gland** end in the neighbouring parotid lymph-glands. One or two lymph-vessels of the **submandibular gland** end in the submandibular lymph-glands, but most of them go to the upper deep cervical glands. Lymph-vessels from the anterior part of the **sublingual gland** end in the submandibular lymph-glands, and others from the posterior part run to upper deep cervical glands between the digastric and the omo-hyoid muscles.

Lymph-Vessels of Pharynx.—From the nasal part of pharynx, including the **naso-pharyngeal tonsil,** and from the posterior wall and lateral borders of the oral and laryngeal parts, the lymph-stream flows to the median line posteriorly. There the larger vessels pierce the walls of the pharynx; they then turn laterally and end in the retro-pharyngeal and upper deep cervical glands.

From the anterior wall of the laryngeal part of the pharynx, that is, from the region of the piriform fossæ and the posterior surface of the larynx, the lymph-vessels pass along the course of the superior laryngeal artery, pierce the thyro-hyoid membrane, and end in the upper deep cervical glands.

The lymph-vessels of the **tonsil** and the adjacent parts of the palato-glossal and palato-pharyngeal arches pierce the lateral wall of the pharynx and end in upper deep cervical glands immediately below the posterior belly of the digastric—many of them in the jugulo-digastric gland.

Lymph-Vessels of Thyroid Gland.—These vessels arise in the intervesicular tissue of the gland and form a dense subcapsular plexus on its surface (Figs. 694, 695, p. 813), common to both lobes and the isthmus; therefore the lymph can pass from the lobe of one side to the terminal glands of the opposite side. The collecting vessels from the upper part of each lobe and of the isthmus end in the upper deep cervical glands and one of them may pass to a retropharyngeal gland; those from the lower part of the isthmus and of each lobe end in the pretracheal and paratracheal glands and one of them may pass down to an innominate gland; those from the side of each lobe pass to the deep cervical glands. It has been stated that a lymph-vessel from the right lobe occasionally ends directly in the right subclavian vein (Mahorner *et al.*, 1927), and that one from the left lobe may end in the thoracic duct without the intervention of a lymph-gland (Rouvière, 1932).

Lymph-Vessels of Larynx.—The lymph-plexus of the larynx is separable into upper and lower portions; they are connected together on the posterior wall of the cavity, but are separated, laterally and anteriorly, by the vocal folds, which contain only a few fine capillary vessels. The lymph-vessels of the upper part pass mainly along the superior larnygeal artery; they pierce the thyro-hyoid membrane with lymph-vessels of the pharynx, and end in the upper deep cervical glands; some of them may be interrupted in the infrahyoid glands. The efferent vessels from the lower part of the larynx emerge in two groups. Those from the anterior region pierce the crico-thyroid ligament and end in the prelaryngeal, the pretracheal and the deep cervical glands. The efferents from the postero-lateral region pierce the crico-tracheal membrane and end in the paratracheal and lower deep cervical glands (Fig. 1176).

Lymph-Vessels of Cervical Parts of Trachea and Œsophagus.—The collecting vessels of the cervical parts of the trachea and œsophagus end in the paratracheal and the inferior deep cervical glands. From the upper part of the trachea some vessels pass to the prelaryngeal glands also.

DEVELOPMENT OF LYMPHATIC SYSTEM

The lymphatic system is an adjunct of the venous system, sharing its absorbent function and emptying into the great veins in the root of the neck. The main question in the development of lymph-vessels is whether they were originally independent formations which secondarily acquired connexions with the veins, or were derived primarily from the veins as endothelial outgrowths which spread into the body from one or more definite sites.

The first obvious sign of the development of the lymphatic system is the appearance of the structures known as **lymph-sacs** which are closely related to the veins in certain situations. The first of these to appear is the jugular lymph-sac, which is present in the human embryo

of 10-11 mm., and six of them are present in the 30 mm. embryo (Sabin, 1909). Whatever the origin of these sacs, there is agreement about their position and their subsequent history.

An *anterior* or *jugular lymph-sac* is found at the union of the chief vein of the upper limb with the anterior cardinal vein; a *posterior lymph-sac* appears at the union of the chief vein of the lower limb with the posterior cardinal vein; a *retroperitoneal lymph-sac* develops at the root of the primitive mesentery; and another on the posterior wall of the abdomen is identified with the *cisterna chyli*. It may be noted that the anterior and posterior lymph-sacs are developed in the same positions as the "lymph-hearts" of the Amphibia.

Four of the lymph-sacs are thus situated at the junctions of the limbs with the trunk and the other two on the back of the abdomen. All of them—with the exception of the anterior part of the sac from which the cisterna chyli is developed—become broken up into anastomosing channels and converted later into groups of lymph-glands; and the jugular sacs acquire secondary connexions with the veins which remain as the permanent terminations of the lymph-trunks.

According to Sabin (1909, 1912, 1916), the lymph-sacs are developed as outgrowths of the endothelium of the veins near which they appear, and from the sacs all the lymph-vessels of the body sprout—radiating from them to the parts drained by the principal lymph-trunks. Thus, from the jugular sacs vessels spread into the head and neck, the upper limbs and upper part of the trunk; from the posterior sacs they spread into the lower part of the trunk and the lower limbs; and from the retroperitoneal sac at the root of the mesentery they grow towards the intestines, and from the sac which forms the cisterna to other abdominal organs. According to this view, the lymph-sacs lose their primary connexions with the veins, and only later, at the root of the neck, do the jugular sacs acquire connexions again.

According to Huntingdon (1911) and M'Clure (1915), on the other hand, all lymph-vessels are originally formed as clefts in the mesenchyme exactly as blood-vessels are formed (see p. 89). These clefts acquire an endothelial lining and unite into plexuses of capillary vessels. At first they are indistinguishable from developing veins, and indeed contain blood-cells. Later the blood in those vessels destined to become lymph-channels disappears or is discharged into the veins. According to this view, the lymph-sacs are formed by the running together of parts of the capillary plexuses which develop along the primitive venous trunks, the thoracic duct is developed by the formation of channels in these plexuses, and all the peripheral lymph-vessels arise locally by the fusion of mesenchymal spaces. For example, according to Heuer (1909), the deep plexus of the small intestine develops independently and gives rise to the superficial plexus by its growth.

There is a parallel between these two contrasting views and the older conflict on the single or multiple origin of the blood-vessels themselves. Formerly it was maintained (His) that all the blood-vessels of the embryo grow into it from those primarily developed in the wall of the yolk-sac; but it is now agreed that blood-vascular channels arise from the mesenchyme not only on the yolk-sac, in the body-stalk and in the chorion, but in exactly the same manner in the body of the embryo also, where they run together to form anastomosing channels from which the primitive blood-vessels take form. The essential feature of Huntington and M'Clure's view of the origin of lymph-vessels is the belief that endothelium may be formed directly from mesenchyme anywhere; and since that is true in the case of blood-vascular channels, it is difficult to deny that lymph-vascular channels also may arise independently in the mesenchyme. The technique of the investigation of these questions is admittedly difficult, but it may be that the chief difficulty is in the interpretation of results. The injection methods on which Sabin relied certainly appear to show that lymph-vessels radiate from the lymph-sacs; but they demonstrate only those vessels that are in communication with the sacs; they do not prove that there are no developing lymph-channels farther afield that have not yet acquired their central connexions. It is true that endothelium grows, so that capillary plexuses may sprout; but it is probable that the apparent spread of lymph-vessels from centres is due to progressive fusion rather than to peripheral outgrowth.

Lymph-Glands.—Lymph-glands are developed by the aggregation of lymphocytes in the mesenchymal strands of plexuses of lymph-vessels. As the lymphocytes accumulate they form a nodule of lymphoid tissue, and the vessels around it are transformed into the peripheral portion of the lymph-sinus. The lymphoid tissue is then broken up into cords by anastomosing lymph-channels which grow into it from the sinus, mainly on the side of the efferent vessels. The capsule is formed by condensation of areolar tissue on the surface of the peripheral sinus, and the trabeculæ of the larger glands grow inwards from it.

The great majority of lymph-glands are developed in central positions, and those that form in relation to peripheral lymph-vessels are smaller and often rudimentary. Groups of numerous glands develop in the plexuses formed by the breaking up of the lymph-sacs, including the lower part of the cisterna chyli from which cœliac and aortic glands are thus derived.

In early stages of development lymph-glands possess blood-vascular as well as lymph-capillary networks, and if the blood-vascular network preponderates over the lymph-vascular, the developing gland has a reddish appearance and is known as a hæmal gland. Such glands are found in Man as well as in other mammals, and it would appear, from the observations of Vincent & Harrison (1897), that hæmal glands are merely rudimentary forms of true lymph-glands.

Thoracic Duct.—A rich plexus of lymph-vessels is formed in the thorax around the aorta but principally behind and at its sides. The plexus, whether developed *in situ* or as anastomosing outgrowths from the sacs, communicates below with the lymph-sac that forms the *cisterna chyli*

and above with both jugular lymph-sacs. From the plexus two longitudinal vessels, with numerous transverse anastomoses, are developed. Each of these vessels may persist and terminate above in the innominate vein of its own side, and there are then two thoracic ducts. Usually the continuity of each vessel is broken at the level of the fifth thoracic vertebra, where one of the transverse anastomoses enlarges. The lower part of the left vessel and the upper part of the right disappear. The component parts of the thoracic duct are, therefore, the lower part of the right longitudinal vessel, the upper part of the left longitudinal vessel, and a transverse anastomosis between them. Its origin from the cisterna chyli may remain plexiform or double.

It is obvious that from the primitive condition many varieties of the thoracic duct might be evolved and the majority of the various possible variations have been found in adult bodies (Davis, 1915).

SURFACE AND SURGICAL ANATOMY

by SIR JAMES LEARMONTH, *K.C.V.O.*, *C.B.E.*, M.B., Ch.M., M.D.(Oslo), F.R.C.S.Ed., Hon.F.R.C.S.Eng., Hon. F.A.C.S., LL.D., F.R.S.E.

Professor of Surgery and Regius Professor of Clinical Surgery, University of Edinburgh

With an Appendix on RADIOGRAPHIC ANATOMY

by ROBERT McWHIRTER, M.B., Ch.B., F.R.C.S.Ed., D.M.R.E.(Camb.), F.F.R., F.R.S.E.

Professor of Medical Radiology, University of Edinburgh

SURFACE Anatomy and Surgical Anatomy are associated studies which occupy an important and significant place in the medical curriculum, as they are an expression of the application of anatomical knowledge to the everyday practice of Medicine and Surgery. Their inclusion in a text-book of Anatomy is therefore fully justified; and it may serve to remind students of the importance of that study of the living body which has been mentioned in the General Intorduction as their chief aim (p. 2).

Surface Anatomy fulfils a twin-purpose; it is a description of the topography of the body-surface as influenced by the conformation of superficial structures (including skeletal landmarks), combined with a surface-orientation of related structures that lie at a deeper level. It is therefore the essential basis for the primary physical examination of a patient and for the appreciation of the significance of the symptoms and signs of disease in general.

Surgical Anatomy is directed towards a more special purpose. It is a presentation of the anatomical facts which have a local significance in relation to injury and particular diseases or to the surgical interference which these may entail.

The use of X-rays is of the greatest value in the study of both these practical aspects of Anatomy. Frequent reference is therefore made to radiographic observations and to the Plates which illustrate them—supplementing the relevant paragraphs throughout the text-book; and, since the interpretation of radiographs requires some elementary acquaintance with the methods employed in their production and some knowledge of the meaning of the appearances which they present, an Appendix has been added on the Principles of Radiography and of Radiographic Anatomy.

The Section itself is arranged on a regional basis.

HEAD AND NECK

CRANIUM

Scalp.—The first and third layers of the scalp, namely, the **skin** and the **occipito-frontalis muscle**, are firmly united by fibrous processes which pass from the one to the other through the second or subcutaneous **fatty layer**. These three layers are separated from the pericranium by a **layer of loose areolar tissue** which supports the small vessels passing between the scalp proper and pericranium. The **pericranium**, although regarded anatomically as periosteum, possesses limited bone-forming properties; over the vertex it can be readily separated from the skull-cap

except along the lines of the sutures, where it is united by sutural ligaments to the external layer of the dura mater.

The free **blood-supply of the scalp** nourishes its abundant hair-follicles and glands. The main vessels lie in the dense subcutaneous tissue, and are therefore superficial to the occipito-frontalis muscle (Fig. 1183). The arteries that supply the frontal region are derived from the internal carotid, and those for the remainder of the scalp spring from the external carotid. The two groups of vessels anastomose with one another, and also with those of the opposite side—hence it is impossible to control bleeding from one side of the scalp by ligature of the corresponding external carotid artery.

Wounds of the scalp bleed freely, and the vessels are difficult to ligature on account of the fixation of their walls to the dense subcutaneous tissue. In extensive flap-wounds and in

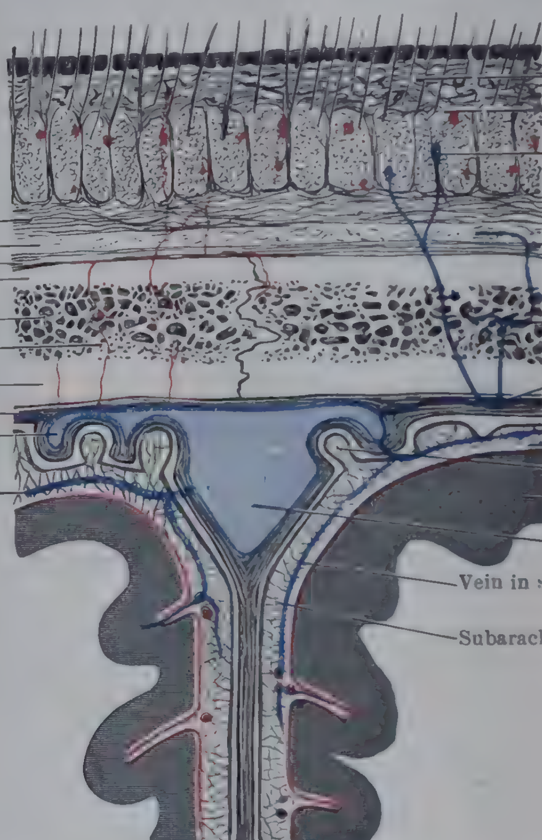

FIG. 1183.—DIAGRAMMATIC REPRESENTATION OF CORONAL SECTION THROUGH SCALP, CRANIUM, MENINGES, AND CEREBRAL CORTEX.

diffuse suppuration deep to the occipito-frontalis muscle there is little danger of sloughing of the scalp. **Abscesses** and **hæmorrhages** superficial to the occipito-frontalis muscle are usually limited on account of the density of the subcutaneous tissue. Hæmorrhage deep to the occipito-frontalis muscle is seldom extensive on account of the small size of the vessels, but suppuration in that situation may rapidly undermine the whole muscle and its aponeurosis—the epicranial aponeurosis. The area under cover of the occipito-frontalis is sometimes termed "the dangerous area", and in cases of extensive infection the swelling may extend from the superior nuchal lines to the superciliary arches, and from one zygomatic arch to the other. Incisions to evacuate the pus are made early, parallel to the main vessels of the scalp (Fig. 1076) and at a level which will ensure dependent drainage. Extravasation of blood deep to the pericranium leads to a hæmatoma which is limited by the sutures (cephalhæmatoma).

The **veins** of the scalp communicate with the intracranial venous sinuses: (1) directly through their anastomoses with the large emissary veins—the parietal, which open into the superior sagittal sinus, and the mastoid and condylar, which open into the sigmoid sinus; (2) through the anastomoses of the supra-trochlear and supra-orbital veins with the ophthalmic vein, which opens into the cavernous sinus; (3) through the veins of the diplöe, which connect the veins of the scalp and the pericranium with those of the dura mater and the venous sinuses; (4) through small veins which pass from the pericranium through the bones and the sutural ligaments to the dura mater. It is along these various channels that pyogenic infection may extend from the scalp and pericranium, through the bone, to

the dura mater and venous sinuses, and from the sinuses to the cerebral veins, the pia-arachnoid, and the substance of the brain. More rarely infection spreads from the skull or from the cranial cavity along the emissary veins to the scalp.

The **lymph-vessels** of the anterior part of the scalp join the facial lymph-vessels; those of the temporal and parietal regions end in the parotid lymph-glands, situated in front of and below the ear, and in the mastoid glands on the insertion of the sterno-mastoid muscle. The lymph-vessels of the occipital region end in the occipital glands, which lie close to the occipital artery and the greater occipital nerve after they have pierced the origin of the trapezius (Figs. 1177, 1178).

Bony Landmarks of Cranium (Fig. 1184).—At the root of the nose there is the fronto-nasal suture, the mid-point of which is the **nasion**; and immediately above is the **glabella**—a slight prominence which connects the superciliary arches. About 2·5 cm. below the posterior pole of the cranium, and 5 cm. above the spine of the axis vertebra, is the external occipital protuberance (the centre of which is the **inion**). In the child this protuberance is not developed; but its position is identified as a point at the junction of the upper and middle thirds of a line drawn from the posterior pole of the skull to the spine of the axis vertebra.

About a third of the distance from the nasion to the inion is the **bregma** or junction of the coronal and sagittal sutures; with the head in the natural erect posture the bregma is at, or close to, the middle of a line carried across the vertex from one tragus to the other. At birth the position of the bregma is occupied by the **anterior fontanelle**—a rhomboidal membranous area which is usually completely ossified towards the end of the second year. The size and date of closure of the fontanelle, as well as its tension and pulsation, are points to be carefully noted in the clinical examination of children (Fig. 174, p. 208, and Pl. V, p. 150).

The **lambda**, or junction of the sagittal and lambdoid sutures, situated 6·5 cm. above the inion, can generally be felt through the scalp as a slight depression; a line drawn from it to the **asterion**—the articulation of the postero-inferior angle of the parietal bone with the temporal and occipital bones—corresponds to the **lambdoid suture**.

The **parietal eminence**, which varies considerably in the definiteness with which it can be recognized, overlies the **termination of the posterior ramus** of the **lateral sulcus** of the cerebrum. The **frontal eminence** (better marked in the child) overlies **the middle frontal gyrus**.

Crossing the supra-orbital margin, a finger's breadth from the median line, are the **supratrochlear nerve** and **vessels**; the artery nourishes the flap in the operation of rhinoplasty. On the supra-orbital margin, two finger-breadths from the median line, is the **supra-orbital notch** or **foramen**—the guide to the **supra-orbital nerve** and **vessels**. A little above the level of the lateral angle of the eye is the **fronto-zygomatic suture**, immediately above which is the **zygomatic process** of the frontal bone. At the posterior end of the suture, the **zygomatico-temporal nerve** pierces the temporal fascia to reach the skin; and 1·3 cm. above the suture is the **lower margin** of the **cerebral hemisphere**. The **temporal line** marks the upper limit of the temporal muscle. It begins at the zygomatic process of the frontal bone, arches upwards between the temple and the forehead; then, curving backwards, it skirts the lower part of the parietal eminence, and, finally, turning downwards, it joins the supramastoid crest near the top of the root of the auricle; the anterior part of the line is the only part easily felt. The **supramastoid crest** curves upwards and backwards from the external auditory meatus for 2·5 cm., but it is obscured by the auricle.

The **zygomatic arch**, an important landmark, is horizontal when the head is in the natural position, and it is at the same level as the inferior margin of the orbit and the inion; its upper border is at, or not infrequently a little above, the level of the infero-lateral margin of the cerebral hemisphere. The upper border of the zygoma may be traced backwards immediately above the tragus and the external auditory meatus to become continuous with the supramastoid crest. The **superficial temporal vessels** and the **auriculo-temporal nerve** cross the zygoma immediately in front of the tragus. The termination of the auriculo-temporal nerve in the neighbour-

conditions at the external auditory meatus—the meatus being in part supplied by that nerve.

Five centimetres vertically above the middle of the zygomatic arch is the **pterion.** This is a point which cannot be felt, but is nevertheless of topographical importance, as it overlies the point where the lateral sulcus of the cerebrum breaks up into its three rami and the point where the **anterior branch** of the **middle meningeal artery** is most deeply embedded in the bone.

Fractures of Skull.—The thickness of the skull-cap varies at different parts and in different subjects. The inner table is only half the thickness of the outer table, but both possess the same degree of elasticity. When the vault is fractured from direct violence, the inner table is more extensively fissured than the outer table, the reason being that the force having passed through the outer table shows a wider distribution in respect of the inner table. The weak areas at the base of the skull through which fractures are liable to extend are:—(1) In the anterior cranial fossa—the orbital plates of the frontal bone, and the cribriform plate of the ethmoid. (2) In the middle cranial fossa—the region of the articular fossa and of the foramen ovale. (3) In the posterior fossa—the fossæ of the occipital bone. The petrous part of the temporal bone, though strong, is weakened by the tympanic cavity and by the jugular fossa.

Cranio-Cerebral Topography.—While there are methods by which cranio-cerebral topography is indicated in considerable detail, it is better to employ a scheme by which the primary sulci of the brain may be outlined on the skull. It should be pointed out that the position of the cerebral landmarks may vary within normal limits, and that when pathological cerebral conditions are present they are usually displaced. The lines which are used to indicate their position are only approximate, though they are sufficiently reliable for clinical and operative purposes. The following scheme is recommended (Figs. 1185, 1186). **A base-line** is drawn from the lower margin of the orbit backwards through the upper border of the external auditory meatus to the occipital region; the cerebrum lies entirely above the level of this line, while the greater part of the cerebellum occupies a position below the level of the posterior third of the line.

Primary Sulci.—The position of the **central sulcus** is now outlined by a line which begins 1·3 cm. behind the mid-point of a sagittal line passing from the nasion to the inion and extends downwards and forwards to the mid-point of the posterior ramus of the lateral sulcus.

The stem of the **lateral sulcus** reaches the lateral surface of the cerebrum opposite the *pterion.* It divides there into three rami; the **anterior two rami** are short, and pass forwards and upwards, diverging from each other; the **posterior ramus** is the most important part of the sulcus. It is indicated by a line that begins at the pterion, is drawn backwards and slightly upwards to a point below the parietal eminence, and is curved sharply upwards to end at that eminence.

The upper end of the **parieto-occipital sulcus** is 1·3 cm. or less above the lambda in the adult, and a line drawn laterally from this point for a distance of 2·5 cm. indicates the position of the part of the sulcus which appears on the supero-lateral surface of the cerebral hemisphere.

Lobes.—By means of the lines for these sulci, the position of the lobes can be gauged roughly. The **frontal lobe** is the part in front of the central sulcus; the **temporal lobe** is below the posterior ramus of the lateral sulcus and extends from the margin of the orbit to the lower half of a line from the parieto-occipital sulcus to the back of the root of the auricle. The **occipital lobe** is behind that line; the **parietal lobe** is between the central sulcus and the upper half of that line (Fig. 1186).

Gyri and Secondary Sulci.—Each lobe is divided into gyri by secondary sulci. In the frontal lobe the **pre-central sulcus** runs parallel to the central sulcus 1·5 cm. in front of it, cutting off the **pre-central gyrus.** The remainder of the frontal lobe is divided into the *superior*, *middle*, and *inferior frontal gyri* by two sulci—*superior* and *inferior frontal.* The lower part of the inferior frontal gyrus is divided into three portions by the anterior rami of the lateral sulcus. These three portions, together with the lower part of the pre-central gyrus, comprise the **motor speech-centre**, which is developed on the left side of the brain in right-handed people.

In the parietal lobe the **post-central sulcus** is 1·5 cm. behind and parallel to the

central sulcus, and delimits the **post-central gyrus**. The *intra-parietal sulcus* runs backwards from the post-central sulcus, and divides the rest of the lobe into two parts named the *superior* and *inferior parietal lobules*. The inferior lobule is divided into three parts that surround the upturned ends of the lateral sulcus and the temporal sulci. These parts contain centres for the interpretation of printed and written words ; and it should be noted that the anterior part underlies the parietal eminence of the skull.

The **motor area** for individual movements occupies the anterior wall of the

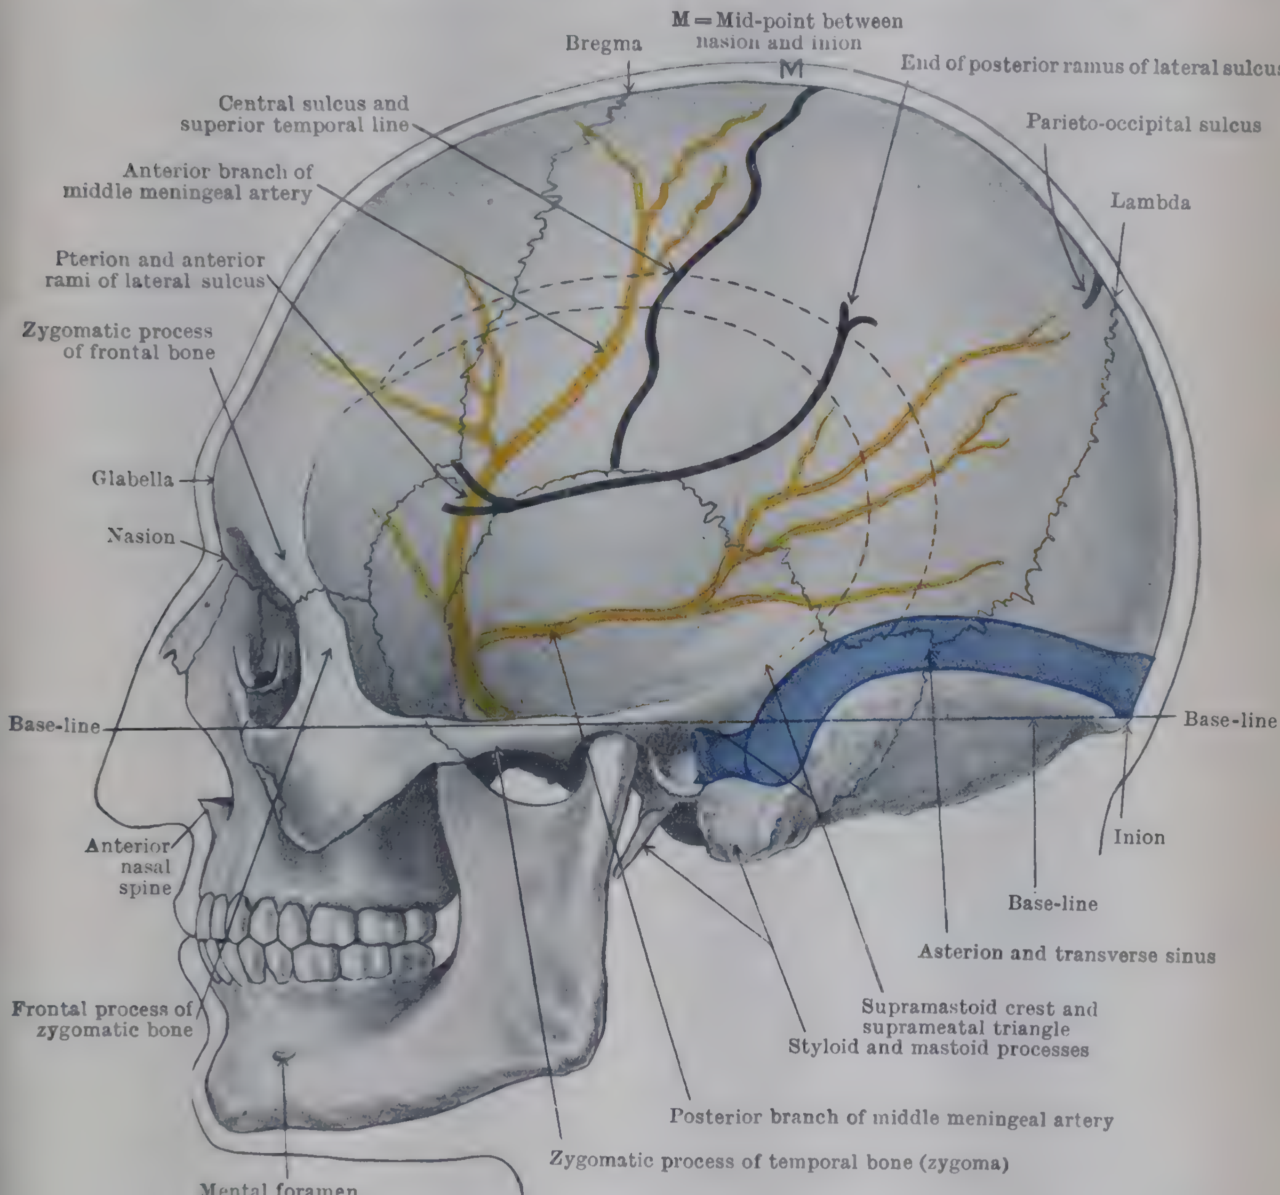

FIG. 1184.—CRANIO-CEREBRAL TOPOGRAPHY I : Landmarks of Skull ; Chief Sulci of Cerebrum ; Transverse and Sigmoid Venous Sinuses ; Middle Meningeal Artery.

central sulcus and the adjoining free surface of the pre-central gyrus ; it also extends into the paracentral lobule on the medial surface. The body is inverted in this area, and the relative position of the parts as represented in the cortex is shown in Fig. 1186. The **sensory area**—that is the centre for the reception of common sensation—is in the posterior wall of the central sulcus and the adjoining free surface of the post-central gyrus ; in it also the body is inverted.

The lateral surface of the temporal lobe is divided into *superior*, *middle*, and *inferior temporal gyri* by the *superior* and *inferior temporal sulci*, which are parallel to the posterior ramus of the lateral sulcus. The **auditory area**—that is, the centre for the mere reception of sound—is in the middle of the superior tmeporal gyrus.

The arrangement of sulci and gyri in the lateral surface of the occipital lobe

of light—is on the medial surface of the lobe in relation to the calcarine and post-calcarine sulci, but in some hemispheres the post-calcarine sulcus extends on to the supero-lateral surface, carrying a portion of the centre for sight with it. This portion is immediately above the external occipital protuberance.

Lateral Ventricle.—The central part of the lateral ventricle occupies a level between the posterior ramus of the lateral sulcus and the middle part of the

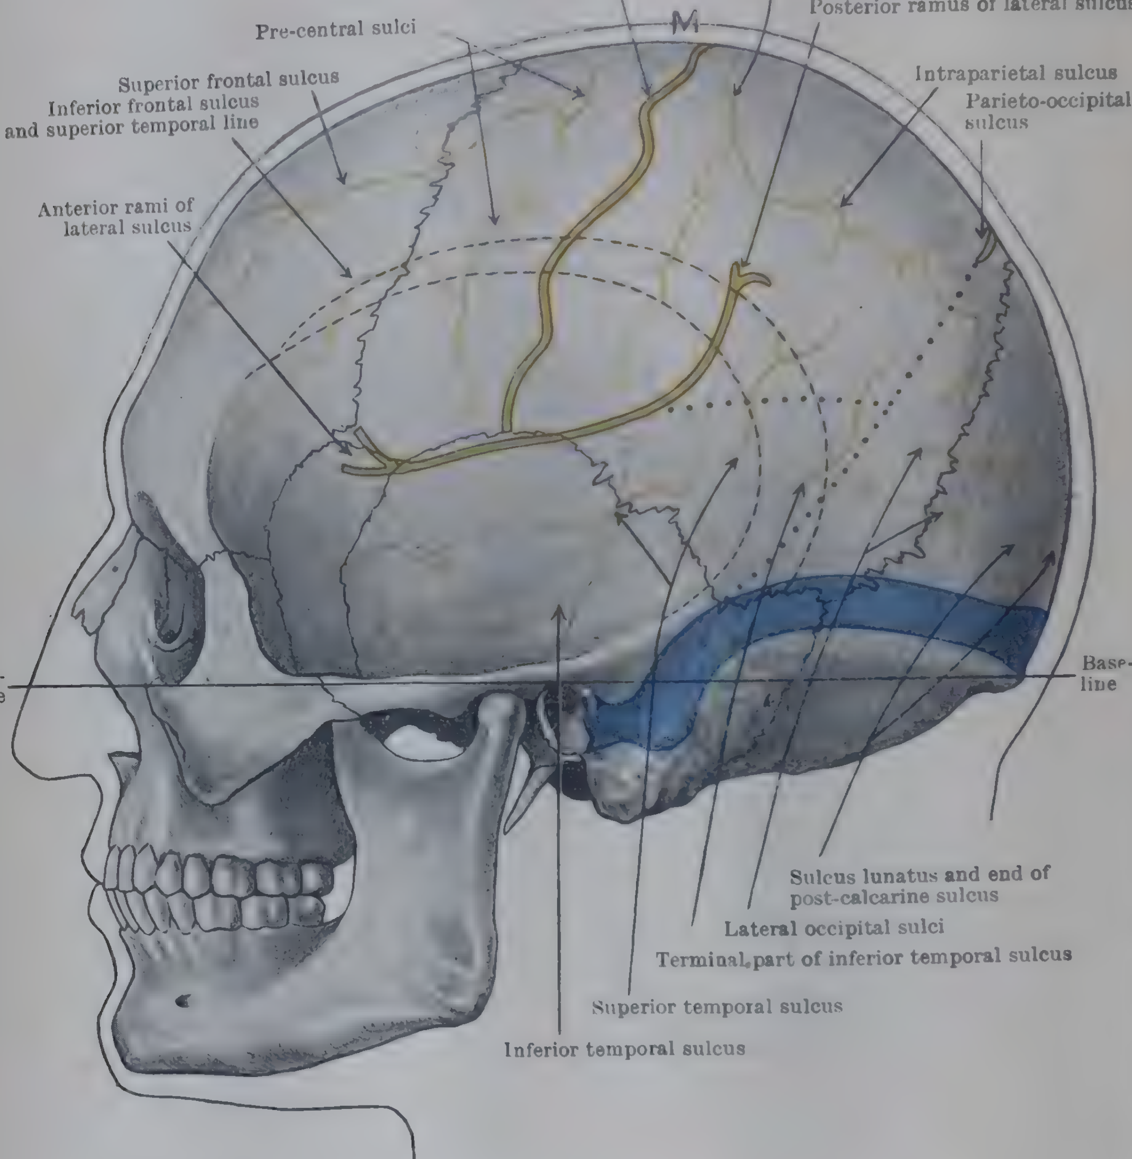

FIG. 1185.—CRANIO-CEREBRAL TOPOGRAPHY II: Venous Sinuses (blue); Chief Sulci (thick yellow); Secondary Sulci (thin yellow); Artificial Boundaries between Lobes (dotted lines); Temporal Lines (curved lines of dashes).

temporal line. The anterior horn of the ventricle is immediately above the level of the pterion; the posterior horn is opposite the posterior part of the temporal line but is very variable both in length and width; the inferior horn corresponds to the middle temporal gyrus.

The lateral ventricles may be tapped or drained after holes have been drilled 9 cm. anterior to the inion and 4 cm. from the midline. Cannulæ are inserted anteriorly, slightly downwards and parallel to the sagittal plane; they enter the ventricles at the junction of body and posterior horn, at a depth of 7-8 cm. from the skin (Dott, 1928). The procedure of *ventriculography* is carried out by positioning the head so that cerebro-spinal fluid escapes through the lower of the two cannulæ, while a corresponding volume of oxygen or air is introduced through the upper. When replacement is complete, stereoscopic radiographs are taken in various planes. The ventricles are outlined by the oxygen, and changes in their size and shape may be used to identify the site of a pathological process (p. 1557, Pl. LXXIV, p. 945 and Pls. LXXV, LXXVI p. 960).

The **cerebello-medullary** cistern is situated between the under surface of the cerebellum and the medulla oblongata; it may be tapped by suboccipital puncture—the needle passing through

the posterior atlanto-occipital membrane. The needle is inserted close to the median line immediately above the atlas vertebra, and its direction is from the point of insertion towards the nasion.

To expose both hemispheres of the cerebellum, two flaps are reflected by a "cross-bow" incision. The curved, horizontal limb is made a little above and parallel to the superior nuchal lines, and, if possible, the ends of the incision should not reach the mastoid emissary vein (a finger's breadth behind the root of the auricle at the level of the meatus), for it may give rise to

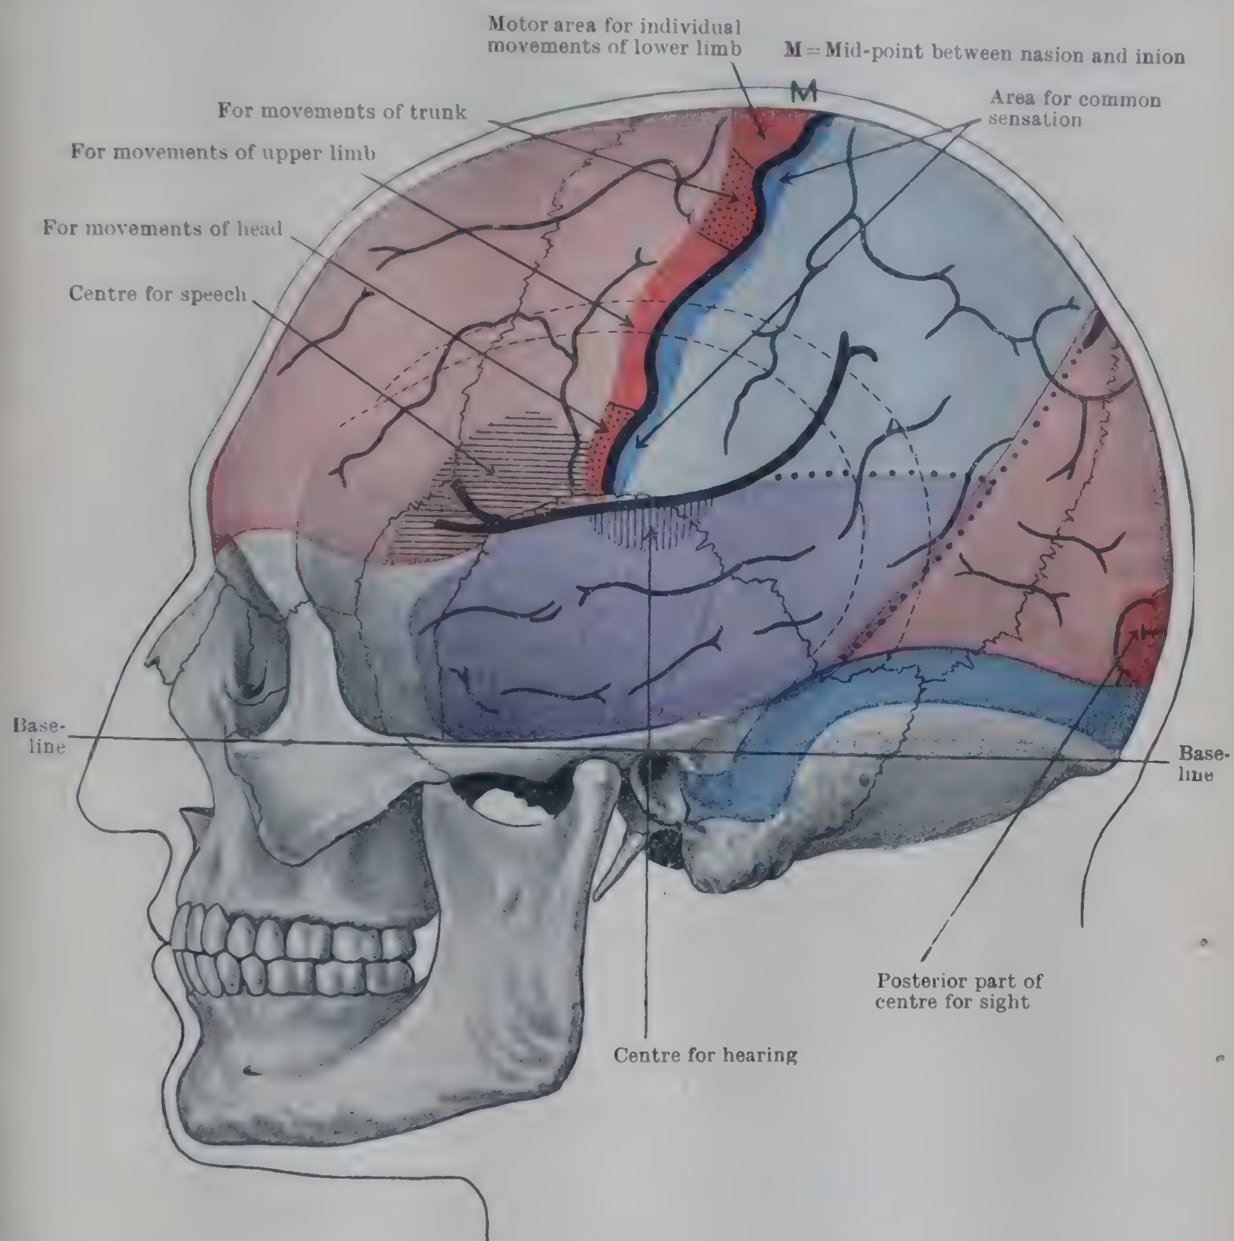

FIG. 1186.—CRANIO-CEREBRAL TOPOGRAPHY III: Lobes of Cerebrum; Motor and Sensory Areas; Centres for Speech, Hearing, and Sight. *Frontal* and *occipital* lobes (red); *parietal* lobe (blue); *temporal* lobe (purple).

troublesome bleeding. The occipital arteries (2·5 cm. lateral to the inion) are divided. The vertical limb of the incision descends in the median line to the level of the spine of the axis vertebra. The occipital sinus is divided between two ligatures. After division of the dura, either hemisphere of the cerebellum may be displaced towards the median plane to expose a tumour of the auditory nerve, which occupies the angle between the cerebellum and the pons.

Meningeal Arteries.—When the calvaria is removed the **meningeal arteries** remain attached to the dura mater, for they are in its outer layer. Of these vessels the middle meningeal artery is the only one of surgical importance. It may be lacerated in fractures of the skull; the blood is generally extravasated between the dura and the bone, and the bleeding point is deep to the clot. After entering the cranial cavity through the foramen spinosum, the *main trunk* runs laterally and slightly forwards to divide into anterior and posterior branches at or a little above the level of the zygomatic arch, midway between the orbit and the auditory meatus (Fig. 1184).

convexity) to the pterion and then upwards and backwards towards the mid-point between the nasion and the inion, giving off branches on its way. Its main trunk is opposite and parallel to the motor area and is therefore encountered in operations on that part (Pl. VII, p. 154).

The *posterior branch* passes backwards and upwards towards the lambda.

To expose the *trunk* of the vessel and its bifurcation, bone is removed immediately above the middle of the zygomatic arch. At the pterion, the artery frequently runs in a canal for a distance of 1·5 cm., and during the removal of bone bleeding may occur from the artery as it lies in the canal. The trunk of the vessel may be traced proximally to the foramen spinosum, where it is secured.

Venous Sinuses of Dura Mater.—The **superior sagittal sinus**, which enlarges as it extends backwards, occupies the median plane of the vertex from the glabella to the internal occipital protuberance, where it becomes continuous usually with the right transverse sinus. Opening into the sinus, especially in the posterior part of the parietal region, are the **lacunæ**, into which arachnoid villi and granulations project.

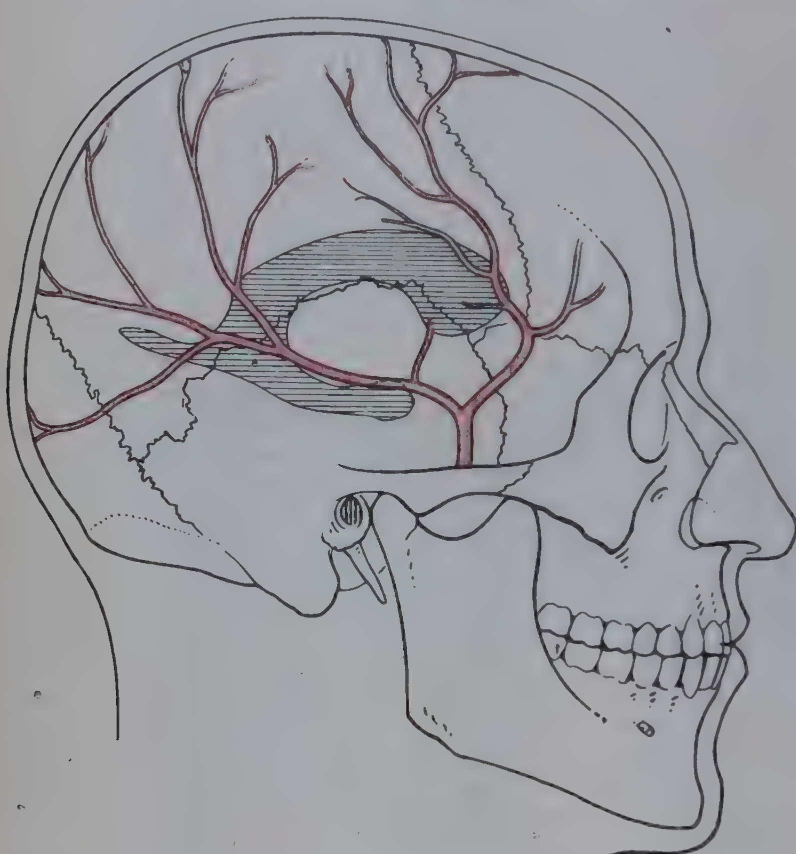

Fig. 1187.—Topography of Normal Lateral Ventricle and Middle Meningeal Artery. (Fraser & Dott, 1922.) See also Pls. VII, p. 154, LXXIV, p. 945 and LXXV, p. 960.

The **transverse sinus** may be mapped out on the surface by a line, slightly convex upwards, *drawn* from a point a little above the inion to the upper part of the back of the root of the auricle. The **sigmoid sinus** is indicated by a line which begins at this point and is drawn downwards along the back of the root of the auricle to the level of the lower margin of the meatus, and then forwards to the margin of the meatus, which is opposite the jugular foramen. In wounds of the sinus the hæmorrhage is very free, owing to the inability of its walls to collapse.

Cerebral Arteries.—Of the **cerebral arteries**, the *middle* supplies almost the whole of the motor area, and one of its striate branches, which enter the brain at the anterior perforated substance, is called "*the artery of cerebral hæmorrhage*" from the frequency of its rupture in apoplexy. The extravasated blood involves the motor part of the internal capsule. The postero-medial central branches of the *posterior cerebral* artery, which enter the brain at the posterior perforated substance, supply the thalamus and walls of the third ventricle; hæmorrhage from one of those branches is apt to rupture into the ventricle. The postero-lateral central branches of the posterior cerebral artery supply the thalamus, and when one of these vessels ruptures the hæmorrhage is apt to invade the posterior part of the internal capsule, where the fibres for *sight* and *hearing* are situated. (For radiography of the cerebral arteries during life, see Pl. LXXX, p. 1217.)

Trigeminal Ganglion.—The topography of the trigeminal ganglion is important in relation to the operation of division of its sensory root for the relief of

trigeminal neuralgia. The ganglion is situated between the layers of the dura mater in the middle cranial fossa, at the apex of the petrous portion of the temporal bone.

The surgeon reaches it by an extradural route through an opening immediately above the zygomatic arch. The bone is removed down to the level of the infratemporal crest, which forms the boundary line between the lateral wall and floor of the middle cranial fossa. The dura mater is elevated from the floor of the fossa so as to admit of the ligature of the middle meningeal artery immediately after its entrance through the foramen spinosum. The dura mater is separated from the bone still farther in a medial and backward direction till the mandibular nerve is reached. The sheath of the nerve is then incised horizontally, and the upper surface of the ganglion is exposed. The sensory root passes backwards from the ganglion, and is enclosed in a tube of arachnoid mater. The arachnoid is incised posterior to the

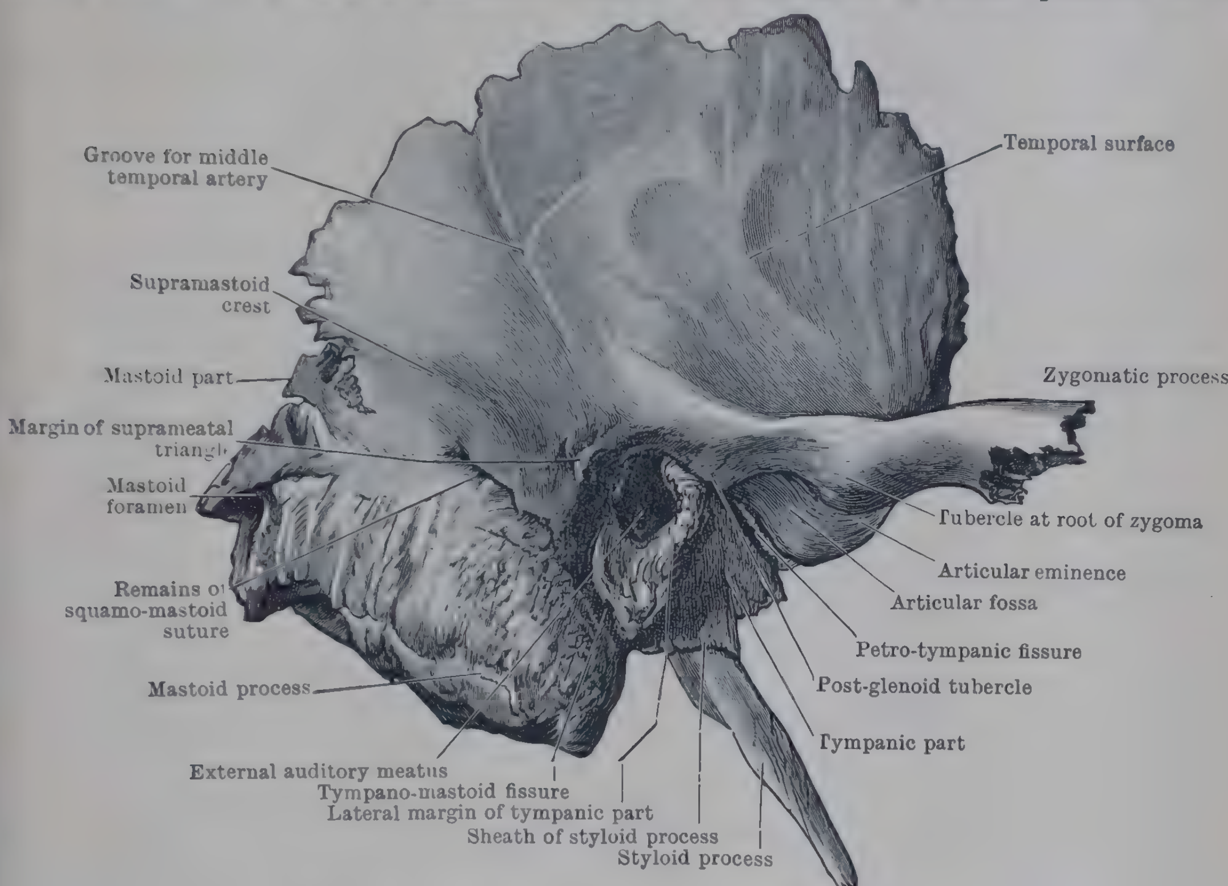

FIG. 1188.—LATERAL ASPECT OF RIGHT TEMPORAL BONE.

ganglion. The sensory root is then gently raised on a hook and its bundles carefully divided without injury to the motor root, which lies deep to the sensory root.

Ear.—The skin of the lateral surface of the **auricle** is tightly bound down to the perichondrium; and inflammations of it are attended therefore with little swelling but much pain. The **posterior auricular artery**, which ascends along the groove at the posterior attachment of the auricle, is immediately in front of the incision for opening the tympanic antrum.

The general direction of the **external auditory meatus** is medially, forwards, and downwards; it is thus curved both vertically and horizontally. The highest part of the upward convexity, which is also the narrowest part of the canal, is situated at the middle of its osseous portion; beyond that the floor sinks to form a recess in which foreign bodies are apt to be imprisoned. Of the two horizontal curves the lateral is convex forwards, the medial concave forwards. The skin of the osseous portion of the canal is thin and adherent to the periosteum. Boils in the canal are extremely painful; when situated on the posterior wall and associated with cellulitis the condition may be difficult to distinguish from mastoiditis.

The relations of the osseous walls of the meatus are of importance to the surgeon. The whole of the upper wall and the upper half of the posterior wall, developed from the squamous portion of the temporal bone, consist of two layers of compact bone, an upper and a lower, which are continuous with the inner and

outer tables of the skull. The upper plate passes medially to the petro-squamosal suture, where it becomes continuous with the lateral edge of the tegmen tympani, which roofs over the epitympanic recess and the tympanic antrum; the lower plate bends downwards and medially at its deepest part to form the infero-lateral wall of the recess and the anterior part of the lateral wall of the antrum. On the upper and posterior segment of the external auditory margin is the **suprameatal spine**. It occupies the middle of the base of a small depression, called the **suprameatal triangle**, which lies between the supramastoid crest and the postero-superior quadrant of the external osseous meatus. The spine can sometimes be felt in the living subject if the forefinger is placed in the external meatus and pressed upwards and backwards.

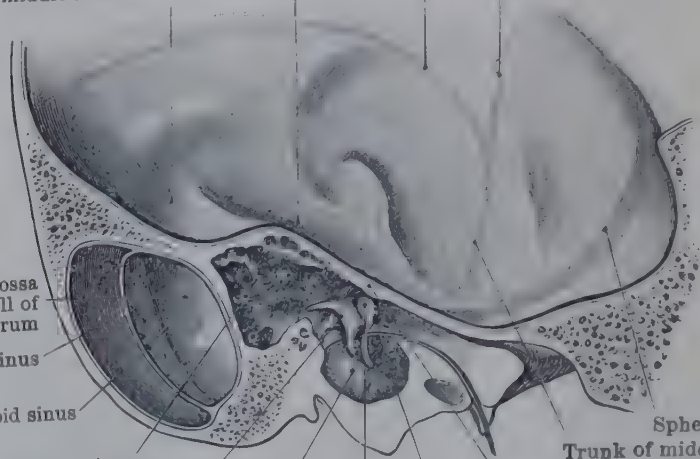

FIG. 1189.—VIEW OF LATERAL WALL OF MIDDLE EAR.

Section through the left temporal bone of a child, to show the relations of the tympanum and tympanic antrum to the middle and posterior fossæ of the skull.

The lower half of the posterior wall of the osseous meatus (posterior part of the tympanic plate) is fused with the anterior part of the mastoid portion of the temporal bone, and closes the lower and anterior set of mastoid air-cells (border cells).

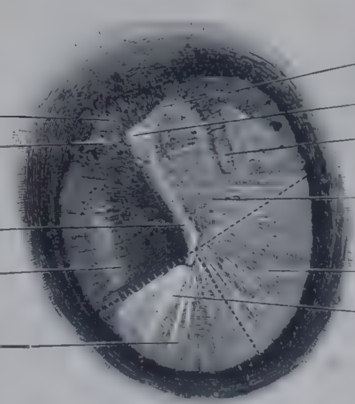

FIG. 1190.—LEFT TYMPANIC MEMBRANE VIEWED FROM EXTERNAL AUDITORY MEATUS. ×3.

Anteriorly and inferiorly the osseous meatus is related respectively to the **mandibular joint** and the **parotid gland**. Hence it follows: that blows upon the chin may fracture the tympanic plate as well as the base of the skull; that pain on mastication is usually complained of in acute inflammatory affections of the meatus and middle ear; and that in young children, in whom the tympanic plate is incompletely ossified, suppurative inflammation is apt to extend from the parotid region into the external auditory meatus.

To obtain a view of the **tympanic membrane** a speculum and a reflecting mirror are employed or the membrane is illuminated by direct light. The auricle is pulled upwards, backwards, and laterally in order to straighten the cartilaginous part of the meatus. The healthy membrane is pearly grey, semi-opaque, slightly concave, and obliquely

placed, the upper and posterior portion being nearer to the observer than the anterior and inferior part.

The handle and lateral process of the malleus, both embedded in the tympanic membrane, are the only objects distinctly seen when the healthy ear is examined with the speculum. The lateral process of the malleus projects laterally, and presents itself, therefore, as a distinct knob-like projection at the upper part of the membrane; passing forwards and backwards from that process are the **anterior** and **posterior malleolar folds** of the membrane; they form the lower limit of the *flaccid part* of the membrane, and correspond to the line of the chorda tympani nerve. The handle of the malleus, situated at the junction of the upper two quadrants, is seen passing downwards and backwards to the point of maximum convexity of the membrane (umbo), situated a little below its centre (Fig. 1190); passing downwards and forwards from

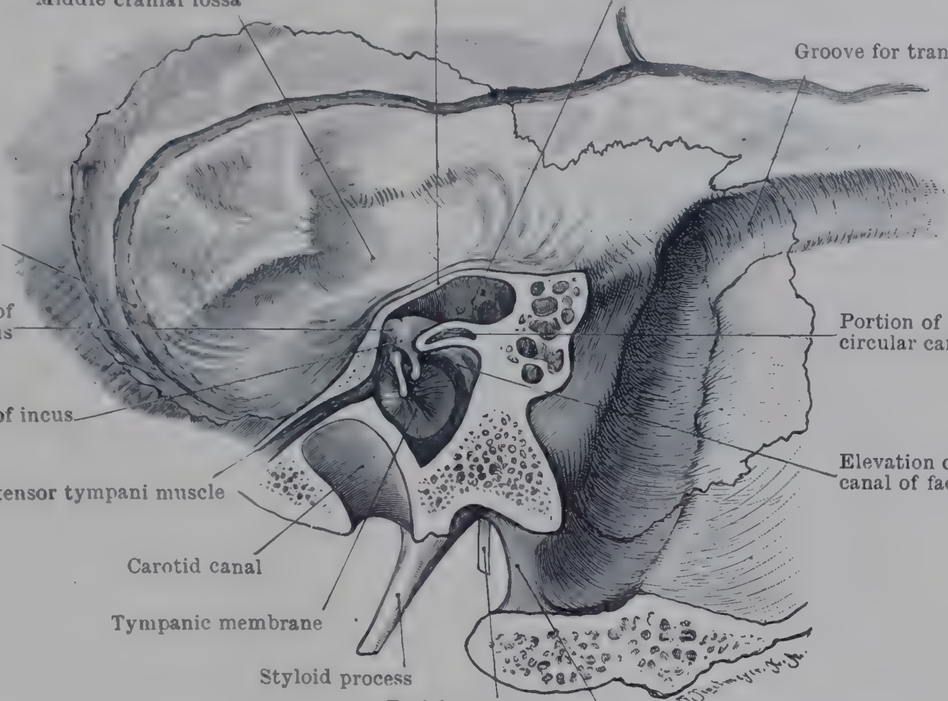

Fig. 1191.—Section through Petrous Portion of Right Temporal Bone of Adult viewed from the Deep Surface.

Showing the relation of the tympanum to the middle and posterior fossæ of the skull.

the umbo is the *triangular cone of reflected light*, to which too much importance must not be attached, since its appearances vary considerably in healthy ears. Normally, the long process of the incus is but faintly visible, and still less so are the promontory and fenestra cochleæ; in the condition of obstruction of the pharyngo-tympanic tube, however, in which the membrane is indrawn, those structures, along with the malleolar folds, become more distinct.

In the operation of *paracentesis of the tympanic membrane* the incision is made through the two posterior quadrants, as, in addition to good drainage being provided, they are farthest removed from important structures such as the chorda tympani nerve.

In order that the clinical importance of the parts seen through the translucent membrane may be understood, it is necessary to study the relative position of the structures in that part of the tympanum which lies opposite the tympanic membrane. The head of the malleus and the body and short process of the incus are altogether above the tympanic membrane, and they occupy the **epitympanic recess** (Fig. 1191). At the junction of the upper two quadrants of the membrane is the **handle** of the **malleus**, which is directed downwards, backwards, and medially; the tendon of the tensor tympani muscle crosses the tympanic cavity from its medial wall to be attached to the upper part of the handle. The **lateral process** of the **malleus** is directed laterally a little below the deepest part of the roof of the osseous external auditory meatus. Opposite the postero-superior quadrant are the **long process** of the **incus**, which descends behind and almost parallel to the handle of the malleus, and the **stapes**, which is directed medially and also slightly upwards and backwards to the fenestra vestibuli. The **chorda tympani**

nerve runs from behind forwards between the lateral surface of the upper part of the long process of the incus and the medial surface of the neck of the malleus. At the deepest part of the roof of the osseous external meatus, above the chorda tympani nerve and the lateral process of the malleus, is the **tympanic notch**, which is occupied by the flaccid, highest portion of the tympanic membrane; the notch is due to a deficiency in the tympanic ring, which forms only about five-sixths of a circle. Opposite the postero-inferior quadrant of the drum-head is the **promontory** caused by the first coil of the **cochlea**, below and behind which is the **fenestra cochleæ**. Opposite the antero-superior quadrant are the **cochleariform process**, the **tendon** of the **tensor tympani**, and the passage leading towards the **pharyngo-tympanic tube**.

The *medial wall* of the tympanic cavity is related to the internal ear. The *roof* separates the tympanic cavity (epitympanic recess) from the middle cranial fossa and the brain. It is formed by the **tegmen tympani**—a thin plate of bone which is continued backwards to roof over the tympanic antrum, and forwards to form the roof of the canal for the tensor tympani muscle immediately above the osseous portion of the pharyngo-tympanic tube. Laterally the tegmen is limited by the **petro-squamous suture**, which may persist for some years after birth, thus affording a channel along which pyogenic infection may spread from the middle ear to the meninges and brain. Infection may spread also along the small veins which convey blood from the tympanum to the superior petrosal and transverse sinuses, and to the posterior fossa of the skull along the vessels which pass from the medial wall of the tympanic antrum through the subarcuate fossa, beneath the dome of the superior semicircular canal.

The floor of the tympanum is constituted mainly by the bone bounding the **jugular fossa**, which is occupied by the upper bulb of the internal jugular vein. When the sigmoid sinus is large and unusually far forward the bulb also is large; the fossa is consequently deeper, and arches up into the floor of the tympanic cavity, from which it may be separated merely by a thin and translucent plate of bone which occasionally shows an osseous deficiency. In cases where that condition existed the jugular bulb has been wounded in the operation of paracentesis of the tympanic membrane.

Anteriorly the tympanic cavity leads into the **pharyngo-tympanic tube**, which brings it into communication with the nasal part of the pharynx. In the child the tube is shorter and wider than in the adult; inflammations of the pharynx are therefore more apt to reach the tympanum along this route in an infant than in an adult.

Above the level of the tympanic membrane is the **epitympanic recess**, which communicates posteriorly by means of a triangular opening (*aditus ad antrum*) with the tympanic antrum. The epitympanic recess contains, from before backwards, the head of the malleus, the body and short process of the incus—the process being attached by a ligament to the floor of the aditus. When these structures are covered with inflamed mucous membrane or granulations, drainage from the tympanic antrum into the tympanum is interfered with. The *boundaries of the aditus*, important surgically, are as follows: superiorly, the tegmen tympani; medially, an eminence of compact bone containing the lateral semicircular canal; below and in front of them is a second smaller prominence, corresponding to that portion of the canal for the facial nerve which curves immediately above and behind the fenestra vestibuli. The wall of the facial canal in that situation is thin or even deficient, so that inflammation may readily spread from the tympanum to the facial nerve. The lateral wall of the aditus is formed by the deepest part of the upper wall of the osseous external auditory meatus.

The *posterior wall* of the tympanum, below the aditus ad antrum, is formed by diploic bone which contains the descending portion of the canal for the facial nerve. Immediately below the floor of the aditus, on the posterior wall of the tympanum, is the pyramid, through which the tendon of the stapedius muscle emerges to be attached to the neck of the stapes (Fig. 1192).

The lymph-vessels from the auricle and external meatus open into the mastoid and parotid lymph-glands—the latter receiving also the lymph from the middle ear. The efferent vessels from these glands open into the glands that lie deep to the upper part of the sterno-mastoid muscle; hence it is that these groups of glands are so frequently found to be diseased secondary to tuberculosis of the middle ear; and care must be taken not to mistake an abscess in one of the mastoid glands for subperiosteal mastoid suppuration associated with middle-ear disease.

The **labyrinth** may become infected in cases of suppurative otitis media. In acute cases the infective process may pass into the inner ear through the fenestra vestibuli or fenestra

cochleæ. In chronic cases, on the other hand, the route of infection is by way of the prominence of the lateral semicircular canal, which not infrequently becomes eroded in cases of chronic purulent otitis media associated with accumulation of cast-off epithelium in the tympanic antrum —a condition known as *cholesteatoma*.

Tympanic Antrum.—The tympanic antrum is a backward and upward extension of the tympanum (Fig. 1192), and it is relatively larger and more superficial in the child than in the adult. Situated above and behind the tympanic cavity proper, its *lateral wall* is a triangular plate of bone which descends behind the external auditory meatus from the squamous temporal. Posteriorly, that triangular plate is separated in the child from the petro-mastoid element by the **squamo-mastoid suture**, which overlies the posterior part of the antrum and transmits small veins to the surface. The suture does not disappear until a year or two after birth, and remains of it may frequently be detected in the adult bone. The anterior and upper portion of the triangular plate turns medially at an angle to

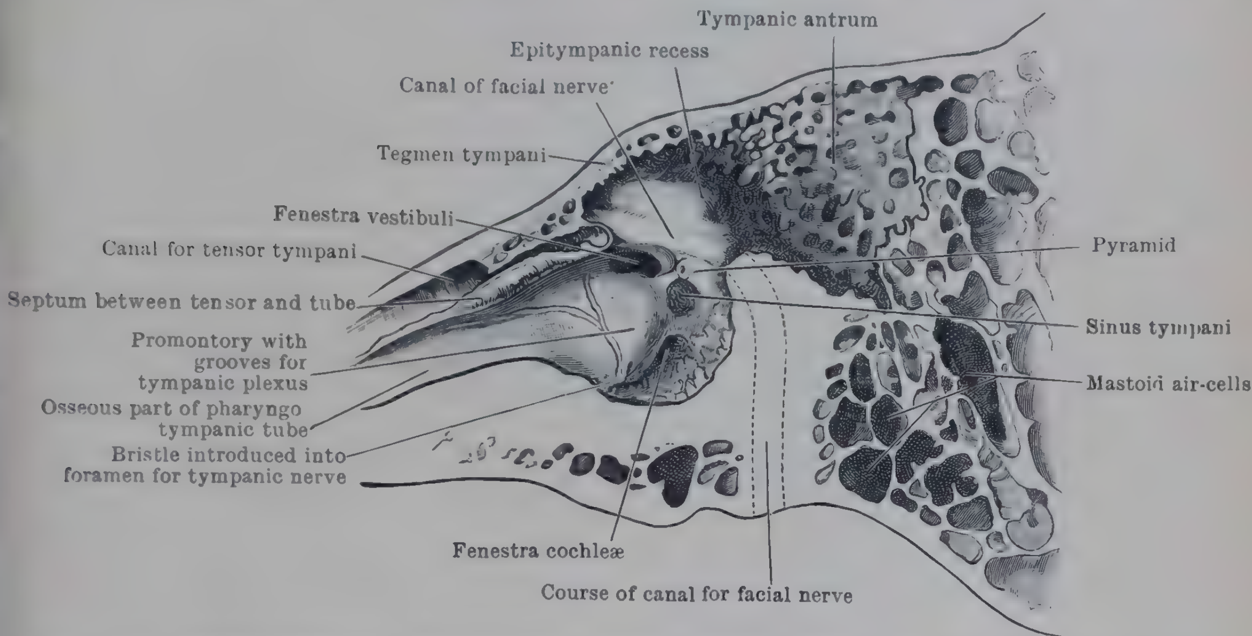

FIG. 1192.—SECTION THROUGH LEFT TEMPORAL BONE, SHOWING MEDIAL WALL OF TYMPANIC CAVITY.

form the upper and posterior wall of the rudimentary osseous meatus, as well as the floor of the epitympanic recess.

In the adult the lateral wall of the tympanic antrum is a plate of bone, from 1·3 to 1·9 cm. in thickness, that separates the antrum from the suprameatal triangle, and may therefore be felt through the skin as a slight depression. It occupies the centre of a triangle formed by the supramastoid crest, the posterior-superior quadrant of the auditory meatus and an imaginary line drawn vertically through the posterior margin of the meatus. The supramastoid crest, which varies considerably in its obliquity, is sometimes situated a little above the level of the roof of the antrum; it is safer, therefore, when operating on the antrum, to take the level of the upper border of the osseous meatus as the guide, in order to avoid opening the middle fossa of the skull.

The *medial wall* of the antrum is a thick plate of spongy bone which separates the antrum from that portion of the posterior fossa which lies between the aqueduct of the vestibule and the groove for the sigmoid sinus, and contains the posterior semicircular canal.

The *roof* slopes downwards and forwards, and is the posterior and thinnest part of the tegmen tympani.

The *floor* is on a lower level than the aditus, and is therefore unfavourably placed for natural drainage.

To open the **tympanic antrum** the surgeon makes a curved incision a little behind the attachment of the auricle, and removes, with a hammer and gouge, the bone immediately above and behind the postero-superior quadrant of the external osseous meatus. The operator avoids: (1) the *middle fossa* of the *skull* by keeping below the supramastoid crest; (2) the *sigmoid sinus* by

keeping close to the postero-superior arc of the external auditory meatus and by directing the chisel slightly forwards as well as medially in opening the mastoid cells; (3) the descending portion of the *facial nerve* by not encroaching upon the inferior half of the deepest part of the posterior wall of the osseous meatus. If the operation is extended from the tympanic antrum through the aditus into the epitympanic recess, care must be taken not to injure either the *lateral semicircular canal* or the *facial nerve*, both of which lie in relation to the medial wall of the aditus.

Mastoid Part of Temporal Bone.—The **mastoid process** begins to develop in the second year. As development advances the diploë surrounding the antrum in the child becomes excavated to form the **mastoid air-cells**, which radiate from the antrum, and either directly or indirectly communicate with it by small openings. In the pneumatic type of mastoid the whole of the mastoid part of the temporal bone is occupied by these cells; and they extend also upwards into the squamous portion, forwards to the posterior wall of the osseous meatus (border-cells and posterior root of the zygoma), and backwards into the occipital bone. Pus retained within the "*border-cells*" may penetrate the posterior wall of the osseous meatus, and rupture through it. Less frequently the mastoid cells are absent, the bone consisting either of osseous tissue similar to that of the diploë, or of dense bone (sclerosed type).

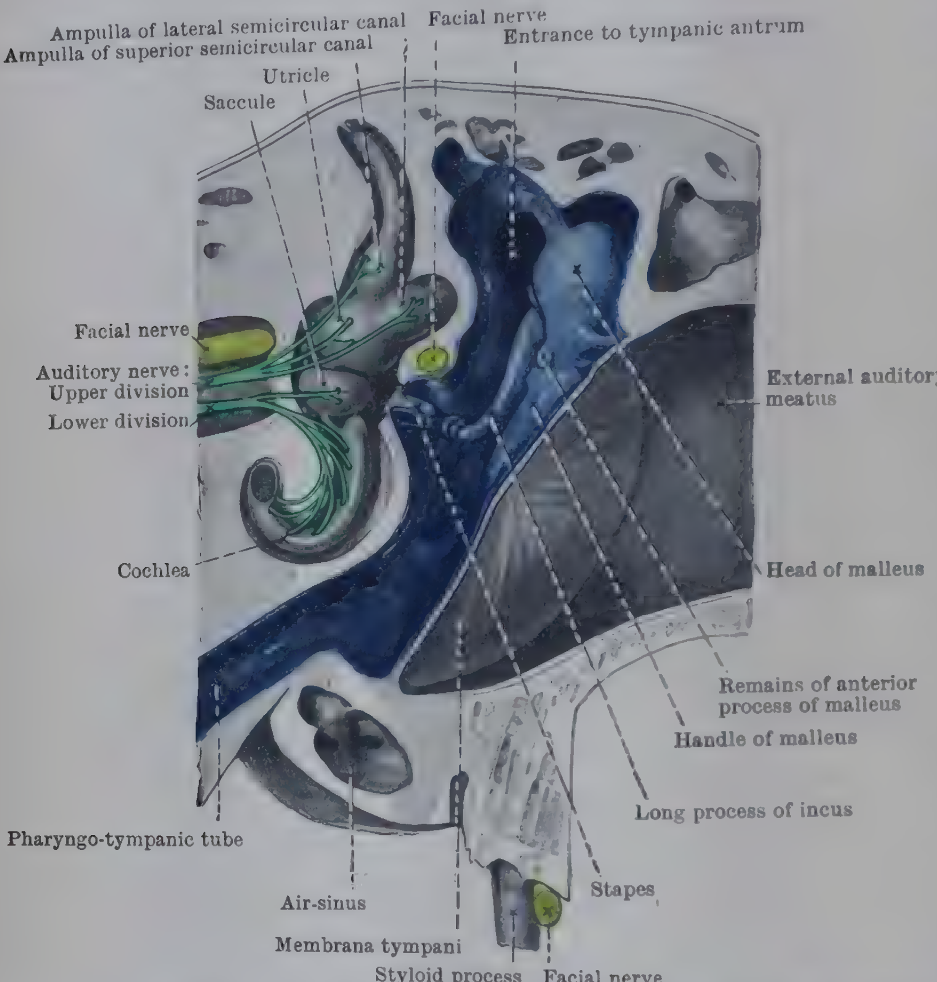

FIG. 1193.—SECTION THROUGH LEFT TYMPANIC CAVITY AND ADJACENT PARTS VIEWED FROM THE FRONT (SEMI-DIAGRAMMATIC).

In the infant the mastoid portion of the temporal bone is composed of sclerotic or sclero-diploic bone. The tympanic antrum is always present and there are a few small air-cells in its lateral wall. In the adult the sclerotic or sclero-diploic type of bone persists in about 20 per cent of skulls; that is to say, that the lateral wall of the antrum is formed either of dense bone, or of bone whose spaces are filled with marrow. In the remaining 80 per cent the mastoid part of the temporal bone is cellular or pneumatic, owing to the extension of the air-cells from the antrum. The difference in anatomical structure is of great importance in cases of mastoiditis because, if a patient with a pneumatic mastoid suffers from severe otitis media and mastoiditis, the inflammatory process extends to all these air-cells and usually comes to the surface on the lateral surface of the mastoid-temporal, giving rise to a subperiosteal abscess. On the other hand, if the patient has a sclerotic or sclero-diploic mastoid—the so-called "persistent infantile" form of mastoid—the inflammatory process is confined to the tympanic antrum and does not manifest itself on the surface. It is in the latter cases that an attack of acute

suppurative otitis media, with infection of the tympanic antrum, is specially liable to become chronic or to result in infection of the labyrinth or an intracranial complication. In operating on cases of chronic middle-ear suppuration the surgeon almost invariably meets with the persistent infantile type of mastoid-temporal, for the reason given above. Formerly it was erroneously supposed that the chronic infection of the mastoid resulted in sclerosis of the bone. We now know that cause and effect were transposed and that it is the sclerotic type of mastoid which has resulted in the chronic inflammatory condition and not the chronic inflammatory condition which has resulted in sclerosis of the mastoid.

The mastoid portion of the temporal bone is grooved, on its medial surface, by the **sigmoid sinus**. The average distance of the foremost part of the sinus from the suprameatal triangle is 1 cm. The right sinus usually receives the superior sagittal sinus, and it is then larger and farther forward than the left; in extreme cases it may reach to within 2 or 3 mm. of the meatus. The average distance of the sigmoid sinus from the *lateral* surface of the mastoid temporal is about 10 mm., but when the sinus is large and far forward the thickness may be reduced to 1 or 2 mm.

Facial Nerve.—The facial nerve, after entering the facial canal at the bottom of the internal auditory meatus, lies immediately above and behind the fenestra vestibuli, between it and the prominence of the lateral semicircular canal; thence it descends almost vertically in the posterior wall of the tympanum 3 mm. behind and medial to the lower half of the deepest part of the posterior wall of the external osseous meatus; and it emerges through the stylo-mastoid foramen (Fig. 1193).

In the infant, in consequence of the absence of the mastoid process, the exit of the facial nerve from the stylo-mastoid foramen is exposed on the lateral surface of the skull rather than on the base, at a point immediately behind the posterior segment of the tympanic horse-shoe. It follows, therefore, that, in infancy, the incision to expose the antrum should not be curved too far downwards and forwards, else the facial nerve may be divided. In the infant the position of the tympanic antrum is relatively higher than in the adult, because in the infant the upper wall of the auditory meatus inclines towards the vertical plane instead of being horizontal.

Paranasal Sinuses.—The **frontal sinuses** are a pair of cavities situated immediately above the root of the nose between the two tables of the frontal bone (Fig. 1194). Each sinus at its most dependent part communicates, by means of the infundibulum, with the middle meatus of the nose. A bony septum, rarely incomplete, separates the two sinuses; it is usually median below, but it may deviate to one or other side above (Pl. LXXVII, p. 1200).

The sinuses vary considerably in their size and shape, independently of the degree of development of the glabella and superciliary arches. Average dimensions are approximately 2·5 cm. in height and in breadth and over 2·5 cm. in depth along its floor. On the other hand, the sinus may exist merely as a small recess above the nose or it may extend upwards into the frontal bone for more than 5 cm., laterally to the side of the skull, while its inferior part may extend backwards, in the orbital roof, as far as the optic foramen. The anterior wall is the thickest, but the thickness may vary from 1 to 5 mm. The floor is the thinnest wall; when pus is retained within the cavity it tends to point, therefore, at the upper and medial angle of the orbital opening. Intracranial suppuration may arise in connexion with sinus-disease by extension through the roof of a sinus. The muco-endosteal lining is thin and pale, and readily strips from the bone.

In many subjects, by the aid of *transillumination*, the extent of the sinuses and the position of the intervening septum may be mapped out upon the forehead. For that purpose a small electric lamp is placed against the floor of the sinus, beneath the medial third of the supra-orbital margin.

The radiographic appearances of the frontal sinuses are of importance clinically and give more information than transillumination. Anterior radiographs (Pls. VIII, p. 155, and LXXVII, p. 1200) show the vertical extent of the sinuses, the degree of asymmetry, and the presence or absence of recesses, and their intervening septa. An orbital expansion is indicated by a well-defined dark area with a sharply defined upper

margin, extending laterally parallel to and immediately above the medial half or more of the supra-orbital margin. Lateral radiographs (Pls. VII, p. 154, LXXIII, p. 944, and LXXV, p. 960) show not only the height of the sinuses but also their antero-posterior diameter, as well as the degree to which their lower parts extend backwards in the roof of the orbit and the relation of the sinus to the underlying ethmoid sinuses. It is exceptional to meet with frontal sinuses before the age of five years, but they are almost invariably present by the seventh or eighth year.

When the sinus is explored, the opening in the bone should be made close to the median plane, immediately above the root of the nose. In marked cases of deviation of the septum one sinus may extend so far beyond the median plane as to reduce the other to a mere slit; in such cases the surgeon may fail to open the diseased sinus when the operation is

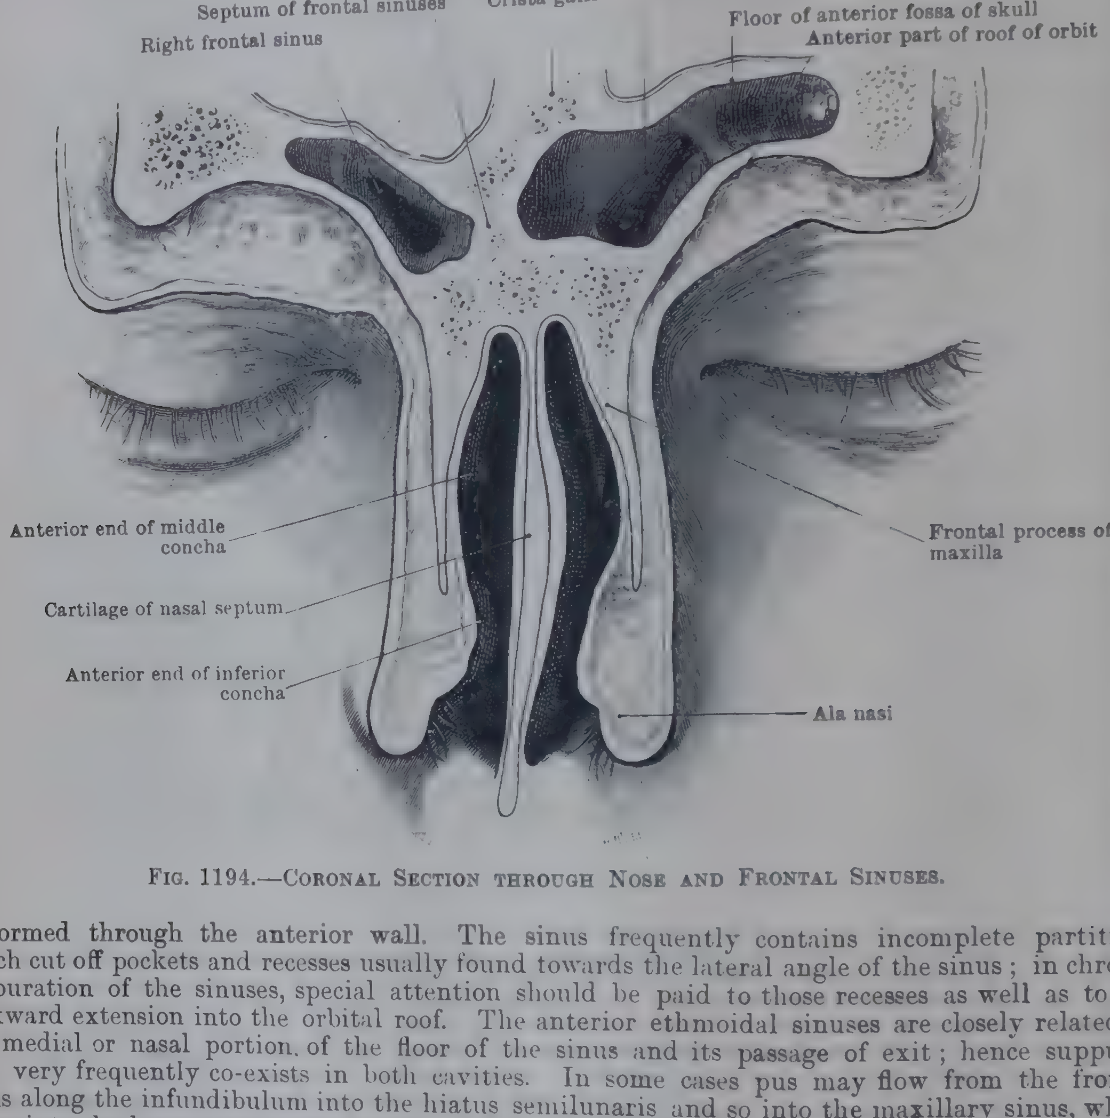

FIG. 1194.—CORONAL SECTION THROUGH NOSE AND FRONTAL SINUSES.

performed through the anterior wall. The sinus frequently contains incomplete partitions which cut off pockets and recesses usually found towards the lateral angle of the sinus; in chronic suppuration of the sinuses, special attention should be paid to those recesses as well as to the backward extension into the orbital roof. The anterior ethmoidal sinuses are closely related to the medial or nasal portion of the floor of the sinus and its passage of exit; hence suppuration very frequently co-exists in both cavities. In some cases pus may flow from the frontal sinus along the infundibulum into the hiatus semilunaris and so into the maxillary sinus, which opens into the lower part of the hiatus. Killian's operation for the cure of chronic suppuration in the sinus consists in removing its anterior and inferior walls—the supra-orbital margin being left to prevent the falling in of the eyebrow. By the removal of the frontal process of the maxilla good access may at the same time be obtained to the ethmoidal sinuses, and free drainage established between the frontal sinus and the nasal cavity.

In an anterior radiograph of the skull (Pl. VIII, p. 155), the dark areas formed by the **ethmoidal sinuses** are seen to occupy a well-defined position, bounded on each side by the still darker area of the orbital cavity and above by the dense horizontal shadow of the cribriform plate, which occupies the frontier line between those sinuses and the frontal sinuses. Anteriorly the ethmoidal sinuses are overlapped by the vertical shadow cast by the frontal processes of the maxillæ. Not infrequently the ethmoidal sinuses will be seen to extend into the roof of the orbit, while inferiorly and laterally they come into close relation to the upper and medial angle of the dark area that corresponds to the maxillary sinus. The comparative transparency of the ethmoidal sinuses is partly accounted for by the fact that they are superimposed upon the sphenoidal sinuses.

In a lateral radiograph the ethmoidal sinuses are seen to extend from the frontal processes of the maxillæ backwards across the orbits to the sphenoidal sinuses, with which they are contiguous (Pl. VII, p. 154). The area is crossed about its middle by the vertical shadow cast by the frontal processes of the zygomatic bones. In front of that, and occupying, therefore, the dark area of the orbital cavity, are the *anterior ethmoidal sinuses*; and behind it are the *posterior ethmoidal sinuses.* In a profile view of the skull, the posterior ethmoidal sinuses, the sphenoidal sinuses, and the hypophysial fossa all lie, from before backwards, in the axis of those rays which pass through the thinnest portion of the cranial box, namely, the anterior part of the temporal fossa; hence the

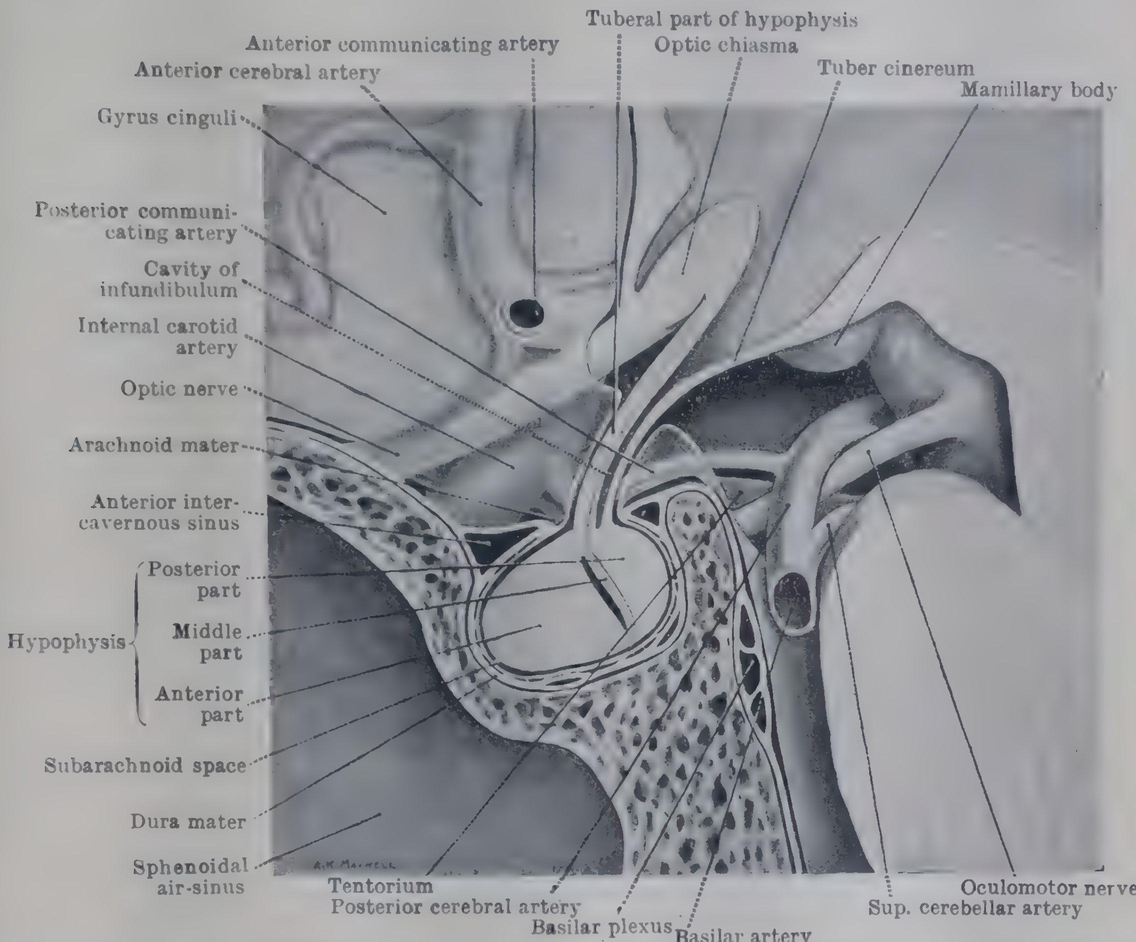

FIG. 1195.—DIAGRAMMATIC MEDIAN SECTION OF HYPOPHYSIS *IN SITU*, SHOWING THE PARTS OF THE ORGAN AND ITS RELATIONS TO ADJACENT STRUCTURES. (The existence of a subarachnoid space around the gland in the hypophysial fossa is doubtful.)

possibility of identifying them in a radiograph taken even from a living subject (Pl. LXXIII, p. 944).

The **sphenoidal sinuses** are distinguished with difficulty in an anterior radiograph owing to the superimposed shadows.

In lateral radiographs of the skull the dark area of the sphenoidal sinuses is seen immediately below and in front of the characteristic well-defined cup-shaped shadow thrown by the floor of the hypophysial fossa (Pls. VII, p. 154, LXXIV, p 945, and LXXV, p. 960). Inferiorly, the sinus-area is to some extent overlapped and obliterated by the dense shadow which corresponds to the zygomatic arch and the horizontal portion of the greater wing of the sphenoid — that is to say, to the floor of the middle cranial fossa. This shadow is continuous, posteriorly, with that caused by the petrous portion of the temporal bone. The posterior ethmoidal sinuses are seen in front of the area of the sphenoidal sinuses, while behind it is limited by the shadow produced by the part of the body of the sphenoid that lies below the dorsum sellæ.

Hypophysis Cerebri.—The *hypophysial fossa* is immediately behind the upper part of the sphenoidal sinuses; and, in a median section of the skull, the anterior half of the fossa is seen to project into what would correspond to the supero-posterior angle

of the sinuses (Fig. 164, p. 193). The more the sphenoidal sinuses project backwards below the hypophysial fossa, the thinner is that part of the floor of the posterior cranial fossa which separates the sinus from the basilar artery and the pons.

In lateral radiographs of the skull (Pls. VII, p. 154, LXXIV, p. 945 and LXXV, p. 960), the outline of the hypophysial fossa is marked out by a crescentic linear shadow, the anterior and posterior horns of the crescent being the shadows of the anterior and posterior clinoid processes. Below and in front of the fossa the outlines of the sphenoidal sinuses may be distinctly traced. In front of the fossa the shadow which outlines the roof of the sphenoidal sinus is formed from before backwards by (1) the tuberculum sellæ, (2) the optic groove, (3) the plane of the lesser wing of the sphenoid. Above the lesser wing there is a second horizontal shadow caused by the roof of the orbit. Below the sphenoidal sinus there is a curved shadow produced by the floor of the middle cranial fossa; and behind the dorsum sellæ a dense triangular shadow corresponds to the petrous portion of the temporal bone.

Enlargements of the hypophysis cerebri can often be clearly demonstrated by an increase in the depth and antero-posterior diameter of the radiographic outline of the hypophysial fossa, by the unusual extent to which the fossa encroaches on the sphenoidal sinus, by pressure atrophy of the clinoid processes, and by the thinning of the dorsum sellæ.

Adenomata and cysts of the hypophysis frequently enlarge upwards through the diaphragma sellæ towards the brain. After emerging from the fossa the tumour bulges upwards through the space bounded in front by the anterior segment of the circulus arteriosus, and behind by the optic nerves and the chiasma. As a result of the pressure upon the medial borders of the optic nerves and on the chiasma, a common sign of such a tumour is bitemporal hemianopia.

Tumours arising in the hypophysis or in its neighbourhood are usually approached by exposing the frontal lobe in its dural covering by an osteoplastic bone-flap above the superior border of the orbit. The frontal lobe is elevated upwards and backwards until the optic nerve is reached, or the tumour is identified. Rarely, when a hypophysial growth expands downwards and forwards towards the sphenoidal sinus, it is dealt with by the intranasal route, which requires removal of the cartilaginous and bony parts of the nasal septum.

THE FACE

Skin.—The skin of the face is thin, vascular, and rich in sebaceous glands and sweat-glands; it is intimately connected with the subcutaneous tissue, in which the facial muscles and the main blood-vessels are embedded. Owing to its mobility and to the presence of the main blood-vessels in the lax subcutaneous tissue, the face is an admirable site for plastic operations. The laxity of the tissues accounts for the marked swelling which attends œdematous and inflammatory conditions about the face. Whenever possible, incisions should be made along the line of the natural furrows and creases of the skin, in order that the resulting cicatrix may be less noticeable.

Landmarks.—The bony landmarks of the face which can be readily palpated are: the **superciliary arches** and the **glabella**, the **nasion**, the **bridge of the nose**, the **bony anterior aperture of the nose** and the **anterior nasal spine**, the **supra- and infra-orbital margins**, the **zygomatic** and **maxillary processes** of the **frontal bone**, the anterior part of the **temporal line**, the **zygomatic bone**, the **zygomatic arch**, and the region of the **canine fossa** of the maxilla (Fig. 154, p. 155, and Fig. 1184).

Immediately below the root of the zygoma, and in front of the upper part of the tragus, is the **head of the mandible**. If the finger-tip is pressed on the head while the mouth is being widely opened, the bone will be felt to glide forwards, while the finger sinks into the hollow corresponding to the **articular fossa**. The close relation of the first part of the **maxillary artery** to the medial side of the neck of the mandible must be kept in mind in operations calling for disarticulation or excision of the head. The **ramus of the mandible** is sandwiched between the masseter and the medial pterygoid muscles, and can be removed without opening

into the cavity of the mouth. Below the head, one can palpate the borders of the ramus and the **angle** and **body of the mandible**. The anterior border of the **coronoid process** is felt in front of the upper part of the anterior border of the masseter, immediately below the anterior part of the zygomatic arch.

A line dropped vertically from the supra-orbital notch to the lower border of the mandible opposite the interval between the two lower premolar teeth, will cross the **infra-orbital** and **mental foramina**—the former 5 mm. below the infra-orbital margin, the latter midway between the borders of the mandible.

Maxillary and Mandibular Nerves.—In the treatment of neuralgia of the trigeminal nerve, alcohol is sometimes injected into the maxillary or the mandibular nerve at its exit from the skull.

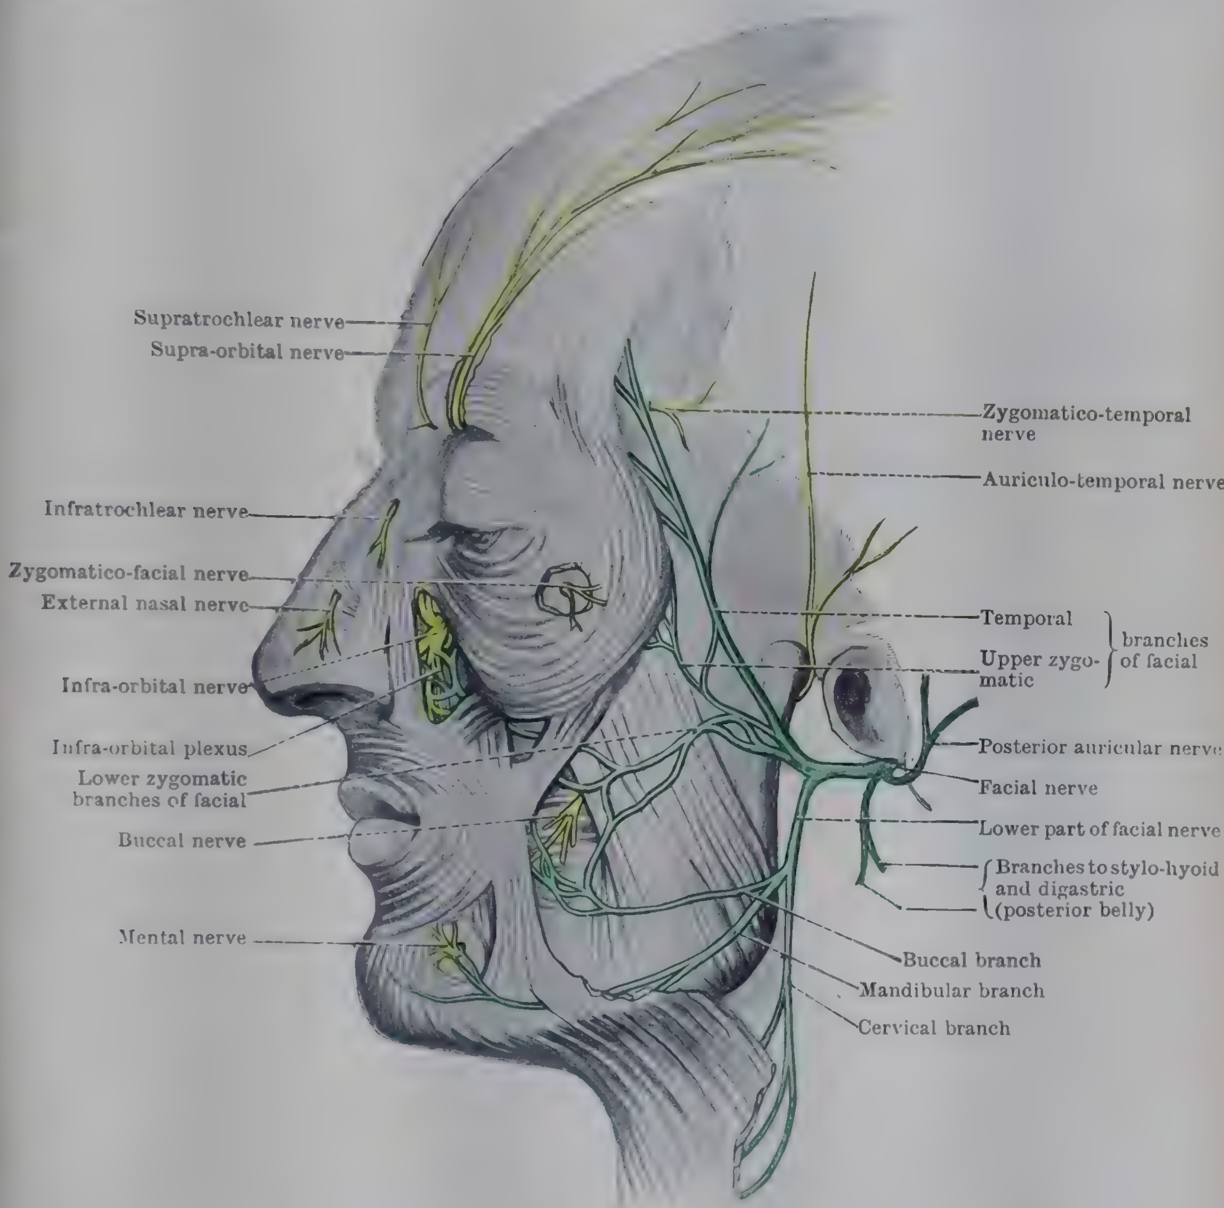

Fig. 1196.—Distribution of Trigeminal and Facial Nerves on the Face.

The **mandibular nerve** is injected immediately below the foramen ovale, which is about 5 cm. from the skin in the same coronal plane as the articular eminence. When the mouth is opened widely the head of the mandible travels forwards and can be distinctly felt immediately below the eminence. To avoid the mandibular joint the needle is introduced through the skin immediately below the zygoma, a little in front of the eminence, 3 cm. in front of the middle of the external auditory meatus. It is pushed medially, slightly upwards and backwards through the mandibular notch, and thence through, or immediately above, the lateral pterygoid muscle, into the nerve.

To reach the **maxillary nerve**, the needle is introduced at the same point on the cheek, and pushed medially and forwards in the direction of the external angle of the orbit, so that its point will impinge upon the lateral pterygoid plate. It is then directed a little anteriorly, and pushed onwards for 0·5 cm., when it will strike the nerve as it lies in the pterygo-palatine fossa, immediately below the foramen rotundum, at a distance of about 5 cm. from the skin.

Facial Artery.—The pulsation of the **facial artery** may be felt as the vessel crosses the lower margin of the mandible at the anterior border of the masseter, 3 cm. in front of the angle of the mandible (Fig. 1197). To map out the course of the artery on the face, a line is drawn from that point to a point 1·3 cm. lateral to the angle of the mouth, and thence to a point a little behind the ala nasi and along the side of the nose to the medial angle of the eye. The **anterior facial vein** is behind the facial artery, and takes a straighter course from the medial angle of the eye to the anterior inferior angle of the masseter. The vessel is devoid of valves; infective phlebitis and thrombosis are therefore apt to spread along it to the cavernous sinus by way of the ophthalmic and pterygoid veins.

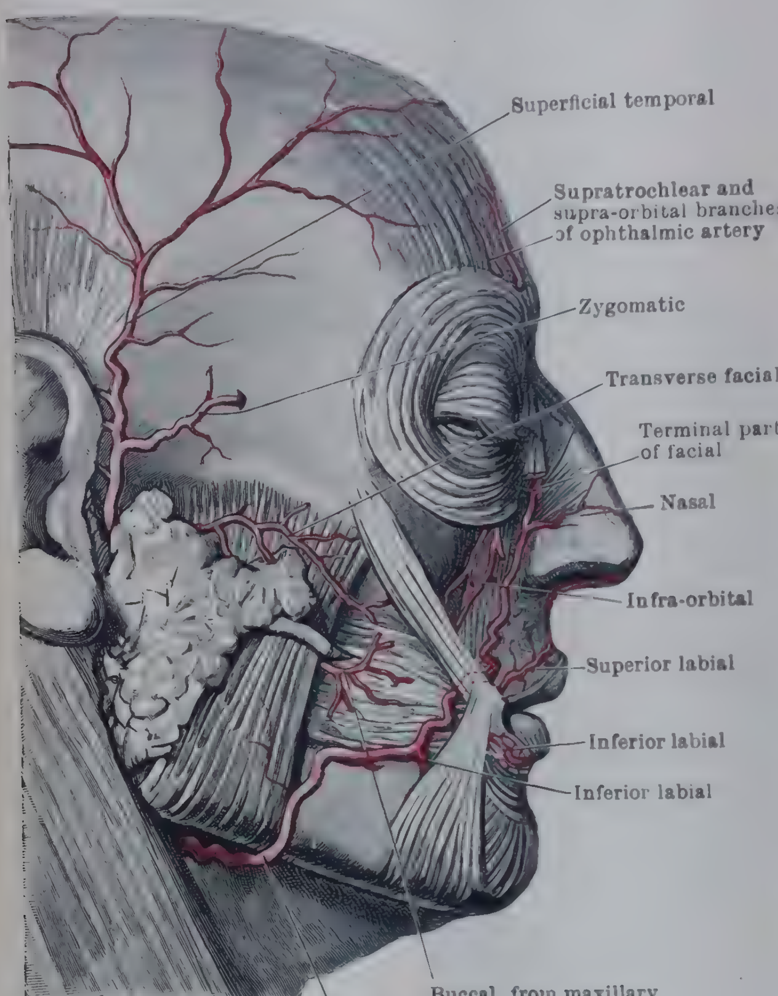

FIG. 1197.—ARTERIES OF THE FACE.

Facial Nerve.—The facial nerve, after emerging from the stylo-mastoid foramen, enters the substance of the parotid gland 2·5 cm. deep to the middle of the anterior border of the mastoid process. It is superficial to the external carotid artery. Branches of the nerve can be rolled under the finger as they cross the neck and head of the mandible (Fig. 1196); incisions continued along the mandible above that point should be only skin-deep if the branches are to be avoided. To expose the trunk of the nerve an incision is made along the anterior border of the upper third of the sterno-mastoid muscle. Dissection in the upper end of the wound exposes the posterior belly of the digastric muscle, along the upper border of which the nerve courses. Incisions on the cheek should, whenever possible, be planned so as to run parallel with the branches of the nerve, which radiate from the lower end of the tragus. The nerve may be paralysed by wounds of the cheek and by malignant tumours of the parotid, and also by intracranial and middle-ear lesions.

Parotid Gland and Duct.—The **parotid gland** (Figs. 1197, 1205) is surrounded by a fascial envelope, the strongest portion of which is continued from the deep cervical fascia over its lateral surface to become attached to the zygoma; hence abscesses in the parotid tend to burrow deeply towards the pterygo-palatine fossa and the upper part of the pharynx; the pus should therefore be evacuated early through an oblique incision through the skin only, a little behind and below the angle of the mandible. The abscess is opened by passing a blunt instrument (forceps) through the opening in the skin, in order to avoid injuring branches of the facial nerve (Hilton's method).

The **parotid duct** can be rolled beneath the finger as it crosses the masseter, rather less than a finger's breadth below the zygoma. After winding round the anterior border of the muscle it pierces the buccinator and opens into the mouth opposite the second upper molar tooth. The duct corresponds to the middle third of a line drawn from the lower margin of the concha of the auricle to a point midway between the ala nasi and the margin of the upper lip.

Superficial to the parotid and a little in front of the tragus there is a **parotid lymph-gland** which is frequently found to be inflamed in children suffering from eczematous conditions of the eyelids, face, scalp, and external ear. When an abscess connected with that gland is opened, the incision is made as low down as possible, in order to avoid the parotid duct.

The deep parotid lymph-glands, which lie partly in the substance of the parotid and partly deep to it, are especially liable to become infected secondary to tuberculous disease of the middle ear and to malignant affections about the root of the tongue, the throat, and the naso-pharynx. In their removal it is generally impossible to avoid the cervical branch of the facial nerve, which pierces the cervical fascia immediately below and behind the angle of the mandible. The cervical branch supplies the platysma and the depressor labii inferioris muscles; its division therefore results in inability to depress the lower lip on the affected side. At the same operation some trouble may be caused by bleeding from the posterior facial vein and its divisions, which traverse the substance of the parotid gland.

Eyelids.—The skin of the eyelids, more especially of the upper, is very thin and is connected with the orbicularis oculi muscle by delicate, lax subcutaneous tissue destitute of fat; hence the marked swelling which occurs in a "black eye" and in œdema of the lids. Along the anterior edge of the free margin of each lid are the eyelashes and the orifices of the ciliary glands, suppurative inflammation of which gives rise to a "*stye*"; along the posterior edge are the minute orifices of the **tarsal glands**. These glands, embedded in the deep surface of the tarsi, are seen through the palpebral conjunctiva as a row of parallel, yellowish, granular-looking streaks. From the deep position of the glands it follows that the skin over a *Meibomian cyst*—a retention cyst resulting from occlusion of the orifice of a tarsal gland—is freely movable, and that to reach the cyst an incision must be made through the conjunctival surface of the lid.

The **palpebral conjunctiva** is closely adherent to the ocular surface of the tarsi; at the fornix—the zone of reflexion of the conjunctiva from the deep surface of the eyelid on to the eyeball—it is loose and contains small lymph-follicles which become hypertrophied in the condition known as granular conjunctivitis. The **ocular conjunctiva** is thin, transparent, and loosely attached to the sclera, so that, in an operation on the eye, a fold of the membrane can be picked up with forceps to steady the eyeball.

In inflammatory affections of the eye the state of the visible vessels gives important information as to the seat of the mischief. For example, in inflammation of the *conjunctiva* the posterior conjunctival vessels (derived from the palpebral arteries)—scarcely visible normally—appear as a close network which fades away towards the corneal margin; those vessels move freely with the conjunctiva, and disappear under pressure. In superficial inflammations of the *cornea* the anterior conjunctival vessels (the most superficial of the terminal branches of the anterior ciliary arteries) are seen to spread in a freely branching manner into its superficial layers. In *iritis* and deep inflammations of the cornea there is a pink circumcorneal zone of vascular dilatation consisting of delicate straight vessels which do not disappear under pressure and do not move with the conjunctiva; they are the subconjunctival (episcleral) terminations of the anterior ciliary arteries; in health they are invisible.

Lacrimal Apparatus.—The **lacrimal gland**, situated behind the lateral part of the supra-orbital margin, cannot be felt unless enlarged. If the upper eyelid is raised and everted, the palpebral process of the gland is seen to bulge below the lateral third of the fornix, in which situation also the minute orifices of the lacrimal ducts may be detected.

When the lower lid is drawn gently downwards the **punctum lacrimale** is seen on a slight papillary elevation of its margin about 4 mm. from the medial angle of the eye; the corresponding orifice of the upper lid is a little more medial. Normally the puncta are directed towards the ocular conjunctiva, and are accurately applied to it immediately lateral to the lacrimal caruncle.

Drawing the lids laterally puts the **medial palpebral ligament** on the stretch, and it can be felt as a narrow, tense band passing medially to be attached

to the frontal process of the maxilla. The ligament is a guide to the position of the lacrimal sac, which it crosses a little above its middle. Continuous with the lower end of the lacrimal sac is the **naso-lacrimal duct**, which passes downwards and slightly backwards and laterally to open into the inferior meatus of the nose under cover of the anterior part of the inferior concha. The lacrimal sac and naso-lacrimal duct each measure about 1·3 cm. in length; the duct is slightly contracted at its beginning and end, and it is in those situations that pathological strictures of the duct are most common. Spontaneous rupture of an abscess of the lacrimal sac occurs almost invariably immediately below the medial palpebral ligament; it is in that situation that the abscess should be opened, the incision being made a little lateral to the terminal part of the facial artery.

The **lacrimal canaliculi**, which convey the lacrimal fluid from the puncta to the lacrimal sac, run for the first 1-2 mm. almost vertically from the free margins of the lids, and then parallel to them. The **lacrimal caruncle** is placed between those portions of the lids in which the canaliculi lie. In the various morbid conditions which give rise either to misdirection of the puncta or to stricture at any part of the lacrimal drainage apparatus, overflow of the tears (*epiphora*) is the chief sign. When a probe is passed along a lacrimal canaliculus, the instrument, in consequence of the bend of the canaliculus, is passed at first vertically from the margin of the lid, and afterwards parallel to it, until the point is felt to strike against the medial wall of the lacrimal sac; to pass the instrument onwards along the naso-lacrimal duct the handle is rotated forwards and upwards through a quarter of a circle, and then pushed gently downwards and slightly backwards and laterally into the inferior meatus of the nose.

The **tarsi** are attached to the periosteum of the orbital margins by the *palpebral ascia,* which shuts off the communication between the subcutaneous tissue of the eyelids and the fatty tissue of the orbital cavity. In fracture of the floor of the anterior cranial fossa involving the roof of the orbit, the blood extends forwards between the periosteum and the musculo-fascial envelope of the orbit, and appears under the conjunctiva.

To obtain free access to the cavity of the orbit, the surgeon first enlarges the palpebral fissure by making a horizontal incision from the lateral angle of the eye to the lateral margin of the orbit, and then, after everting the eyelid, divides the conjunctiva along the fornix of the upper or of the lower lid, or of both, as may be necessary.

Nose.—To examine the cavity of the nose from the front (*anterior rhinoscopy*) the nostril is dilated with a nasal speculum and the interior is illuminated by reflected or direct light. The **anterior end of the inferior concha** appears as a rounded body projecting from the side-wall of the nose; when its muco-periosteum is turgescent it is apt to come into contact with the nasal septum and so occlude the cavity. The **inferior meatus** is between the inferior concha and the side-wall of the nasal cavity; it is brought into view by tilting the head backwards. The **lower end of the naso-lacrimal duct** is concealed by the anterior part of the inferior concha. The **floor** of the nose is horizontal and is on a slightly lower level than the nostrils. The **septum**, generally more or less deviated to one or other side, is seen when the head is slightly rotated away from the side to be examined. The **anterior end of the middle concha**, which lies a little behind and medial to the infero-medial angle of the orbital margin, is seen when the patient's head is thrown well back; it is separated from the septum only by a slit-like interval. To bring the **anterior part of the middle meatus** of that side into view, the patient's face is rotated towards the shoulder; pus in that situation may originate from the frontal sinus, the anterior ethmoidal sinuses, or the maxillary sinus, all of which open into the middle meatus.

When bleeding from the nose (epistaxis) occurs it usually proceeds from the small vessels of the septum, and it may be arrested by compressing the superior labial arteries, by plugging the nostrils, or by grasping the cartilaginous part of the nose firmly between the finger and thumb.

Maxillary Sinus.—This sinus is a pyramidal cavity with its base formed by the side-wall of the nose and its apex directed towards the zygomatic bone. The cavity

is lined with a thin muco-endosteum, easily separable from the bone and in which mucous cysts may develop. The floor of the sinus, which is a little below the level of the floor of the nose, is separated from the roots of the upper premolar and molar teeth by a plate of bone of varying thickness. When that plate is thin and devoid of spongy bone, suppuration at the roots of one of the teeth may extend to the sinus. The *orifice* is situated at the highest part of the sinus, and is therefore unfavourably placed for natural drainage; it opens into the middle meatus of the nose through the lower part of the *hiatus semilunaris*. Not infrequently a second communication exists between the sinus and the middle meatus, the opening being situated behind and below the normal orifice; when that accessory aperture exists, pus from

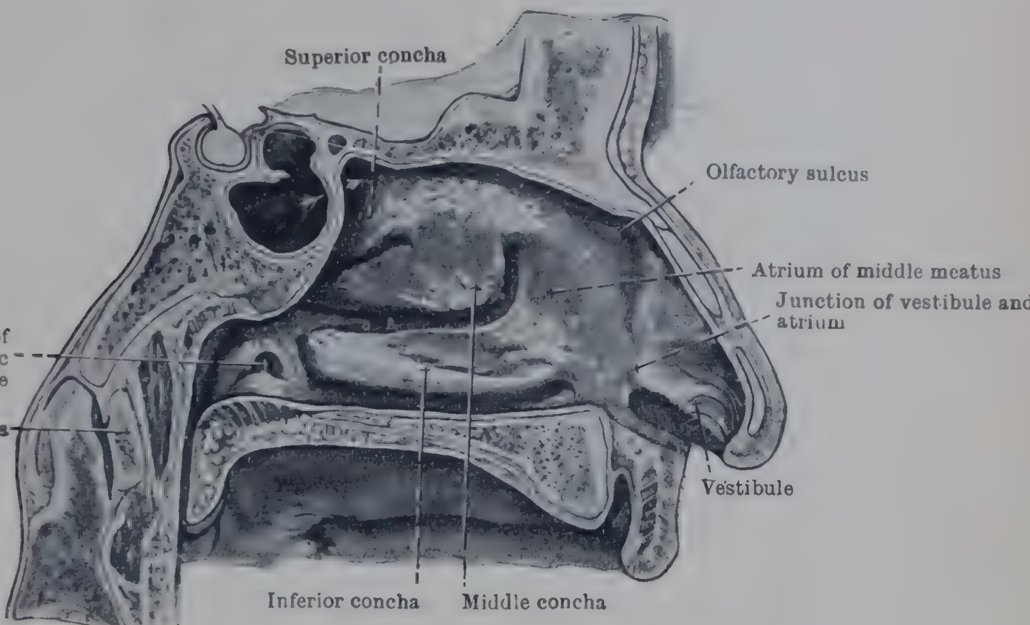

Fig. 1198.—Lateral Wall of Left Nasal Cavity.
The arrow passes from the sphenoidal sinus to the spheno-ethmoidal recess.

the sinus may drain backwards into the nasal part of the pharynx (Logan Turner, 1901).

In *empyema of the sinus* the opening to evacuate and drain the cavity may be made: (1) through the canine fossa; (2) through the side-wall of the inferior meatus of the nose.

In an anterior radiograph of the skull (Pl. VIII, p. 155), the maxillary sinus, presents a pyramidal outline, the base corresponding to the floor of the orbit and the rounded apex to the alveolar recess of the sinus. The medial outline of the sinus-area is the foreshortened shadow of the nasal wall of the sinus; laterally it is outlined by the zygomatic bone. The petrous part of the temporal bone throws a deep shadow across the upper half of the sinus. When the radiograph is taken, the head should therefore be tilted backwards so that the petrous part of the temporal is projected below the sinus which can then be seen clearly (Pl. LXXVII, p. 1200, Fig. 1).

In a lateral radiograph of the facial region of the dried skull (Pls. VII, p. 154, and XLVII, p. 558, Fig. 1), the outline of the maxillary sinus is well defined. It is represented below by the white line which crosses the tips of the roots of the molar teeth. Above, it is limited anteriorly by the white, curved shadow of the floor of the orbit; while above and posteriorly are the posterior ethmoidal cells. Behind the maxillary area are the vertical shadows of the pterygoid plates, overlapped by that of the coronoid process of the mandible. The anterior part of the sinus-area is overlapped and to a considerable extent obscured by the dense and more or less triangular shadow cast by the zygomatic bone.

MOUTH AND PHARYNX

Lips.—The lips are abundantly supplied with **mucous glands** which can be felt nearer their attached than their free borders immediately outside the mucous membrane; the glands are a frequent seat of mucous cysts; occasionally they undergo a congenital enlargement which results in one form of hypertrophy of the lip.

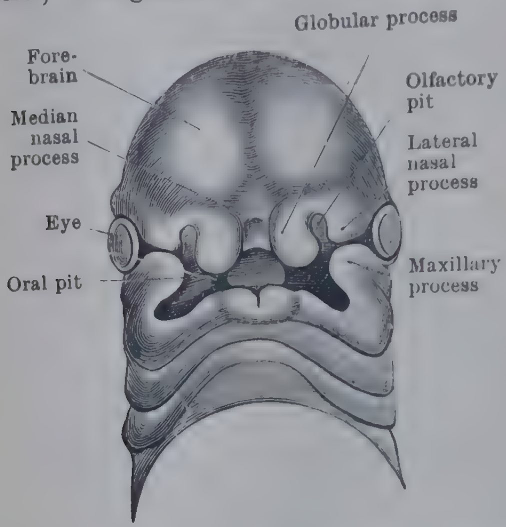

Fig. 1199.—Head of Human Embryo showing early stage of Development of Face.

Hare-lip is due to failure of the union of the superficial part of the maxillary process with the globular part of the median nasal process (Figs. 1199 and 1028, p. 1202). The deformity is spoken of as complete or incomplete according to whether the cleft extends into the nostril or involves merely a portion of the lip. The fissure may involve the lip only, or it may include the alveolar process of the maxilla; in the latter case the cleft may or may not be associated with a cleft of the palate. Lastly, the hare-lip may be single or double; when single, it is usually on the left side.

Palate.—Fig. 1200 shows how the mouth is shut off from the nasal cavities by the growth inwards from the deep surface of the maxillary process of a pair of horizontal plates (palatine processes) which unite in the median plane with each other and with the lower border of the septum of the nose; the septum, which develops as a downgrowth from the primitive basis cranii, is continuous anteriorly with that portion of the fronto-nasal process which forms the premaxillæ and the median portion of the upper lip. The various degrees of *cleft palate* are due to the more or less complete failure of union of the palatine processes with each other and with the premaxillary part of the median nasal processes. The cleft in the soft palate, which is always median, may be either partial or complete, and it may or may not extend forwards into the hard palate. The cleft in the hard palate is spoken of as single or double according to whether the palatine processes have failed to unite with the lower edge of the nasal septum on one side or on both sides. When the cleft extends forwards through the alveolar process to become continuous with a cleft of the lip, the medial (premaxillary) edge of the cleft is usually projected forwards in advance of the lateral (maxillary) edge. Closure of the labial cleft leads to correction of this deformity.

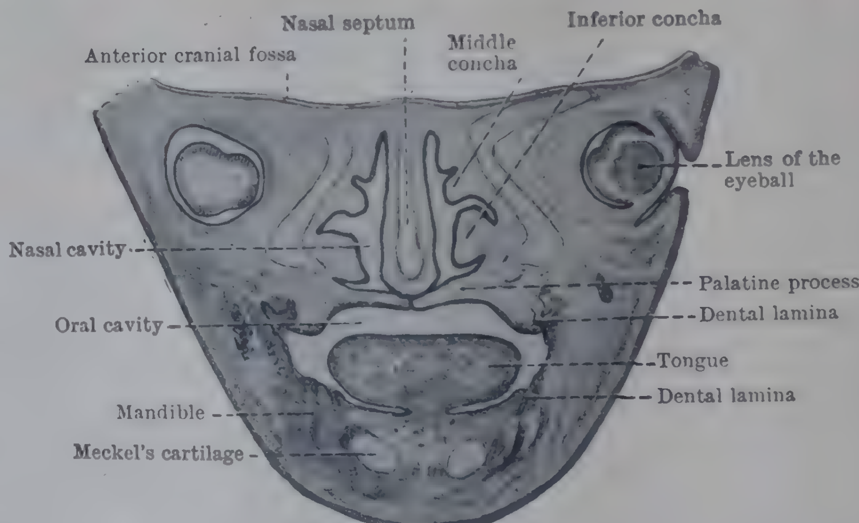

Fig. 1200.—Coronal Section through Face of Human Embryo about 9 Weeks Old.

In what is known as a complete double cleft palate, the palatine processes fail to join the nasal septum and the premaxillæ on both sides; the result is a wide median cleft which communicates with both nasal cavities. The free, lower border of the vomer extends along the middle of the cleft to be continuous anteriorly with the rounded premaxillary mass; that mass, along with the central portion of the upper lip, is projected forwards between the two labial clefts, often to such an extent that it appears to spring from the tip of the nose (Fig. 1201). In the operation for closure of such a double hare-lip, the problem of the correction of the premaxillary projection has to be

faced. Surgeons favour a preliminary closure of the lip-defect on the plea that the constant pressure of the restored lip-outline results in a gradual correction of the pre-

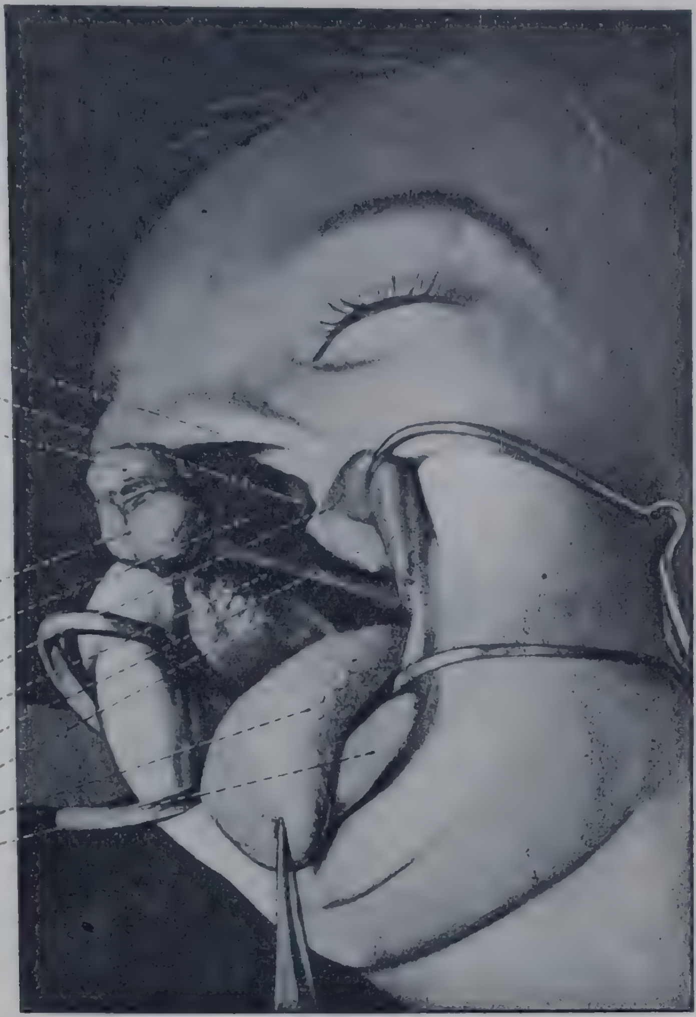

FIG. 1201.—PHOTOGRAPHIC ILLUSTRATION OF DOUBLE COMPLETE HARE-LIP AND CLEFT PALATE.

maxillary displacement. In the rare cases in which the maxillary plates meet in the median line, this method cannot be employed.

Teeth.—The **milk teeth** begin to appear about the sixth month—the first to emerge being usually the lower central incisors. The first dentition is completed about the thirtieth month. Of the **permanent set** the first to erupt are the first molars, which appear about the end of the sixth year; the third molars—the last to appear—may erupt any time between the seventeenth and the twenty-fifth year, or even later. As the permanent teeth push their way towards the surface, absorption of the roots of the first set takes place, and the first set either fall out of their own accord or are easily removed. Loss of the permanent teeth is followed by absorption of the alveolar margin of the jaw. The tooth-sockets are lined with a thin periosteum which is anatomically continuous both with the tissue of the teeth and with the dense fibrous tissue of the deep layer of the gum.

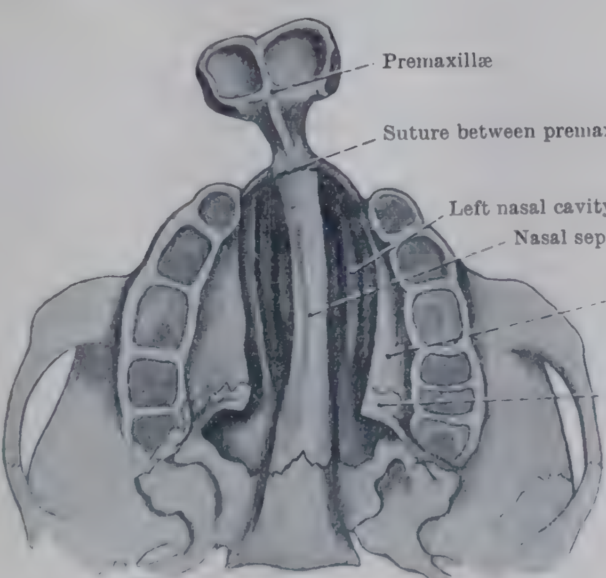

FIG. 1202.—ARRANGEMENT OF BONES IN DOUBLE CLEFT PALATE. (Bergmann, Bruns, & Mikulicz, 1904.)

The upper incisors and canines and the lower premolars have *cylindrical* roots; hence in extracting these teeth, they are first loosened by a slight rotary movement; the roots of the lower incisors and canines and of the upper premolars are *flattened*, and must therefore be loosened by a side-to-side movement. The roots of the third molars are *convergent*, generally welded together and curved backwards, especially in the mandible. The first and second upper molars have three roots, and they are often *divergent*.

Tongue.—For practical purposes, as well as on developmental and structural grounds, it is convenient to divide the tongue into an anterior two-thirds (the **oral part**) and a posterior third (the **pharyngeal part**) (Fig. 1205). At the junction of the two portions, immediately behind the median vallate papilla, is the **foramen cæcum**, which represents the remains of the pharyngeal end of the **thyro-glossal duct**. *Congenital cysts* and *fistulæ* which develop from persistent remains of that duct are always median, and are met with both above and below the hyoid bone.

The mucous membrane of the pharyngeal part of the tongue is much more sensitive than that of the oral part; hence, when a tongue depressor is used, the instrument should, except under special circumstances, rest only upon the oral region; otherwise a reflex arching of the tongue will be set up which prevents the operator from obtaining a satisfactory

FIG. 1203.—CORONAL SECTION THROUGH TONGUE AND SUBMANDIBULAR REGION IN PLANE BEHIND THE MOLAR TEETH.

view of the throat. Scattered over the pharyngeal part are clusters of **lymphoid follicles** (lingual tonsil) which appear on the surface as a number of nodular umbilicated elevations provided with little crypts into which mucous glands open (Fig. 492, p. 575). The lingual tonsil is liable to chronic inflammation and hypertrophy—conditions which are often accompanied by a varicose condition of the veins that lie immediately beneath the mucous membrane that covers the palato-glossus muscle. To obtain a satisfactory view of the lingual tonsil in the living subject, a laryngoscopic mirror is used.

The pair of mucous glands situated in the lower part of the tongue a little behind its tip, and known as the **anterior lingual glands**, are of interest in that they occasionally give rise to mucous cysts similar to those which develop in connexion with the labial glands (Fig. 1204).

The **muscular bundles** of the tongue are separated by a quantity of loose areolar tissue, rich in blood-vessels and lymph-vessels (Fig. 1203); hence acute inflammatory œdema of the tongue may be attended with a degree of swelling sufficient to obstruct the respiratory passage.

The main **blood-vessels** of the tongue run from behind forwards, nearer its lower surface than its upper surface (Fig. 1203); incisions into the substance of the tongue to reduce swelling and tension should therefore be made longitudinally on the dorsum. Bleeding from the lingual artery, divided in the substance of the tongue, is temporarily arrested by the finger passed behind the tongue to hook it well forward and compress the vessel against the lingual surface of the mandible. On account of the very slender anastomosis between the vessels of the two halves of the tongue, scarcely any bleeding occurs when it is split in the median plane.

The collecting **lymph-vessels** which arise from the lymph-networks in the mucous membrane and muscular substance of the tongue may be divided into four

groups:—(1) **Apical trunks,** which open partly into the submental glands and partly into a gland (jugulo-omohyoid) that lies immediately above the tendon of the omo-hyoid muscle. (2) **Marginal trunks,** some of which pass lateral to the sublingual gland and through the mylo-hyoid muscle to join the most anterior of the submandibular lymph-glands, while others pass medial to the sublingual gland, in front of and behind the hyo-glossus muscle, to join the glands in the carotid triangle. The more *anterior* their lingual origin the *lower* is the gland to which they pass. (3) The **basal trunks**, from the posterior third of the tongue, pass from before backwards towards the lower end of the tonsil, where they pierce the superior and middle constrictors of the pharynx, and, after surrounding the lingual artery, open into a gland (jugulo-digastric) placed on the internal jugular vein immediately below the posterior belly of the digastric. (4) The **central trunks**, which descend in the median plane between the genio-glossi, pass deep to the hyo-glossus and mylo-hyoid muscles into the submandibular space, and thence in front of the hyoid bone (having embraced the tendon of the digastric) to join glands in the carotid triangle (Figs. 1180, 1181). Both apical and marginal trunks may cross the median line of the neck to join glands on the opposite side. Thus in malignant lesions of the tongue it is important to examine both sides of the neck for evidence of glandular spread.

Cavity of Mouth.—The groove between the tongue and the gums is crossed in the median plane by the **frenulum linguæ** (Fig. 1204). At each side of the lower part of the frenulum is the **orifice of the submandibular duct**. A little to one side of the frenulum the **profunda vein** is seen through the thin mucous membrane; to the lateral side of the vein are the profunda artery and the lingual nerve, both of which lie deeper in the tongue than the vein and are therefore not visible.

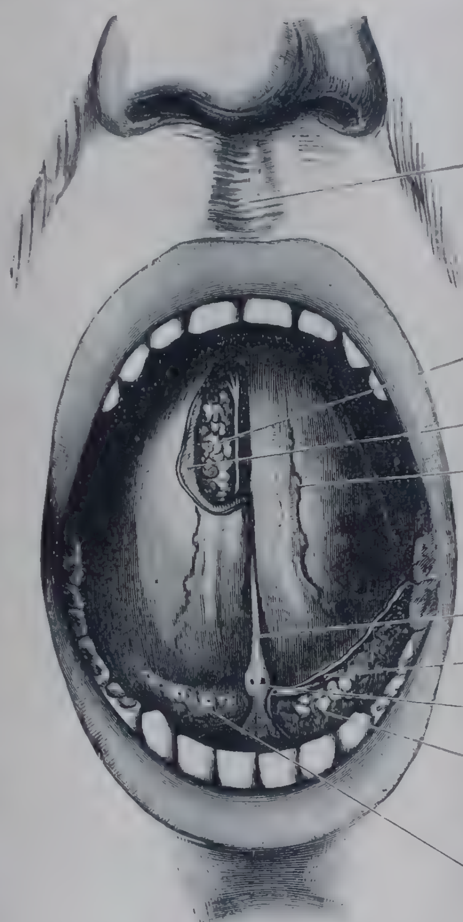

Fig. 1204.—Open Mouth with Tongue raised and Sublingual and Anterior Lingual Glands exposed.

A branch of the lingual nerve is seen running on the medial side of the sublingual gland.

The position of the profunda artery is indicated by the overlying edge-like fold of mucous membrane—the fimbriated fold.

The mucous membrane at the anterior part of the floor of the mouth is thrown into a slight elevation which overlies and is caused by the corresponding **sublingual salivary gland**. The duct of the submandibular gland and the lingual nerve lie below and to the medial side of the sublingual gland.

When a shortened frenulum is divided for "tongue-tie" the deep lingual vessels and the orifices of the submandibular ducts must be avoided. Behind the frenulum linguæ are the anterior borders of the **genio-glossus muscles**, which ascend from the superior genial tubercles. In removing a small salivary calculus from the floor of the mouth, the calculus is fixed against the lingual surface of the mandible before the incision is made over it.

When the teeth are clenched the only communication between the vestibule of the mouth and the oral cavity proper is an opening behind the last molar tooth which can barely admit a medium-sized catheter. Therefore, when the

jaws cannot be separated it is generally necessary to feed the patient through a tube passed along the floor of the nose.

When the mouth is opened widely and a deep inspiration is taken, the soft palate is elevated, and the palato-glossal and palato-pharyngeal arches are made prominent. The **palato-glossal arches** spring from the anterior surface of the soft palate close to the base of the uvula, and they arch downwards and laterally in front of the tonsils to end at the posterior part of the side of the tongue. The **palato-pharyngeal arches** are really the continuation of the free border of the soft palate downwards behind the tonsils to be lost upon the side-

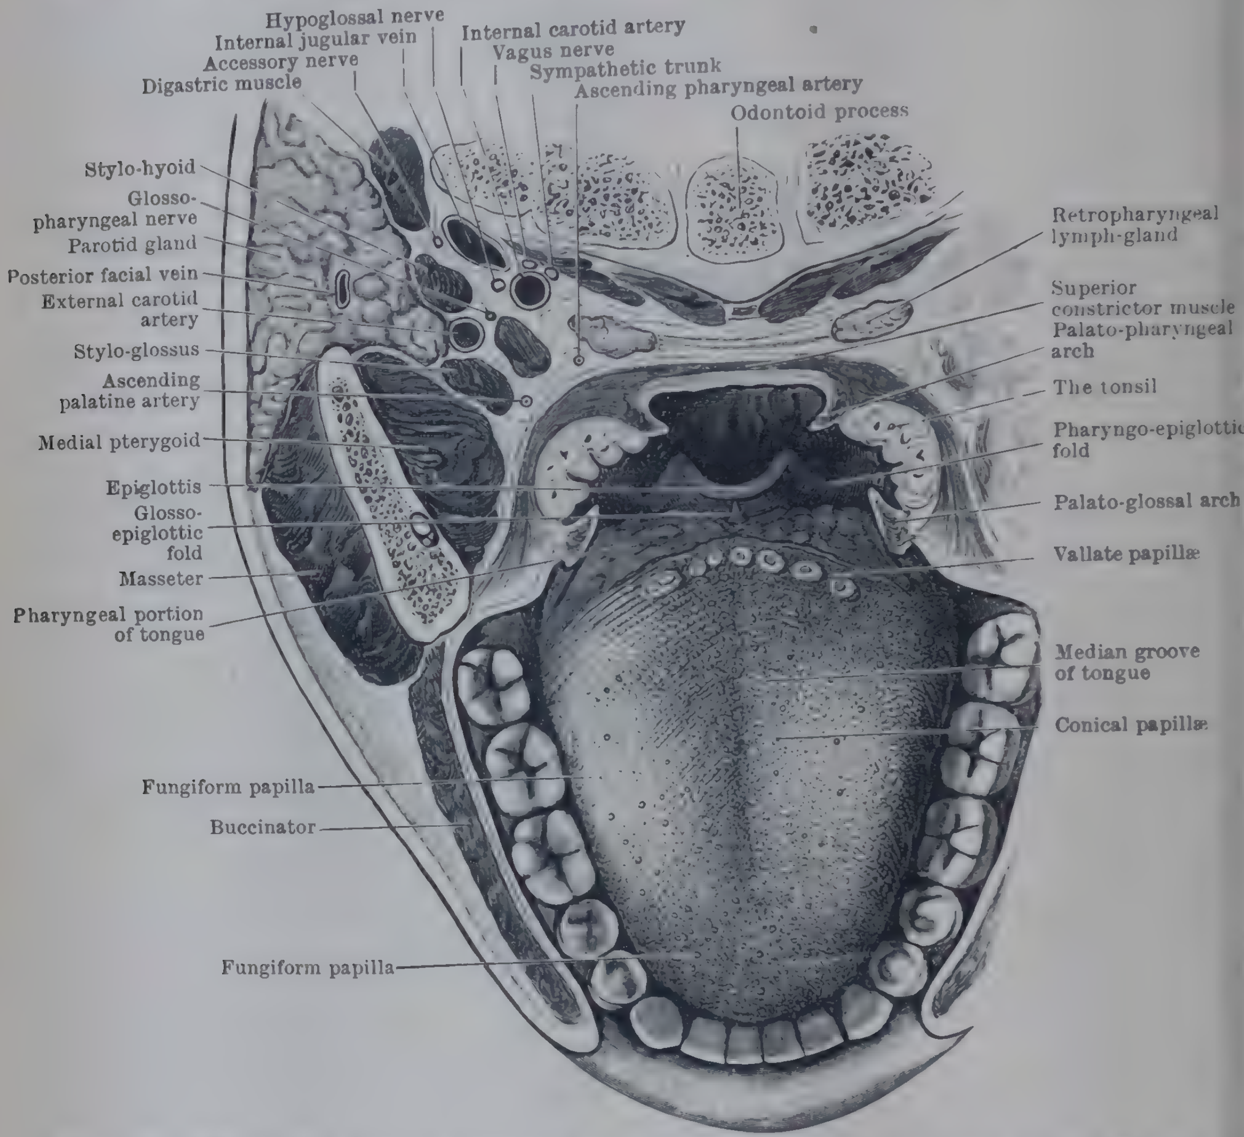

FIG. 1205.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE TONSILS. The stylo-pharyngeus (which is seen on the medial side of the external carotid artery) and the prevertebral muscles are not indicated by reference lines.

wall of the pharynx. Together with the lower edge of the soft palate and the posterior wall of the pharynx, they bound an oblique opening **(pharyngeal isthmus)** through which the mucous membrane of the posterior wall of the nasal portion of the pharynx is visible.

In the *adult* the upper four cervical vertebræ can be explored from the mouth (Pl. XXIX, Fig. 1, p. 342); in the *child* the finger can reach still farther—down to the sixth vertebra and the back of the cricoid cartilage.

Tonsils (Fig. 1205).—The **tonsil** lies in the side-wall of the pharynx between the palatine arches, opposite a point a little above the angle of the mandible. It is covered, on its free surface, with mucous membrane upon which are seen the orifices of the *tonsillar pits* ; the lateral or deep surface is covered with a layer of fibrous tissue which forms an imperfect sheath for the organ and is separated from the superior constrictor by a quantity of loose areolar tissue and fat, and the tonsil can therefore

be grasped with a volsellum and pulled forwards without dragging the muscle with it. The tonsil receives its *blood-supply* mainly from the tonsillar branch of the facial artery; when that branch is larger than usual and adherent to the sheath of the tonsil, the bleeding which attends the operation of removal of the tonsils may be considerable. To arrest the hæmorrhage the bleeding point is pressed outwards against the medial pterygoid and the ramus of the mandible. If the bleeding is from a spurting vessel of larger size, its source is probably the *facial artery*, which has been wounded as it arches upwards deep to the digastric and stylo-hyoid muscles and is separated from the lateral surface of the tonsil only by the superior constrictor muscle. In children and adolescents the tonsils are frequently hypertrophied; the enlargement may be either general, or local; in the latter event the enlargement may be towards the median line, downwards along the pharynx, or upwards behind the soft palate.

The mucous membrane and the periosteum of the **hard palate** are so closely united as to form practically one membrane. The **greater palatine arteries**, after leaving the greater palatine foramina, run forwards in shallow grooves in the bony palate, close to its alveolar margin. In the operation for cleft palate (*staphylorrhaphy*), if lateral incisions are employed, they should be made *lateral* to those vessels in order that nourishment for the muco-periosteal flaps may be ensured. In the operation to close a wide cleft of the soft palate the tension of the **tensor palati muscle** is lessened if the **pterygoid hamulus** is fractured at the posterior end of the lateral relief-incisions.

Nasal Part of Pharynx.—To explore the nasal part of the pharynx the finger is hooked upwards behind the soft palate. *Anteriorly*, the finger readily detects the sharp, posterior border of the vomer, the posterior aperture of the nose, and the posterior ends of the middle and inferior conchæ. The *roof* of the space is formed by the basilar part of the occipital bone, while on the *posterior wall* there is a transverse ridge formed by the anterior arch of the atlas. On each *side-wall* there is the opening of the **pharyngo-tympanic tube** situated 1·3 cm. behind the posterior end of the inferior concha. The orifice, bounded above and behind by a prominent margin, is directed downwards and forwards, and therefore in a direction favourable to the passage of the Eustachian catheter. Behind the posterior margin of the orifice there is the *recess of the pharynx*, in which the point of the catheter is apt to become engaged. On the roof and posterior wall of the pharynx, down to the level of the foramen magnum (Fig. 502, p. 586), and extending laterally as far as the orifices of the tubes, there is a collection of adenoid tissue called the **naso-pharyngeal tonsil**. Hypertrophy of that tissue constitutes the condition known as "*adenoids*", the harmful effects of which are due to their interference with nasal respiration. On the centre of the naso-pharyngeal tonsil there is an orifice leading into a small recess into which numerous mucous glands open. The structures felt in the naso-pharynx may be viewed by means of light reflected on a small mirror placed immediately behind and below the soft palate (*posterior rhinoscopy*). The lower part of the inferior concha is obscured from view by the bulging of the upper surface of the soft palate.

If the posterior wall of the pharynx is observed during the pronunciation of vowels it will be noticed that a transverse ridge appears immediately below the naso-pharyngeal tonsil, opposite the anterior arch of the atlas (Passavant's ridge). It is produced by the contraction of certain fibres of the superior constrictor muscle, and may be regarded as the posterior portion of a naso-pharyngeal valve or sphincter, described by Whillis (1930) as a 'palato-pharyngeal sphincter' (see pp. 441, 445).

When the posterior apertures of the nose have to be plugged it is important to remember that these openings are rather more than 2·5 cm. in height and about 1·3 cm. across. In the child, owing to the small size of the face, the vertical diameter of the naso-pharynx and the height of these apertures are relatively much smaller than in the adult.

The **retropharyngeal lymph-glands** are one or two pairs of glands that lie at the junction of the posterior wall and side walls of the pharynx, opposite the level of the hollow below the auricle. They are embedded in loose areolar tissue and are

afferent lymph-vessels from the mucosa of the nasal cavities and the air-sinuses, the naso-pharynx, the pharyngo-tympanic tubes, and the tympanic cavity. Their efferent lymph-vessels empty into the glands in the upper part of the carotid triangle. After the first year of life they undergo retrogressive changes, but they persist as lymphatic nodes until the tenth or twelfth year. In children, suppuration originating in one of them is the commonest cause of a retropharyngeal abscess.

THE NECK

Compartments.—The processes and partitions which proceed from the deep surface of the general envelope of **deep cervical fascia** divide the neck into compartments which limit and determine the spread of pus (Fig. 380, p. 446).

The most important compartment is the **visceral compartment**, which contains the larynx and trachea, the pharynx and œsophagus, and is bounded *anteriorly* by the pretracheal fascia, *posteriorly* by the prevertebral fascia, and *laterally* by the fascia which encloses the vascular compartment. Inferiorly, the visceral compartment extends into the superior mediastinum ; superiorly, its posterior part extends to the base of the skull, but its anterior part reaches only to the hyoid bone. *Abscesses* in the compartment are either secondary to disease of the lymph-glands or other organs which it contains, or are the result of a primary suppurative cellulitis. A tubercular abscess originating in one of the retropharyngeal lymph-glands (Fig. 1205) lies *in front of* the prevertebral fascia and points into the pharynx ; abscesses secondary to disease of the cervical vertebræ lie *behind* the prevertebral fascia and spread laterally behind the vascular compartment ; they point behind the sterno-mastoid and are evacuated through an incision at the posterior border of the muscle—the surgeon keeping close to the transverse processes in order to avoid the structures in the vascular compartment.

In front of the visceral compartment there is a **small muscular compartment** which contains the infrahyoid muscles ; in front of it again, in the region of the suprasternal notch, is the small **suprasternal compartment**, which contains the anterior jugular veins and their transverse communicating branch (*jugular arch*), a little fat, and one or two lymph-glands.

The **vascular compartment** contains the carotid arteries and the internal jugular vein, and the following nerves: the vagus, part of the hypoglossal nerve, the descendens hypoglossi, and part of the accessory nerve. These structures are enveloped in an ill-defined fascial tube called the *carotid sheath*. The sheath is surrounded by areolar tissue in which a chain of lymph-glands is embedded ; normally, the glands may be readily separated from the sheath of the internal jugular vein, but they become adherent to it when they are inflamed. The sympathetic trunk and the inferior thyroid artery lie in the areolar tissue between the posterior wall of the carotid sheath and the prevertebral fascia ; they can be reached through an incision along the posterior border of the sterno-mastoid muscle—that muscle, along with the carotid sheath and its contents, being pulled well forwards. In the approach to the trunk of the inferior thyroid artery from the front the sterno-mastoid and carotid sheath are displaced laterally and the dissection is continued through the areolar tissue between the carotid sheath and the sheath of the thyroid gland, which is formed by the pretracheal fascia.

A glandular abscess in the vascular compartment usually points on the surface, adhesions being formed, first, between the gland and the fascia, and, subsequently, between the fascia and the cutaneous structures. In diffuse suppurative cellulitis of the compartment the pus burrows towards the root of the neck, and may reach either the mediastinum or the axilla.

Median Line of Neck.—The body of the **hyoid bone** divides the median plane of the neck into **suprahyoid** and **infrahyoid portions**. Above the hyoid bone is the **submental triangle**, with its apex at the symphysis menti and its sides formed by the anterior bellies of the digastric muscles. In the floor of the triangle are the anterior portions of the mylo-hyoid muscles united by the median raphe (Fig. 1207). The most important structures in the triangle are the **submental lymph-glands**, which can usually be felt a little above the body of the hyoid

bone. In children they are a frequent seat of abscess secondary to impetigo of the lower lip and chin. About 2·5 cm. below the hyoid bone is the **laryngeal prominence**—more prominent in men than in women. On each side of the prominence are the laminæ of the thyroid cartilage, while between that cartilage and the hyoid bone there are the **thyro-hyoid membrane** and **ligaments**.

The wound in suicidal *cut-throat* is generally at the level of the thyro-hyoid interval. The more important structures usually divided are: (1) more or less of the left sterno-mastoid muscle, (2) the superior thyroid vessels, (3) the thyro-hyoid membrane, (4) the stem of the epiglottis, and, less frequently, (5) the carotid vessels, the internal jugular vein, and the internal laryngeal nerve. When the wound is above the hyoid bone, the lingual and facial vessels and the muscles of the tongue are the more important structures injured.

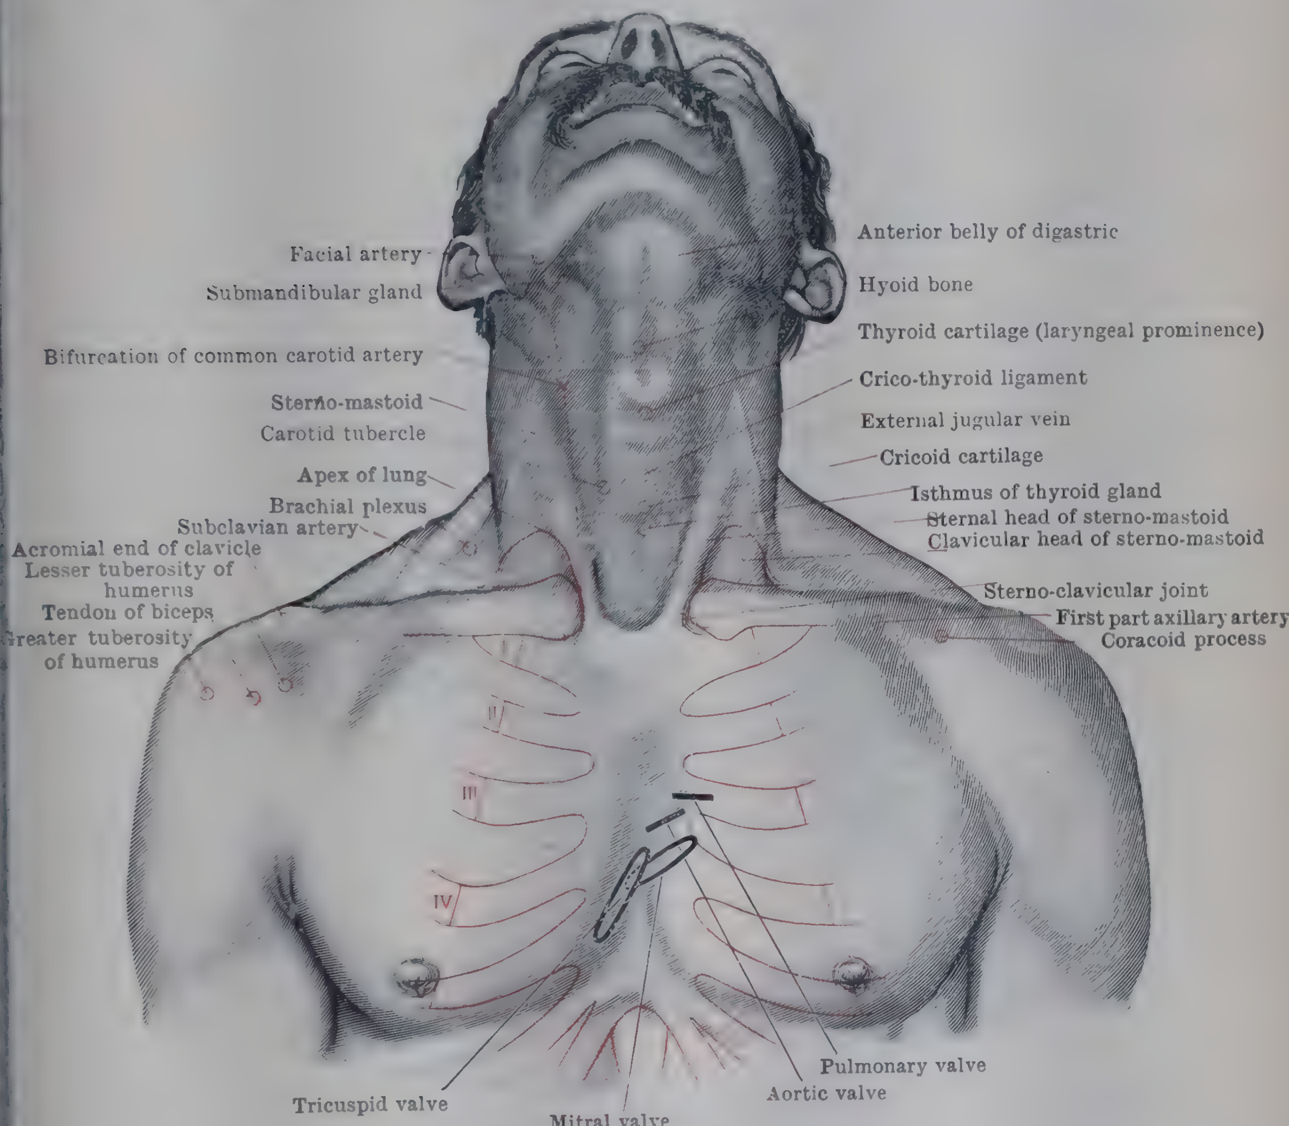

Fig. 1206.—Front of Neck and Shoulders.

The **rima glottidis** is opposite the middle of the anterior border of the thyroid cartilage.

In the operation of thyrotomy, care is taken to divide the thyroid cartilage exactly in the median plane in order that injury to the vocal folds may be avoided.

A little more than 2·5 cm. below the laryngeal prominence is the arch of the **cricoid cartilage**, which may be readily felt, and, when the neck is extended, often seen. Above the cricoid is the **crico-thyroid ligament**; in the operation of laryngotomy only the median portion of the ligament is divided, lest the crico-thyroid muscles be injured. The crico-thyroid branch of the superior thyroid artery lies close to the lower border of the thyroid cartilage.

Below the cricoid cartilage is the **trachea**, which recedes as it descends, so that it lies 4 cm. from the surface at the level of the upper border of the sternum. The **isthmus** of the **thyroid gland** usually lies in front of the second, third, and fourth

rings of the trachea (Fig. 1207), but may reach up to the cricoid. Immediately in front of the trachea, below the isthmus of the thyroid, is the pretracheal fat, containing one or two **lymph-glands** and the **inferior thyroid veins**, each represented by one or more branches which converge as they descend. The pretracheal lymph-glands receive afferent vessels from the larynx and thyroid gland, and their efferent vessels open into the glands along the lower part of the carotid sheath. In the adult the **innominate artery** crosses the front of the trachea at the level of the upper border of the sternum; in the child, however, it often crosses 1·3 cm. higher —a relation which must be remembered in the operation of low tracheotomy.

In the operation of **high tracheotomy** the upper three rings of the trachea are divided by a median incision. The incision divides the skin, the superficial fascia and the tributaries of the anterior jugular veins, the general envelope of deep cervical fascia, and (after

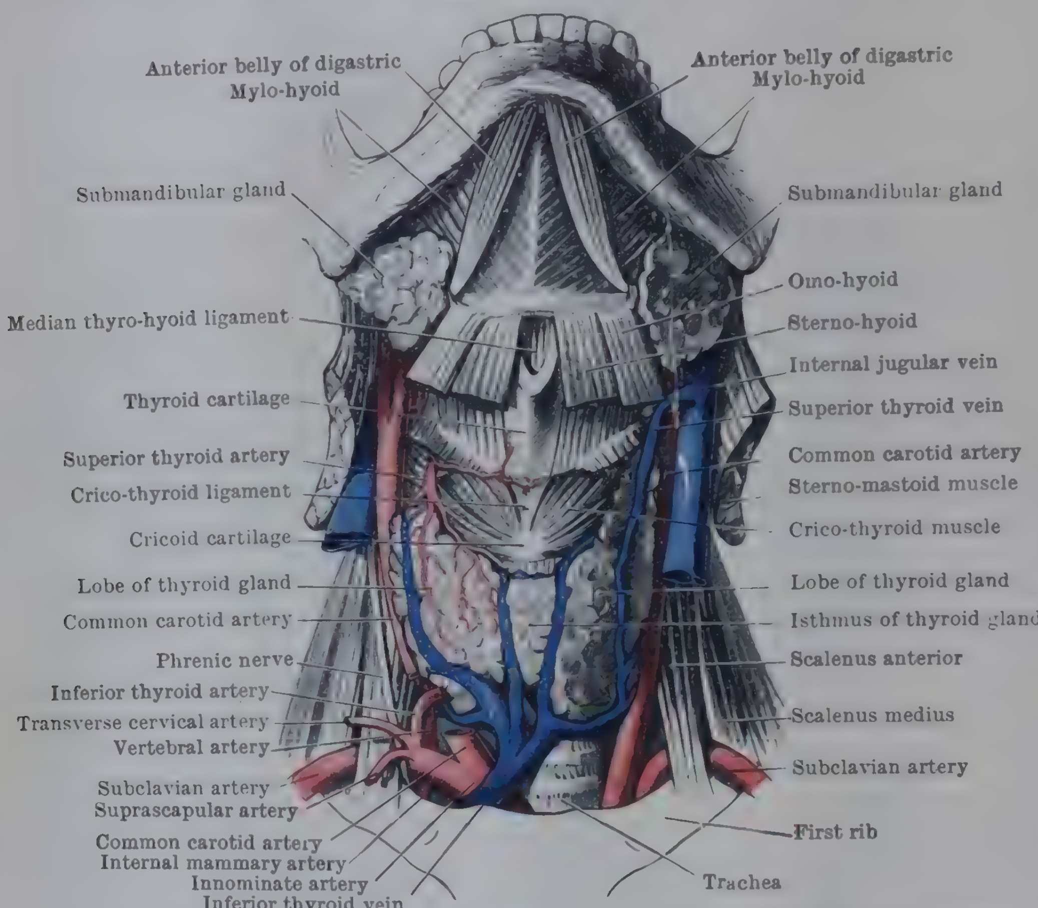

FIG. 1207.—DISSECTION OF FRONT OF NECK. The lower portions of the sterno-mastoid muscles and right common carotid artery have been removed to show the deeper parts.

passing between the right and left infrahyoid muscles) the pretracheal fascia, which descends from the cricoid to enclose the isthmus of the thyroid gland. If this fascia is divided transversely below the cricoid, the isthmus may be pulled downwards and the upper rings of the trachea exposed. In opening the uppermost part of the trachea, the operator keeps the edge of the knife directed upwards to avoid injuring the vessels at the upper border of the isthmus. The anterior jugular veins are in danger of being wounded if the skin incision is not strictly median.

In **low tracheotomy** the trachea below the isthmus is opened; it is a more troublesome operation, on account of the depth of the trachea and the presence in front of it of the inferior thyroid veins and of the anastomosis between the anterior jugular veins. In children the difficulty is increased by the higher position of the innominate artery and left innominate vein, by the presence of the thymus, and by the shortness of the neck.

Thyroid and Parathyroid Glands.—The **thyroid gland** is moulded on and adherent to the front and sides of the upper part of the trachea and the lower and posterior portions of the sides of the larynx, and is covered by the infrahyoid muscles and overlapped by the sterno-mastoid. The posterior borders of its lobes come in contact with the œsophagus and lower part of the pharynx, and overlap the carotid sheath.

ay of

The thyroid gland, like the prostate, has its own proper capsule and also a sheath derived from the fascia. The capsule, like that of the liver, is inseparably connected with the gland. The sheath is derived from the pretracheal fascia, which splits to enclose the gland; and it is separated from the capsule by an interval which is filled with areolar tissue and is crossed by branches of the thyroid arteries and veins on their way to and from the gland. The veins anastomose very freely, making conspicuous networks between the capsule and the sheath.

The surgeon reaches the gland in the median plane through the interval between the infrahyoid muscles. If, in order to obtain more room, he has to divide the infrahyoid muscles on one or both sides, that should be done towards their upper attachments, as their nerves of supply, derived from the ansa hypoglossi, enter the muscles near their lower attachments. By freely dividing the pretracheal fascia where it forms the anterior portion of the sheath of the thyroid,

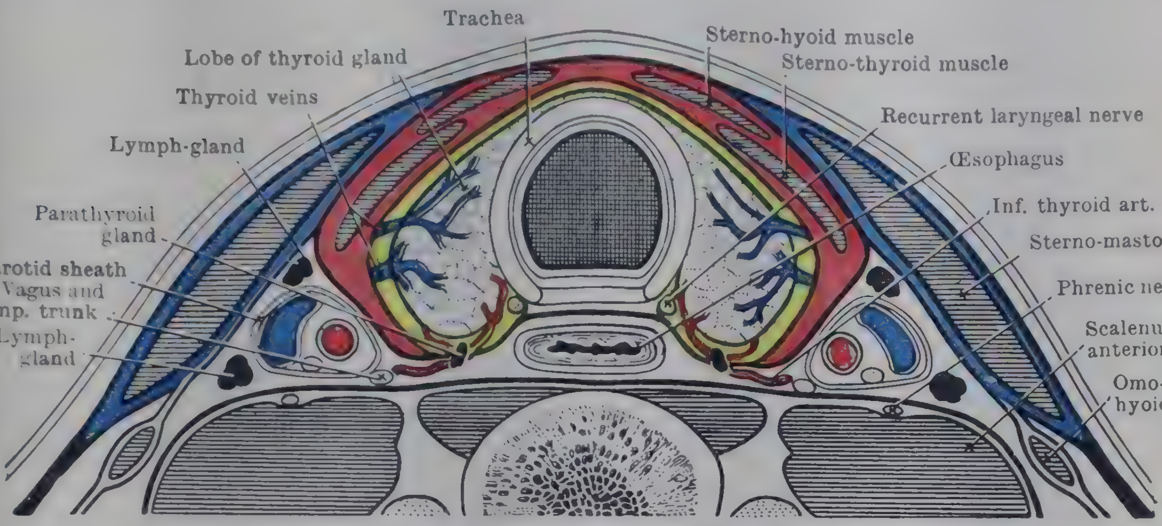

FIG. 1208.—DIAGRAM OF RELATION OF CERVICAL FASCIA TO THYROID GLAND.
Blue = deep cervical fascia (sterno-mastoid layer). Red = sheath of thyroid gland (pretracheal fascia). Yellow = capsule of the thyroid gland. (Modified from De Quervain, 1924.)

the surgeon can deliver the gland out of the wound so that the main vessels may be brought into view and ligatured.

To expose the superior thyroid vessels, the upper pole of the lobe is freed and drawn downwards and forwards. The inferior thyroid trunk may be secured as it lies between the carotid sheath and the prevertebral fascia, or its branches may be ligatured one by one as they enter the gland. In the operation of subtotal thyroidectomy, the postero-medial part of the capsule and a layer of thyroid tissue are preserved, in order to protect the parathyroids and the recurrent laryngeal nerve; the relation of the latter to the inferior thyroid artery is variable.

The **parathyroid glands** can generally be distinguished from the thyroid tissue itself, and from the lymph-glands, by their greyish-yellow colour and by their smooth and shining surfaces. Each superior parathyroid is embedded in the posterior border of the lobe opposite the cricoid cartilage. It is in close relation to the pharyngo-œsophageal junction, from which it is separated by the posterior part of the sheath of the thyroid gland. The inferior parathyroid, on each side, is supplied by a small vessel from one of the branches of the inferior thyroid artery; it also lies within the sheath and is on the back of the lower pole of the gland, a little lateral to the inferior thyroid artery and the recurrent laryngeal nerve. When the inferior thyroid artery has been ligatured, the medial glandular branch of the superior thyroid artery furnishes a sufficient blood-supply to the inferior parathyroid (see also p. 817). The positions of the parathyroid glands are variable.

Triangles of Neck.—The side of the neck is divided into an **anterior** and a **posterior triangle** by the sterno-mastoid muscle; the anterior triangle is further subdivided into *digastric, carotid,* and *muscular triangles* by the digastric and omo-hyoid muscles.

The **sterno-mastoid muscle** is one of the most important superficial landmarks of the neck. The anterior border of the muscle, the more distinct of the two, may be felt along its whole extent. Between the prominent sternal origin

and the broad, ribbon-like clavicular origin there is a slight triangular depression which overlies the lowest part of the internal jugular vein.

By dividing the cervical fascia along the anterior and posterior borders of the muscle the surgeon is able to displace the muscle backwards and forwards and so obtain free access to the structures deep to it. If the posterior fibres of the muscle are divided at their clavicular and cranial attachments the muscle is made still more freely movable. As the fascia along its posterior border is cut, the cutaneous branches of the cervical plexus are usually divided, but care is taken to preserve the accessory nerve. Should it be necessary to remove the upper third or more of the muscle, the divided end is stitched to the levator scapulæ or to the scalenus medius, according to the amount resected. When the muscle is completely cut across at the lower part of the neck, as is done, for example, in congenital wry-neck, the close relation of the anterior and external jugular veins to its two borders must be kept in mind. After division of the muscle, the lower part of the superior belly of the omo-hyoid is seen, lying on that part of the carotid sheath which overlies the internal jugular vein. In block dissection of the neck for malignant glands, the whole muscle is removed with the internal jugular vein and its related **lymph-glands.**

Digastric Triangle.—The chief structure in this triangle is the **submandibular gland**, which is overlapped by the body of the mandible and reaches down to the greater horn of the hyoid bone. The **anterior facial vein** passes downwards and backwards, superficial to the gland, while the **facial artery**, embedded in its deep surface, arches upwards under cover of the angle of the mandible, where it approaches the tonsil, being separated from it, however, by the superior constrictor of the pharynx. The *floor* of the digastric triangle is formed, from before backwards, by the mylo-hyoid, hyo-glossus, and superior constrictor of the pharynx. The **lymph-glands** of the space receive their lymph from the face, lips, teeth and gums, tongue, and floor of the mouth ; hence the frequency with which they become the seat of abscess formation and malignant enlargement. To palpate them the surgeon stands behind the patient and feels the glands between a finger of one hand in the floor of the mouth, and a finger of the other hand thrust well up medial to the mandible, the chin of the patient being depressed to relax the cervical fascia.

Carotid Triangle.—The central landmark of the carotid triangle is the **greater horn of the hyoid bone**, the tip of which, when the fascia is relaxed, may be felt, at the anterior border of the sterno-mastoid, about 2·5 cm. below the angle of the mandible. The deep cervical fascia holds the upper part of the sterno-mastoid forwards towards the angle of the mandible, so that, with the fascia undivided, the anterior border of the sterno-mastoid overlaps the internal jugular vein and the bifurcation of the common carotid artery.

The **course of the carotid vessels** is indicated, on the surface, by a line extending from the sterno-clavicular joint to the lobule of the auricle ; a point on that line, at the level of the upper border of the thyroid cartilage, is opposite the **bifurcation of the common carotid**. The **superior belly** of the **omo-hyoid** crosses the common carotid very obliquely at the level of the lower border of the larynx. The pulsations of the carotid vessels may be felt in the hollow between the larynx and the sterno-mastoid. In the carotid triangle the **external carotid** lies medial and anterior to the internal carotid. Ligation of the external carotid is performed between its superior thyroid and lingual branches (which are also secured) immediately below the tip of the greater horn of the hyoid bone ; the difficulty in the operation is due to the plexus of veins (formed by the common facial, lingual, and superior thyroid veins) which overlies the artery. The lingual and facial arteries sometimes arise from a common trunk which must not be mistaken for the external carotid. The **superior thyroid artery** arises opposite the upper horn of the thyroid cartilage, which may be felt 2·5 cm. or less below the tip of the greater horn of the hyoid bone. The vessel is the common source of arterial hæmorrhage in cut-throat.

From a surgical point of view the **internal jugular vein** is the most important structure in the whole anterior triangle. In the carotid triangle it overlaps the carotid vessels, and its sheath is under cover of the general envelope of deep cervical fascia, from which it is separated by loose areolar tissue. About the level of the hyoid bone it receives the common facial vein, which is a large vessel ; at a lower level it receives the superior and middle thyroid veins, which are often

greatly enlarged in goitre—the superior vein entering it opposite the upper part of the larynx and the middle vein at the lower pole of the thyroid gland.

The term **deep cervical glands** includes a broad chain of lymph-glands which is closely related to the internal jugular vein and stretches from the transverse process of the atlas to the root of the neck (Figs. 1175-1177).

The chain is divided into medial and lateral parts by the internal jugular vein. The medial division extends from the level of the posterior belly of the digastric muscle and the stylo-mandibular ligament to the lower border of the superior belly of the omo-hyoid muscle—the main group, which includes the jugulo-digastric gland (p. 1433), occupying a triangle bounded above by the posterior

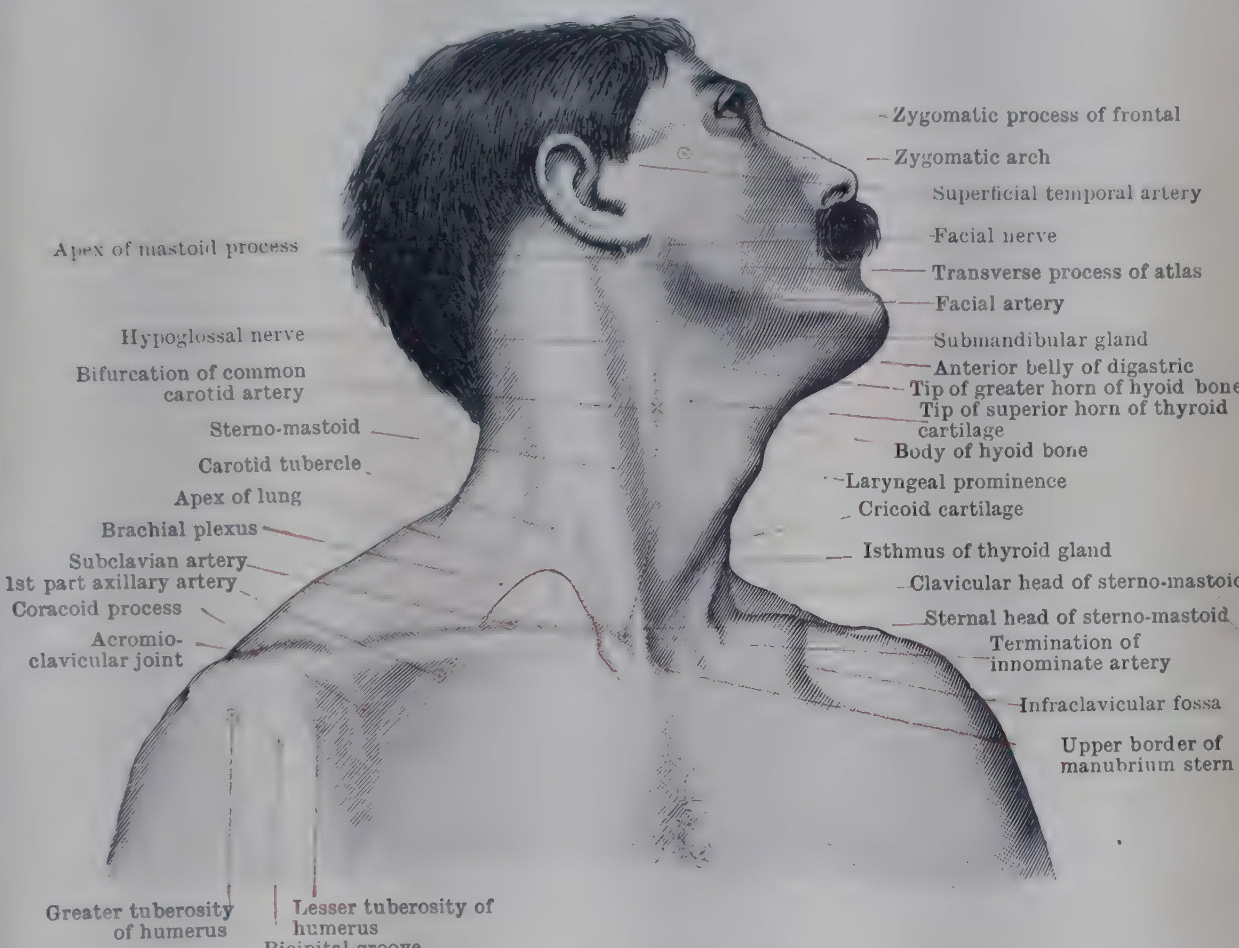

FIG. 1209.—SIDE OF THE NECK.

belly of the digastric muscle, in front by the common facial vein, and posteriorly by the internal jugular vein.

Lymph from the tonsil passes to this group, and, as the tonsil is one of the principal portals of entry of tuberculous infection, the jugulo-digastric glands are those most commonly affected by the disease. These glands receive lymph from the back of the tongue also, and they are therefore affected secondary to malignant disease of that organ (p. 1469).

The lateral chain lies postero-lateral to the internal jugular on the attachments of the scalenus medius and levator scapulæ muscles. These glands are smaller than those of the medial group, but when enlarged they may form a swelling which projects across the posterior triangle as far as the trapezius. They are embedded in a quantity of fibro-fatty tissue which encloses the branches of the cervical plexus including those to the trapezius; and, when the mass is greatly swollen, the accessory nerve may be embedded in it near the sterno-mastoid. They receive lymph from the posterior and lateral walls of the pharynx and the posterior portion of the tongue.

The lowest glands of the group (inferior deep cervical glands) are supra-clavicular in position, and they are divided into a superficial and a deep cluster by

the omo-hyoid muscle and the second layer of deep cervical fascia. The deeper ones receive afferent vessels from the apical (infraclavicular) group of axillary glands.

The **hypoglossal nerve**, in the carotid triangle, is overlapped by the lower border of the posterior belly of the digastric muscle. It runs forwards, superficial to the internal and external carotid and lingual arteries, immediately below the origin of the inferior sterno-mastoid branch of the occipital artery. The **vagus nerve** descends vertically, within the carotid sheath, behind and between the carotid vessels and the internal jugular vein; care must be taken not to include it when ligaturing the common carotid artery or the internal jugular vein. Surgically, the **accessory** is the most important nerve in the anterior triangle; it enters the substance of the sterno-mastoid muscle opposite the angle of the mandible; it is always exposed in the removal of the lateral group of deep cervical glands. The course of the nerve in the carotid and posterior triangles may be mapped out by a line drawn from a point midway between the tip of the mastoid process and the angle of the mandible to a point a little above the middle of the posterior border of the sterno-mastoid, and thence across the posterior triangle to the anterior border of the trapezius about 5 cm. above the clavicle. The deeper guides to the nerve are the posterior belly of the digastric, which is superficial to it, and the internal jugular vein, which it crosses very obliquely, from above downwards and backwards, below and in front of the **transverse process of the atlas** (felt as a distinct bony resistance midway between the tip of the mastoid process and the angle of the mandible). The superior sterno-mastoid branch of the occipital artery lies in close relation to the nerve, and often serves as a guide to the nerve when it is obscured by diseased tissues.

In paralysis of the trapezius muscle from injury to the accessory nerve the shoulder droops and is pulled forwards and medially by the pectoralis major and minor muscles. If the paralysis occurs during childhood the chest on the same side becomes flattened in front, owing to the adaptive shortening of the pectorals and to their diminished pull on the ribs. Unless that mechanism is appreciated the infraclavicular flattening of the chest is very liable to be erroneously attributed to pulmonary tuberculosis. The upper part of the accessory nerve is surrounded by the upper lateral group of deep cervical glands; it is in that situation, and again when it emerges from under cover of the posterior border of the sterno-mastoid muscle, that it is liable to be injured in operations for the removal of tuberculous glands.

The **cervical part of the sympathetic trunk** lies in the posterior wall of the vascular compartment of the neck, and may be reached by an incision along the posterior border of the sterno-mastoid: the anterior surfaces of the roots of the transverse processes of the vertebræ are the deep guides to the trunk.

The **cervical plexus** lies deep to the upper half of the sterno-mastoid on the levator scapulæ and scalenus medius muscles, and it may be exposed through an incision along the posterior border of the upper half of the sterno-mastoid muscle. The **phrenic nerve**—the most important branch of the cervical plexus—arises 2·5 cm. above the carotid tubercle and descends almost vertically towards the medial part of the clavicle; it is overlapped by the lateral margin of the internal jugular vein. Although the surgeon frequently exposes the phrenic nerve in removing the lower medial group of deep cervical glands, it is protected from injury by the fascia which binds it down to the scalenus anterior. In the operation of **phrenic avulsion**, practised in certain cases of pulmonary tuberculosis, the nerve is exposed through an incision parallel to and one finger's breadth above the upper border of the clavicle.

Muscular Triangle.—This is an important triangular intermuscular space bounded by the sterno-mastoid, the superior belly of the omo-hyoid, and the median line of the neck. Behind that space, there is a deeper space which is bounded by the longus cervicis and scalenus anterior muscles, and whose apex is the anterior tubercle of the transverse process of the sixth cervical vertebra. By making an incision along the anterior border of the left sterno-mastoid muscle, and passing through the muscular triangle into the deeper space, the surgeon reaches the internal jugular vein, the common carotid artery, the vagus, the thoracic duct, the middle cervical ganglion of the sympathetic, the inferior thyroid artery, the

vertebral vessels, the recurrent laryngeal nerve, and the œsophagus. The most important bony landmark in the deeper space is the anterior tubercle of the transverse process of the sixth cervical vertebra. The common carotid artery may be compressed against that tubercle, which is therefore termed the "*carotid tubercle*". It is the most important guide to the vertebral artery, for the artery enters the foramen in the transverse process of the sixth cervical vertebra.

The **cervical portion of the œsophagus** begins at the level of the cricoid cartilage and descends behind the trachea, protruding a little beyond its left margin. To expose it the muscular triangle is entered by an incision along the lower two-thirds of the anterior border of the left sterno-mastoid muscle; the pretracheal fascia is divided and the dissection carried between the trachea and the carotid sheath down to the longus cervicis muscle medial to the inferior thyroid artery and vertebral vessels. The lower pole of the lobe of the thyroid gland is pulled medially along with the trachea. The œsophagus lies in the loose areolar tissue in front of the prevertebral fascia, and is therefore sufficiently movable to be brought to the surface. If the œsophagus has to be opened care must be taken not to injure the **recurrent laryngeal nerve**, which ascends in the groove between it and the trachea; and also the loose submucous coat must not be mistaken for the lumen of the tube. The so-called "pulsion-diverticulum of the œsophagus" does not take origin from the upper part of the gullet; it begins as a hernia-like protrusion of the posterior wall of the pharynx, between the oblique and the transverse fibres of the inferior constrictor muscle. During the act of swallowing, the transverse fibres act as a sphincter, while the oblique fibres elevate the larynx. If the sphincter should fail to relax during the detrusor action of the pharynx it is not difficult to understand how a diverticulum might arise, and, when once produced, why it should undergo progressive enlargement.

The **thoracic duct,** after entering the left side of the root of the neck between the œsophagus and the pleura, ascends to about 2·5 cm. above the clavicle. At that level it arches laterally behind the carotid sheath but in front of the vertebral vessels. Great care must therefore be taken not to injure the duct during removal of the lymph-glands which lie in the loose areolar tissue behind the lower part of the internal jugular vein, between it and the vertebral vein, at the medial border of the scalenus anterior. A few small lymph-glands lie along the sides of the cervical portions of the trachea and œsophagus; they receive their afferent vessels from the larynx, trachea, œsophagus, and thyroid gland.

Posterior Triangle.—The posterior triangle is bounded in front by the sterno-mastoid muscle, and behind by the anterior border of the trapezius muscle; its apex is at the meeting-point of these two muscles on the superior nuchal line; and its base corresponds to the middle third of the clavicle. The inferior belly of the omo-hyoid muscle cuts off the lower portion of the large triangle as a small supraclavicular triangle.

The roof of the triangle is the general envelope of deep cervical fascia; the fascia which covers the muscles of its floor, as well as that which covers the brachial nerve-trunks and the subclavian artery, is a lateral continuation of the prevertebral fascia. Numerous lymph-glands are embedded in the areolar tissue between these two layers of fascia. During removal of these glands, every endeavour should be made to preserve the motor nerves.

The **accessory nerve,** after entering the posterior triangle a little above the middle of the posterior border of the sterno-mastoid, crosses the triangle parallel to the fibres of the levator scapulæ muscle. It leaves the triangle by passing under cover of the anterior border of the trapezius about 5 cm. above the clavicle. The **lesser occipital nerve** curves round the accessory from below upwards, superficially, at the posterior border of the sterno-mastoid; it furnishes, therefore, a useful guide to the position of that important motor nerve.

The **nerve to the rhomboids** crosses the triangle below the accessory, and enters the fascial septum between the levator scapulæ and scalenus medius muscles. The **nerve to the serratus anterior** arises from the fifth, sixth, and seventh cervical nerves. The roots from the fifth and sixth pierce the scalenus medius and join the root from the seventh (which runs superficial to the muscle) in the axilla.

The **suprascapular nerve** is seen arising from the lateral edge of the upper trunk of the brachial plexus a little above the inferior belly of the omo-hyoid muscle.

</table>

TABLE I.—SEGMENTAL INNERVATION OF MUSCLES OF UPPER LIMB.

The loops of the **cervical plexus** lie under cover of the upper part of the sterno-mastoid muscle, between it and the origins of the levator scapulæ and the upper part of the scalenus medius muscles, and they are overlapped by the internal jugular vein.

The **inferior belly of the omo-hyoid** passes deep to the posterior border of the sterno-mastoid at a point about 2·5 cm. above the clavicle. The **external jugular vein**—usually visible through the skin—runs in a line from the angle of the jaw to the junction of the medial and middle thirds of the clavicle. It pierces the deep fascia at the posterior border of the sterno-mastoid about 2·5 cm. above the clavicle, and, as its walls are adherent to the margins of the aperture, its lumen is kept open at that point; hence a wound of the vein in that situation is liable to be followed by the suction of air into the blood-stream during inspiration.

The **third part** of the **subclavian artery** can be compressed against the first rib by pressure directed downwards and backwards, immediately above the clavicle, a little behind the posterior border of the sterno-mastoid muscle. To map out the *course* of the subclavian artery in the neck, a line is drawn, convex upwards, from the upper border of the sterno-clavicular joint to the middle of the clavicle, the highest part of the arch to reach from 1·3 to 2·5 cm. above the bone.

To *ligature the vessel* in the third part of its course, an incision is made parallel to, and one finger's breadth above, the medial two-thirds of the clavicle. It may be necessary to divide the clavicular head of the sterno-mastoid muscle. The most important guides to the vessel are the inferior belly of the omo-hyoid, the lateral border of the scalenus anterior, and the scalene tubercle of the first rib. The close relation of the vessel to the lowest trunk of the brachial plexus and to the cervical pleura must be kept in mind. In the rare instances in which a cervical rib is present the subclavian artery lies either in front of it, or arches above it, according to the degree of development of the rib. The **subclavian vein** lies below and in front of the artery, separated from it by the scalenus anterior, and altogether under cover of the clavicle.

Brachial Plexus.—Entering the posterior triangle, from behind the lateral border of the scalenus anterior, are the roots of the **brachial plexus**. They unite to form the three trunks of the plexus, which lie on the scalenus medius—the lower trunk behind the third part of the subclavian artery, the other two above the artery. The upper part of the plexus can be felt through the skin.

The segmental innervation of the muscles of the upper limb is shown in Table I. For the cutaneous distribution of the nerves of the brachial plexus, see Fig. 928, p. 1074, and for the dermatomes of the upper limb, Fig. 929, p. 1075.

When the first thoracic nerve is ruptured within, or close to, the vertebral canal, the sympathetic fibres which run in it on their way to join the inferior cervical ganglion are torn across. The result is that, among other signs, there will be: (1) contraction of the pupil, due to paralysis of the dilatator pupillæ; and (2) narrowing of the palpebral fissure, due to paralysis of the involuntary fibres of the upper eyelid. This combination is known as *Horner's Syndrome.*

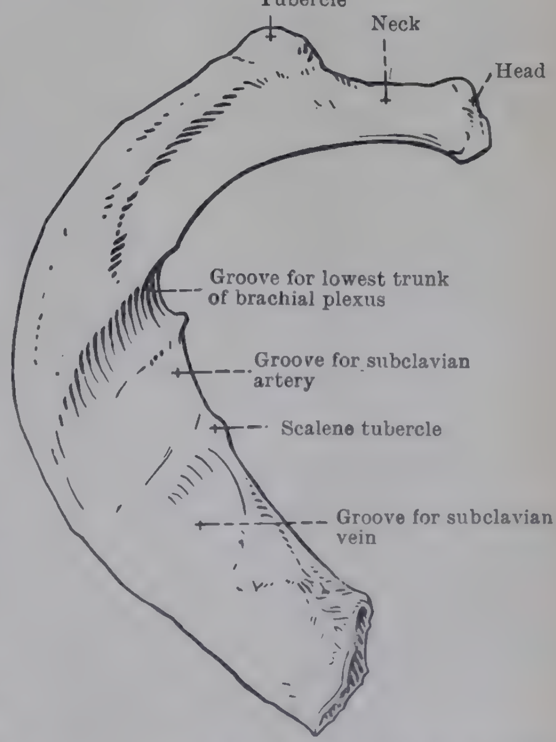

Fig. 1210.—Right First Rib, seen from above.

As regards the cutaneous distribution in the upper limb, the sensory fibres from the lateral (pre-axial) border of the upper arm enter the fifth nerve, while those from the lateral half of the forearm and hand enter the sixth nerve. The fibres from the centre of the surface of the hand on both palmar and dorsal surfaces and adjacent sides of middle and ring fingers enter the seventh nerve. The fibres from the medial (post-axial) part of the hand enter the eighth cervical nerve; those from the medial border of the forearm enter the first thoracic; and those from the medial side of the upper arm run in the second thoracic nerve (Fig. 929, p. 1075).

The carotid tubercle lies between the anterior primary rami of the sixth and

seventh cervical nerves. The fifth and sixth cervical nerves are those which suffer most when the plexus is injured by forcible depression of the shoulder while the head is bent to the opposite side, such as occurs, for instance, in "obstetrical paralysis". The lowest trunk of the plexus is the one most liable to be overstretched when traction is applied either to the upper limb or to the rest of the body when the limb is elevated above the shoulder; the result is a paralysis of the small muscles of the hand.

The trunks of the brachial plexus may be exposed through an incision from the junction of the middle and lower thirds of the posterior border of the sterno-mastoid downwards and laterally to the junction of the lateral and middle thirds of the clavicle.

As the neuro-vascular bundle for the upper limb leaves the thoracic outlet, it may be subjected to pressure to which the following may contribute: an unusually high first rib, an abnormal first rib, or a cervical rib; adjacent parts of the scalenus anterior, scalenus medius or scalenus pleuralis muscles; the first rib and the clavicle. As a result, there may be signs of vascular insufficiency, with or without signs of impaired function of the brachial plexus, usually in the territory of the first thoracic nerve.

Back of Neck.—In the posterior median line of the neck is the **nuchal furrow** at the bottom of which are the cervical spines and the ligamentum nuchæ. At the upper part of the furrow, about 5 cm. below the external occipital protuberance, is the **spine of the axis vertebra**, which is large and can be distinctly felt; a line drawn from it to the transverse process of the atlas corresponds to the position of the inferior oblique muscle and, therefore, to the inferior margin of the **suboccipital triangle**. The course of the deep part of the **greater occipital nerve** may be mapped out by a line from the middle of the above-mentioned line to a point 2·5 cm. lateral to the external occipital protuberance. In the floor of the suboccipital triangle is the posterior arch of the atlas, upon which the third part of the **vertebral artery** lies.

THORAX

WALLS OF THORAX

In the male the **nipple** is placed usually over the fourth interspace, or the fifth rib, 10 cm. from the median plane. In the child the nipple may be as high as the lower border of the third rib. In the female the position of the nipple is so variable that it is of no topographical value.

In muscular subjects there is a well-marked median furrow between the sternal origins of the right and left **pectoralis major muscles**. The medial part of the lower border of each of these muscles forms a curved prominence which lies over the fifth rib. Below that prominence there is a more or less flat surface that corresponds to the upper part of the rectus abdominis muscle. In the axillary and infra-axillary regions there are the prominences caused by the digitations of origin of the **serratus anterior**, the first to appear below the pectoralis major being that which springs from the fifth rib.

The **upper border** of the **sternum** lies in the same horizontal plane as the lower border of the body of the second thoracic vertebra, the distance between the two being about 5 cm. The manubrium and the body of the sternum form a slight angle at their junction, known as the *sternal angle*. At the angle there is a horizontal ridge which, although not always visible, can always be felt. The angle is in the same plane as the upper border of the body of the fifth thoracic vertebra.

The **xiphi-sternal joint** is opposite the ninth thoracic vertebra, and is felt as a short, transverse ridge between the seventh pair of costal cartilages, immediately above a shallow depression called the **epigastric fossa**, in whose floor the xiphoid process can be felt.

The xiphoid process lies in the wall of the abdomen in front of the liver, for the xiphi-sternal joint marks the junction between the thorax and abdomen in

the median plane, and in that situation it is the guide to the diaphragm, the lower border of the heart, and the upper surface of the liver.

Fracture of the sternum is rare, and generally occurs at or close to the junction of the manubrium and the body; it may occur either from direct violence, or indirectly along with fracture of the vertebral column. The periosteum of the sternum, unlike that of the ribs, is firmly adherent to the bone.

The **ribs**, which in well-nourished subjects cause no surface prominences, are visible in thin persons; in the obese it is very difficult even to feel them. When the ribs are counted from the front, the *second* may always be identified by its relation to the sternal angle. The *first rib* is to a large extent under cover of the clavicle. The lower border of the pectoralis major and the first visible digitation of the serratus anterior afford reliable guides to the *fifth rib*. The *seventh costal cartilage* is the one felt on the costal margin nearest the sternum (though occasionally the eighth cartilage, and not the seventh, is the lowest to reach the sternum). The second and third costal cartilages are almost horizontal; below that the cartilages ascend with increasing obliquity, that of the sixth being the first to present a distinct angle. The anterior end of the second intercostal space is the widest, while those of the fifth and sixth are very narrow.

The **costo-chondral junctions** may be indicated, on the surface, by a line drawn from the sterno-clavicular joint to a point a finger's breadth behind the angle of the tenth costal cartilage; the first junction, however, is lateral to that line.

The **internal mammary artery** descends behind the medial ends of the upper five intercostal spaces about 1·3 cm. from the edge of the sternum. The vessel is accompanied by two veins which unite opposite the third interspace to form a single vein which ends in the innominate vein at the inlet of the thorax.

This artery is occasionally injured in punctured wounds of the chest. At the second or third intercostal space it is easily ligatured through a transverse incision, but at a lower level it is generally necessary to resect a portion of one of the costal cartilages.

Operations on Thorax.—The operation of **thoracoplasty** is practised in certain cases of chronic unilateral phthisis. It implies removal of segments of the ribs; it may be total or partial, depending upon the number of rib-portions removed. Its purpose is to permit a "falling-in" of the thoracic cage so that the collapse of the underlying lung is encouraged.

The incision extends from the root of the neck parallel to the vertebral column midway between the median line and the medial border of the scapula. At the level of the lowest rib-resection, the incision curves forward along the line of the rib.

LUNGS, PLEURÆ, AND TRACHEA

Lungs.—The **apex of the lung** and the cervical pleura extend upwards into the root of the neck for a distance of about 2·5 cm. above the sternal third of the clavicle and are intimately related to the subclavian artery anteriorly; they are mapped out by a curved line drawn from the upper border of the sterno-clavicular joint across the sterno-mastoid to the junction of the medial and middle thirds of the clavicle, the highest part of the curve reaching from 1·3 to 3·8 cm. above the clavicle.

Both the **cervical pleura** and the **subclavian artery** may be injured by one of the fragments in a fracture of the clavicle; the scalene muscles, however, afford considerable protection to the pleura. When the third part of the subclavian artery is ligatured, care must be taken not to injure the cervical pleura.

To mark in the **anterior border** of the **right lung**, a line is drawn from the upper border of the sterno-clavicular joint to the centre of the manubrium sterni, and from there vertically downwards, in or slightly to the left of the median plane, to the xiphi-sternal joint (Figs. 1211, 1220).

The **anterior border** of the **left lung** is mapped out by a corresponding line as far as the fourth costal cartilage; thence, it is directed along the lower border of the fourth costal cartilage for 3·8 to 5 cm. and then curved downwards and medially to a point a little below and to the left of the xiphisternal joint. The lower part of the front of the right ventricle is therefore uncovered by lung and gives a completely dull note on percussion; that area is spoken of as the area of "*complete cardiac dullness*".

The level of the **lower border** of the lung is practically the same on both sides; it is mapped out by a line that begins at or near the xiphi-sternal joint and is drawn in a slightly curved direction, with the convexity downwards, across the side of the chest towards the tenth thoracic spine. The line crosses

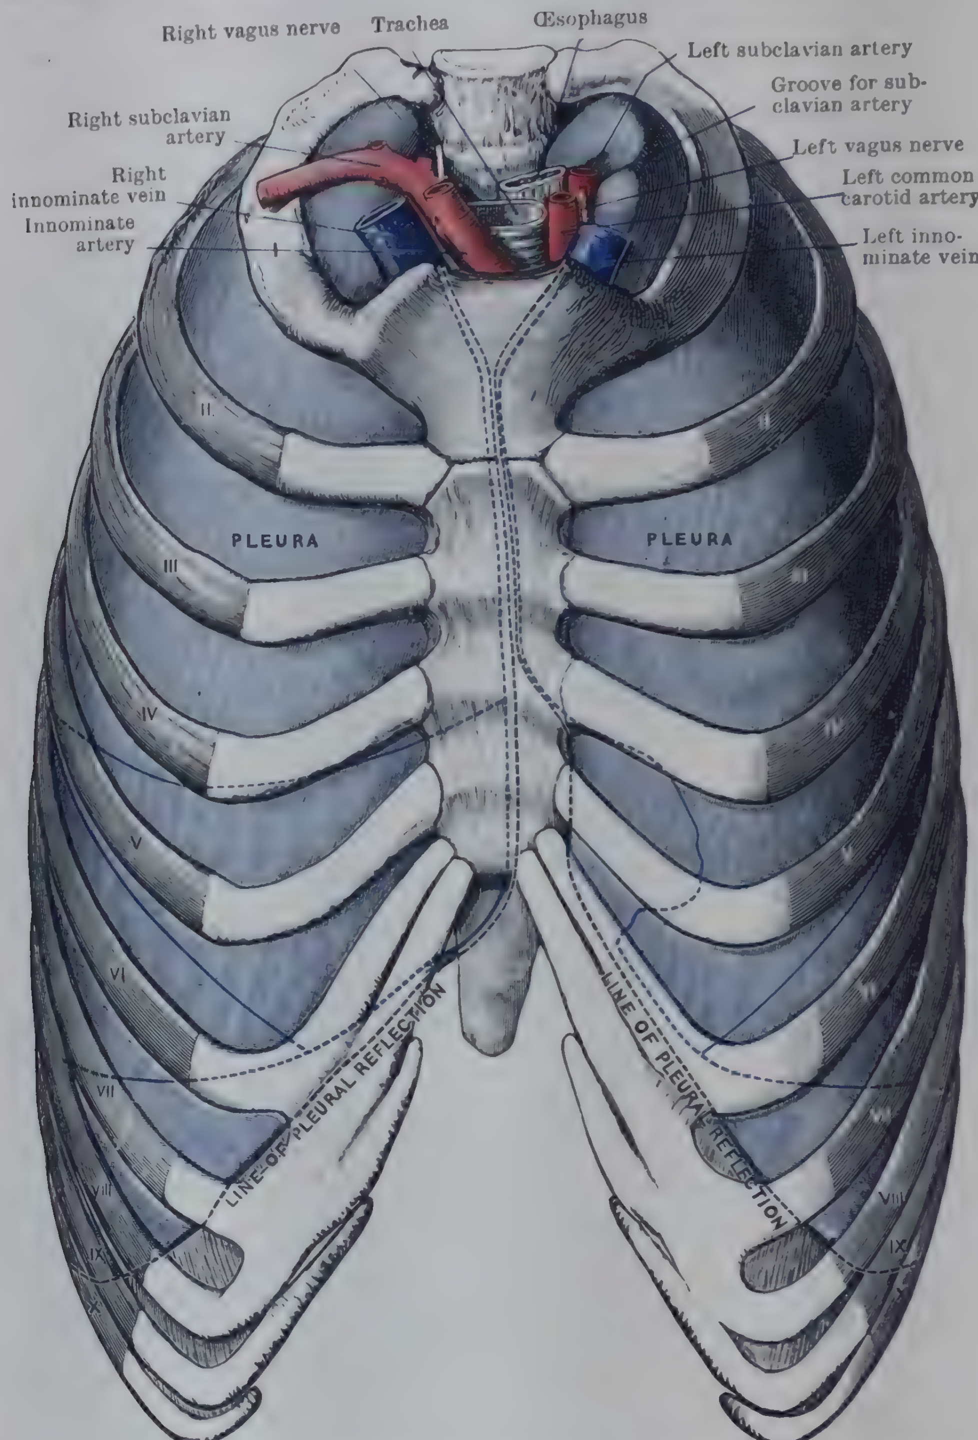

Fig. 1211.—Dissection of Subject hardened by Formalin Injection, to show the Pleural Sacs from the Front. The anterior and diaphragmatic lines of pleural reflexion are indicated by black dotted lines, and the outlines of the lungs and their fissures by the blue lines.

the eighth rib in the mid-axillary line about a hand's breadth above the costal margin (Figs. 1211-1213, 1230).

The position of the **oblique fissure** is indicated by a line drawn from the second thoracic spine to the root of the spine of the scapula, and thence downwards, laterally and forwards to end at the sixth or seventh costal cartilage about three finger-breadths from the median plane. When the arm is raised above the level of the shoulder, and the hand placed on the back of the head, the inferior angle of the scapula is rotated upwards and forwards so that the medial margin practically corresponds with the line of the oblique fissure.

The **horizontal fissure** of the right lung is mapped out by a line drawn from

the median line of the sternum, at the level of the fourth costal cartilage, towards the right and slightly upwards to the mid-axillary line.

Pleuræ.—The **line of reflexion** of the **right pleura** from the back of the sternum may be said to correspond to the anterior border of the right lung.

On the **left side**, the pleural reflexion corresponds to the anterior border of the left lung as far as the lower edge of the fourth chondro-sternal junction, at which point it leaves the lung and descends behind the left border of the sternum to the xiphi-sternal joint (Figs. 1211, 1220).

The **costo-diaphragmatic reflexion** or lower border of the pleura (see Figs. 1212 and 1219) is indicated on the surface by a line drawn from the xiphi-sternal joint towards the twelfth thoracic spine. The line is markedly convex downwards and crosses the tenth rib on the mid-axillary line about two finger-breadths above the costal margin.

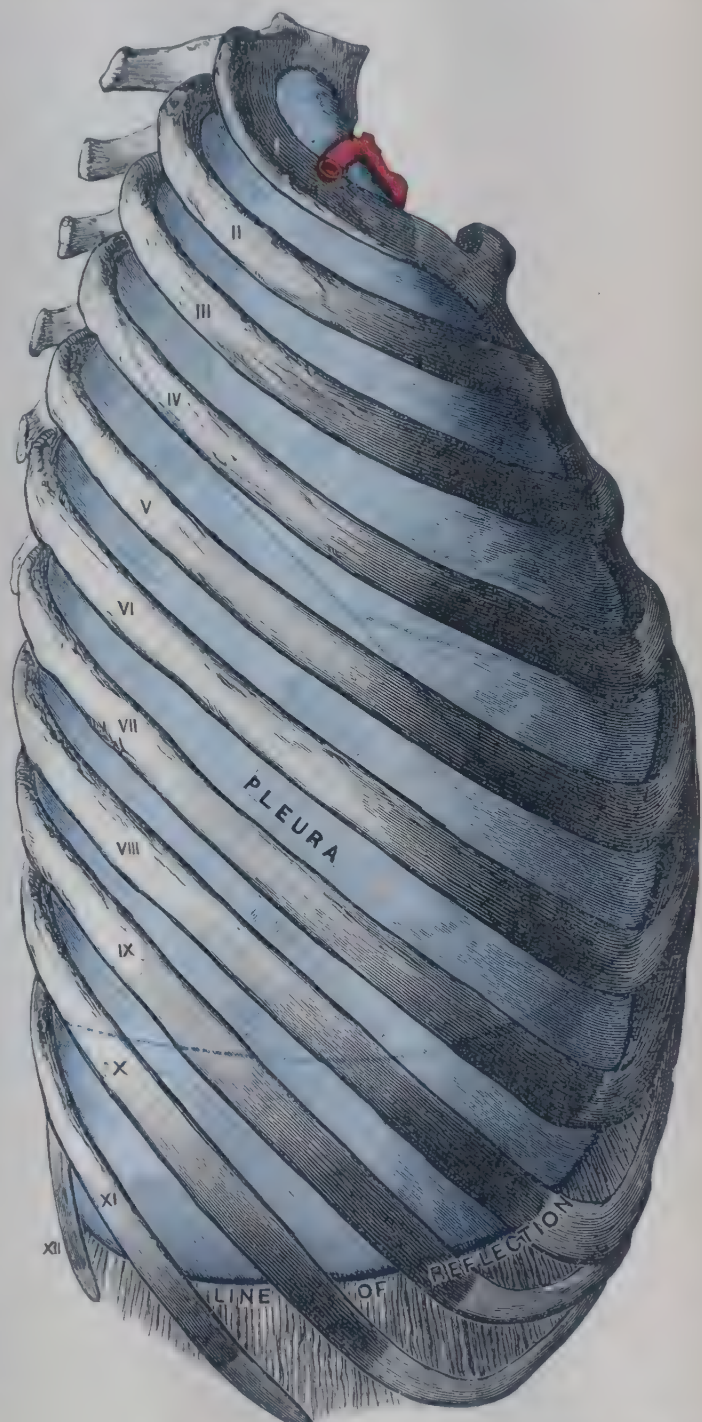

Fig. 1212.—Lateral View of Right Pleural Sac in Subject hardened by Formalin Injection. The blue lines indicate the outline of the right lung, and also the position of its fissures.

The **relations** of the **pleura** to the **twelfth rib** are of importance to the surgeon, especially in connection with operations on the kidney (Figs. 1213, 1214, 1230). When the rib is not abnormally short, the pleural reflexion crosses it opposite the lateral border of the sacro-spinalis muscle; hence an incision may be carried deeply as far as the apex of the angle between the twelfth rib and the lateral border of the sacro-spinalis without risk to the pleura. When, however, the twelfth rib does not reach the lateral border of the sacro-spinalis, the rib felt there is the eleventh; an incision carried upwards to that level is certain to wound the pleura.

Medial to the lateral edge of the sacro-spinalis the pleural reflexion is below the level of the twelfth rib, and not infrequently descends as far as the transverse process of the first lumbar vertebra. This must be borne in mind by the surgeon when he is carrying out a dissection to expose the kidney from the back.

On the *right side* of the posterior mediastinum, the **mediastinal pleura**, as it passes backwards from the pericardium to the vertebral column, sweeps over the right side of the œsophagus; malignant ulcers of the œsophagus are therefore more likely to invade the right pleura than the left. On the *left side* it passes from the bodies of the vertebræ on to the left side of the aorta. Hence, in the operation to evacuate pus from the posterior mediastinum, there is less risk of opening the pleura if the space is entered from the left side of the vertebral column.

Paracentesis or *tapping* of the pleura is used to confirm the presence of pus or other fluid in the pleural cavity. It is most often required for postero-inferior collections; the site of puncture is then the ninth intercostal space in the line of the angles of the

ribs. The needle is kept close to the upper border of the lower rib, to avoid intercostal vessels. Drainage of a collection of pus (*empyema*) is performed by resecting a portion of the ninth rib at its angle, after stripping its periosteum.

Trachea.—Anteriorly, the **bifurcation** of the **trachea** is opposite the *sternal angle*, while posteriorly it is a little below the level of the root of the spine of the scapula,

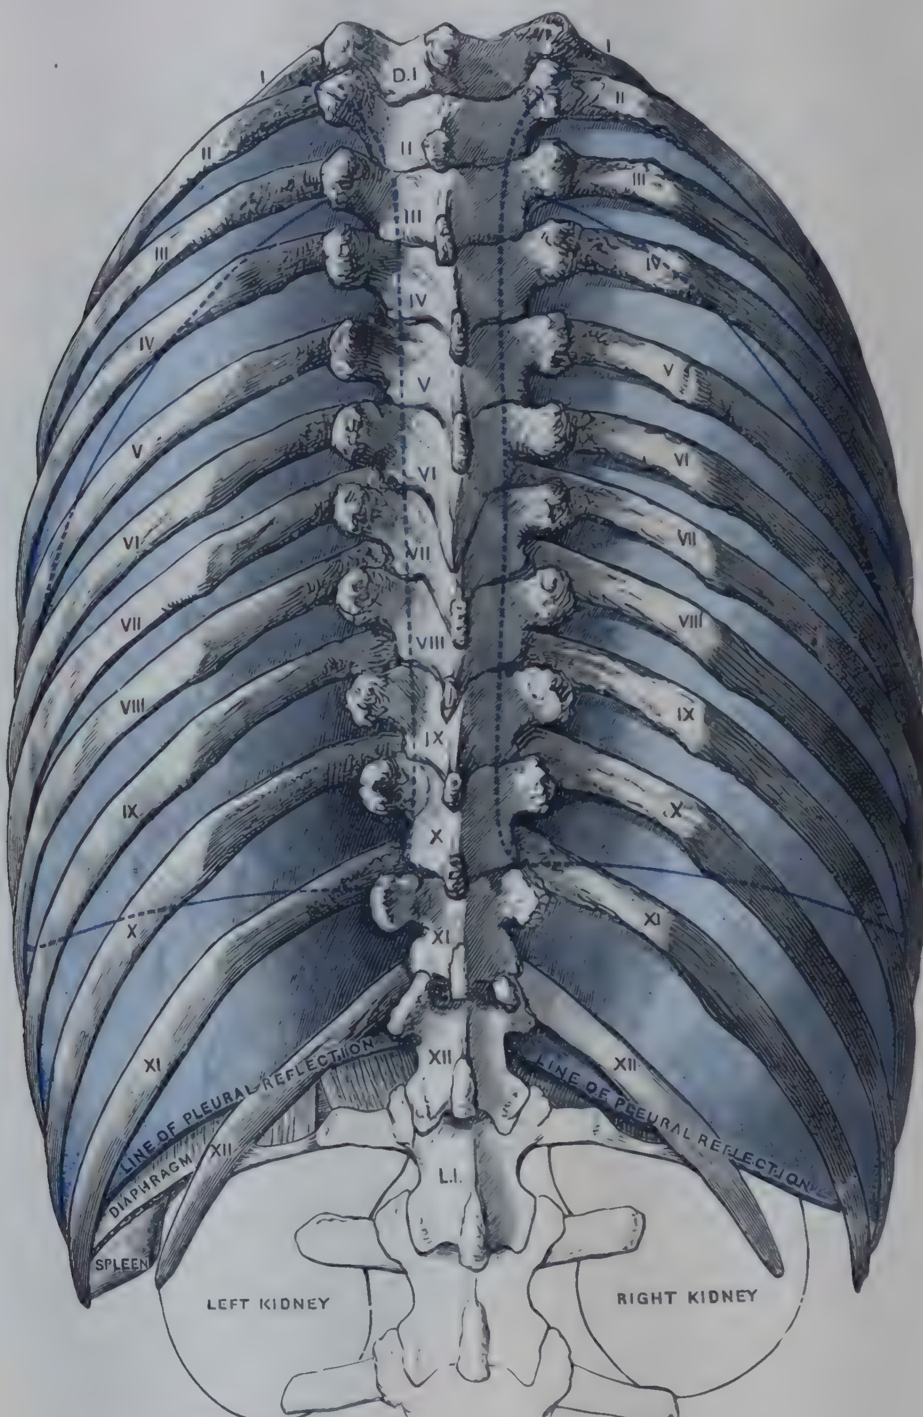

FIG. 1213.—DISSECTION OF PLEURAL SACS FROM BEHIND.
The blue lines indicate the outlines and the fissures of the lungs.

opposite the fourth thoracic spine (Fig. 1230). The bifurcation takes place one vertebra higher in the infant than in the adult (Symington, 1887), and its level varies in the same individual with phases of respiration and changes in position (p. 701).

The septum between the right and the left bronchus is a little to the left of the middle of the trachea, and the right bronchus is wider and more nearly in a line with the trachea than the left bronchus; hence the greater tendency of foreign bodies to enter the right bronchus.

Bronchial Tree and Broncho-Pulmonary Segments.—The branches of the bronchi and their relation to the *broncho-pulmonary segments* (Jackson & Huber,

1943; Brock, 1946) are fully described with the Respiratory System (p. 717). In Fig. 1215 they are represented from the point of view of bronchoscopy and the removal of a foreign body from a bronchus.

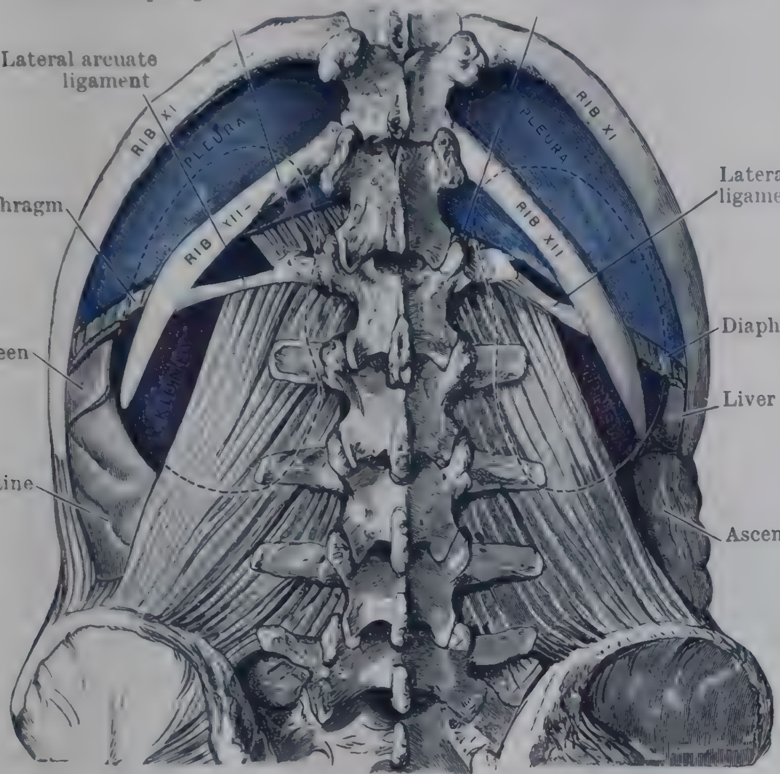

FIG. 1214.—DISSECTION FROM BEHIND TO SHOW RELATION OF PLEURAL SACS TO KIDNEYS.
The outline of the concealed portions of the kidneys (which are more alike in level than usual) is indicated by dotted lines.

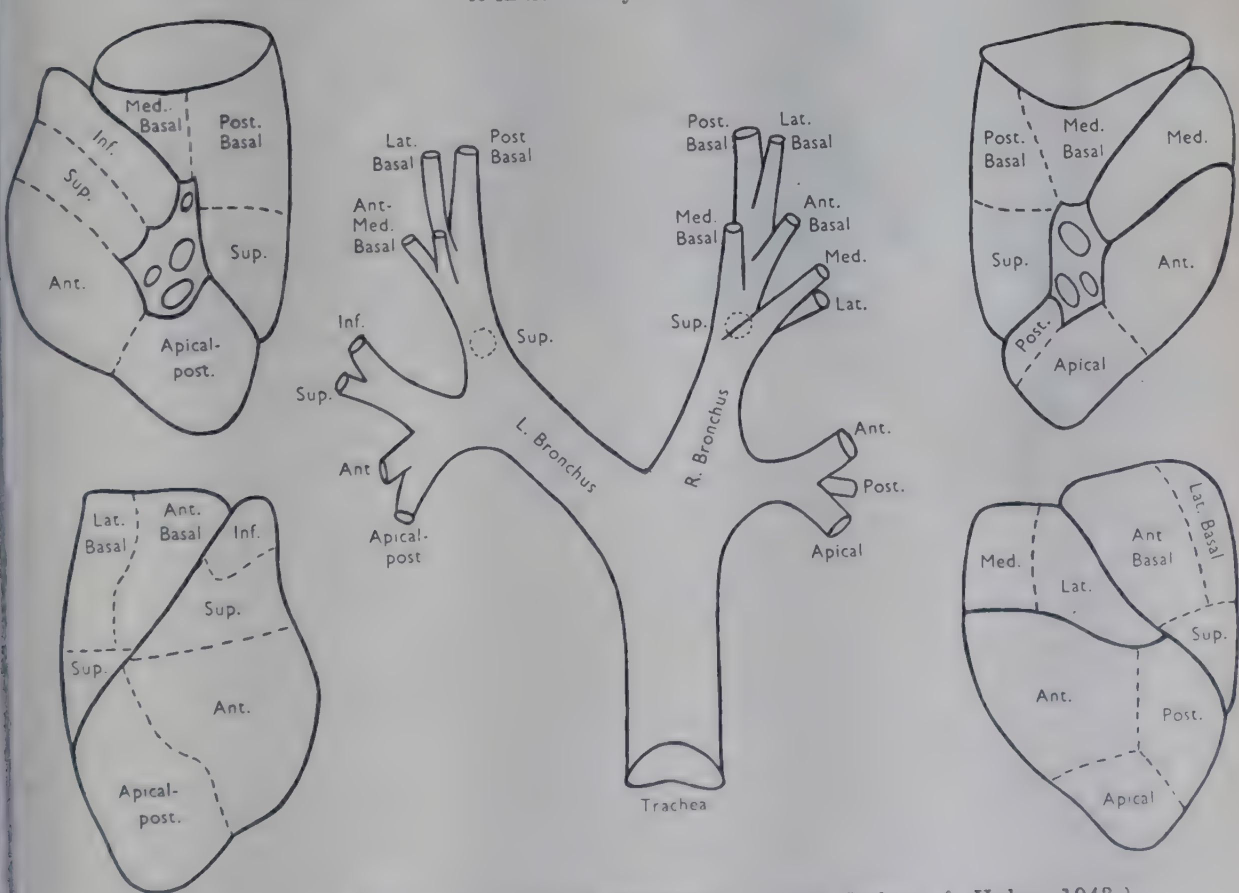

FIG. 1215.—THE BRONCHO-PULMONARY SEGMENTS. (After Jackson & Huber, 1943.)
Each bronchial branch is designated by the name of the subdivision of the lung supplied by it.

The **root** of the **lung** is opposite the fourth, fifth, and sixth thoracic spines midway between them and the medial margin of the scapula

The lower end of the trachea, the bronchi, the vagi, and the left recurrent laryngeal nerve, are all more or less surrounded by lymph-glands which, when enlarged, may exert injurious pressure on them.

Operations on Lungs.—**Lobectomy** is the removal of one or more lobes of the lung on account of tumour-development or of bronchiectasis. An incision is made along the line of the sixth interspace, and portions of the sixth and seventh ribs are resected as close to the vertebral attachment as possible, this permitting of wide retraction of the thoracic wound. The pedicle of the segment of lung to be removed is clamped in a special tourniquet: and after removal the stump is closed by sutures.

HEART, PERICARDIUM, AND GREAT VESSELS

Heart and Pericardium.—On the front, the **outline** of the **heart** is marked out as follows (Figs. 1216, 1220):

The *right border*, formed by the right atrium, is indicated by a line drawn about 2·5 cm. from the median plane from the upper border of the third costal cartilage to the sixth; the line should be slightly convex laterally—attaining its maximum opposite the fourth intercostal space.

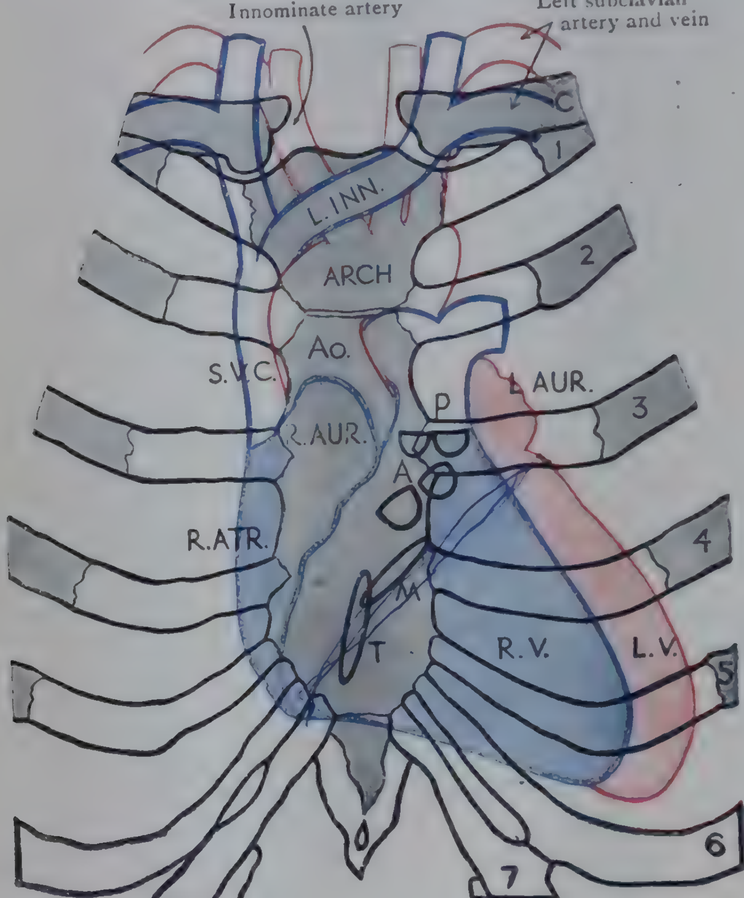

FIG. 1216.—RELATION OF HEART AND GREAT VESSELS TO ANTERIOR WALL OF THORAX.

1 to 7. Ribs and costal cartilages.
A. Aortic orifice.
Ao. Ascending aorta.
C. Clavicle.
L.V. Left ventricle
M. Mitral orifice.
P. Pulmonary orifice.
R.V. Right ventricle.
S.V.C. Superior vena cava.
T. Tricuspid orifice.

The *lower border*, formed by the right ventricle and, to a very slight extent, by the apical portion of the left ventricle, is almost horizontal, and corresponds to a line drawn from the sixth right costal cartilage to the point opposite the apex of the heart, which lies behind the fifth left intercostal space, about 4 cm. from the median plane. The line is opposite the xiphi-sternal joint.

The *left border*, formed almost wholly by the left ventricle, is indicated by a slightly curved line extending from the point opposite the apex of the heart to the second left costal cartilage 3·8 cm. from the median line, the convexity of the curve being directed laterally and slightly upwards.

The upper border is opposite a line drawn from the second left cartilage to the third right (between the ends of the lines for the right and left borders).

The lines indicating the outline of the pericardium are similar, except that the line for the upper border passes from the second left cartilage to the second right.

The situation of the anterior part of the **atrio-ventricular sulcus** is mapped out by a line drawn from the lower border of the third left costal cartilage to the sixth right chondro-sternal junction; the line should be slightly convex upwards and to the right. The **auricle** of the **right** atrium lies in the median plane, or a little to the right of it, at the level of the second intercostal space and the upper border of the third costal cartilage. The **auricle** of the **left** atrium lies behind the second left intercostal space, close to the edge of the sternum.

The *base* or *posterior surface* of the heart is formed mainly by the **left atrium**, which is moulded posteriorly on the œsophagus, the aorta, the bronchi, and the bronchial glands—the pericardium intervening. The left atrium extends behind the right atrium for a considerable distance to the right of the median plane.

In radiographic examination in cases of general visceroptosis, the diaphragm, which should rise and fall opposite the xiphi-sternal junction, will be seen to be 2·5 cm. or more lower down, while the long axis of the heart assumes an almost vertical direction (cardioptosis).

Orifices of Heart.—The *cardiac orifices* and *their valves* are situated below and to the left of the anterior part of the atrio-ventricular sulcus, and lie in the following order from above downwards and from left to right, viz., pulmonary, aortic, mitral, and tricuspid.

The **pulmonary orifice**, directed upwards and backwards, is opposite the third left costal cartilage. The **aortic orifice**, directed upwards, forwards, and to the right, is farther from the surface, behind the left margin of the sternum, opposite the lower border of the third intercostal space. The **mitral orifice** is at a lower level, behind the left half of the sternum, at the level of the fourth costal cartilage; it is directed downwards, forwards, and to the left. The **tricuspid orifice** is nearer the anterior wall of the chest than the mitral, and is opposite the middle of the sternum at the level of the fourth and fifth cartilages and intervening space.

Heart-Sounds.—Although the first and second sounds are heard all over the cardiac area, the sounds produced by the individual valves are heard most distinctly, not directly over their anatomical situation, but over the area where the cavity in which the valve lies is nearest the surface. Hence the **mitral sound** is best heard over the apex (mitral area), the **tricuspid** over the lower left part of the body of the sternum (tricuspid area), the **aortic** over the second right costal cartilage (aortic area), and the **pulmonary** over the third left costal cartilage (pulmonary area).

Operations on Pericardium and Heart.—In *paracentesis* of the pericardium, the needle is entered at the angle between the xiphoid process and the seventh left costal cartilage, and directed upwards and backwards. To drain the pericardium, a portion of that costal cartilage is excised, the diaphragm is displaced downwards, and the pericardial sac is opened at its most dependent point.

Extrapleural exposure of the heart requires resection of the fourth, fifth and sixth costal cartilages on the left side, after a flap of skin and pectoralis major muscle has been turned outwards and upwards. The corresponding intercostal vessels, and the internal mammary vessels, must be ligatured.

Great Vessels.—The **ascending aorta** lies behind the first piece of the body of the sternum, and, unless dilated, does not project beyond its right border. The upper border of the **aortic arch** lies at or a little above the centre of the manubrium sterni, but in the child it may reach as high as the upper border of the manubrium.

The **innominate** and **left common carotid arteries** diverge from the sides of the median plane between the upper part of the manubrium sterni and the front of the trachea and pass towards the sterno-clavicular joints.

The **pulmonary trunk** lies behind the sternal end of the left second interspace and the second costal cartilage.

The **left innominate vein** lies behind the medial part of the left clavicle and the upper part of the manubrium sterni, the **right** behind the medial part of the right clavicle and first costal cartilage. The **superior vena cava** lies immediately to the right of the margin of the sternum, opposite the first and second interspaces and the second cartilage; its opening into the right atrium, behind the third chondro-sternal joint, is opposite the centre of the root of the right lung.

Radiographic Examination.—For the radiographic examination of the thoracic organs, see pp. 721 and 1240. The functional variations in the position of these organs, as determined by radiography, are discussed by Mainland & Gordon (1941) and Lachman (1946).

ŒSOPHAGUS

The average length of the **œsophagus** in the adult is 25 cm. The distance from the incisor teeth to its commencement is 15 cm.; to the point or level where it is crossed by the left bronchus, 22·5 cm.; to the œsophageal opening of the diaphragm,

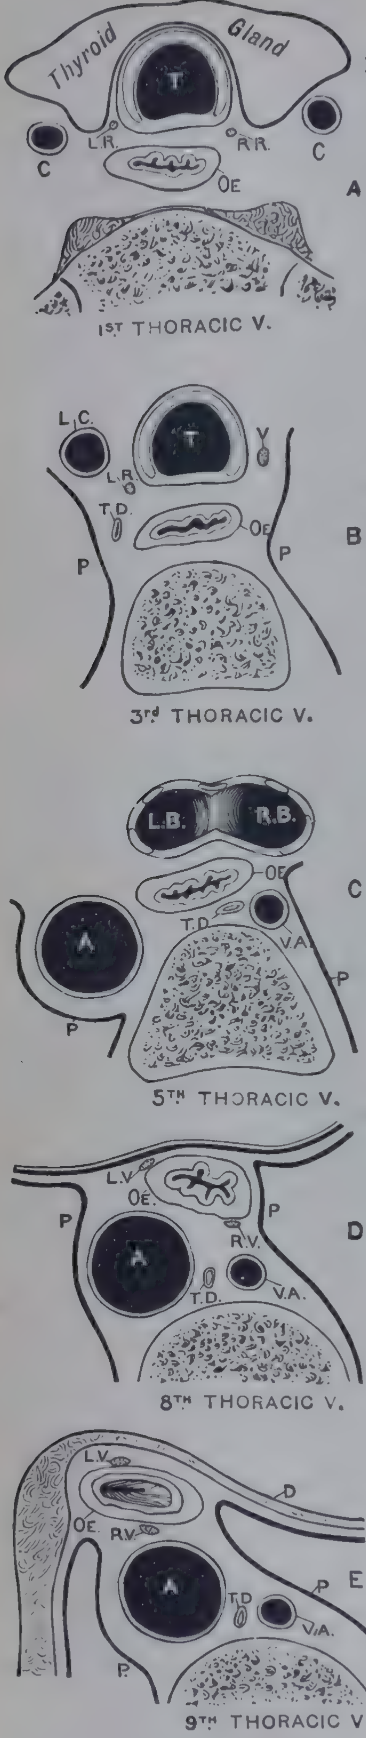

Fig. A is at the level of the superior part of the 1st thoracic vertebra, and shows the chief relations of the œsophagus in the neck and also its divergence to the left.

Fig. B, at the 3rd thoracic vertebra, shows the thoracic duct lying on the left side of the œsophagus. V, Right vagus nerve.

In Fig. C, at the level of the 5th thoracic vertebra, the left bronchus is seen in relation to the anterior surface of the œsophagus.

Fig. D is at the level of the 8th thoracic vertebra, and shows the œsophagus passing behind the pericardium.

Fig. E, at the 9th thoracic vertebra, shows the œsophagus inclining to the left just before piercing the diaphragm.

Fig. 1217.—Relations of Œsophagus at different Levels. A, in Neck; B, in Superior Mediastinum; C, D, E, in Posterior Mediastinum. See also Fig. 593, p. 701.

35 cm.; to the cardiac orifice of the stomach, 40 cm. These measurements, which are of great importance in the diagnosis of the seat of œsophageal obstructions, should be marked off from below upwards upon all œsophageal bougies. Posteriorly, the œsophagus extends from the level of the sixth cervical spine to that of the ninth thoracic, a little to the left of which is the situation at which the stethoscope is placed in order that the sound produced by the passage of fluid into the stomach may be heard (Fig. 1217 and Pl. L, p. 593).

There are three points in the lumen of the œsophagus at which foreign bodies are apt to become impacted, and in which neoplasms commonly occur. They are at the pharyngo-œsophageal junction (15 cm. from the teeth), the level of the crossing of the left bronchus (opposite the body of the fifth thoracic vertebra), and at the passage through the diaphragm (35 cm. from the teeth).

Clinically it is important to bear in mind the relation of the œsophagus to the trachea and left bronchus, to the left recurrent laryngeal nerve, to the bronchial and posterior mediastinal glands, to the descending thoracic aorta, and to the right pleura in the posterior mediastinum. Ulcers of the œsophagus are apt to open into either the trachea, the left bronchus, or the right pleura.

The *veins* of the lower end of the œsophagus open partly into the systemic veins and partly into the portal system; like those at the lower end of the rectum they are liable to become varicose in conditions which give rise to obstruction of the portal circulation.

The *lymph-vessels* of the upper part of the œsophagus open into the glands in the root of the neck, the remainder into the posterior mediastinal glands.

By means of X-ray cinematography the relatively quick movements of the œsophagus have been studied. Three phases may be distinguished in the process of swallowing—the pharyngeal, the œsophageal, and the cardiac. The upper end of the œsophagus opens secondary to contraction of the pharynx; a series of rapid peristaltic waves then appear in the œsophagus—each contraction lasting four to six seconds—and after a perceptible interval, dependent upon the type of food, the cardiac orifice of the stomach opens.

The clinical investigation of the œsophagus is carried out by radiographic examinaton during the swallowing of a thick barium-paste (p. 1555) and by œsophagoscopy. In the latter method, a metal tube carrying a small electric lamp is introduced, and the interior of the œsophagus is brought under direct vision.

Operations on Œsophagus.—The operation to expose the cervical portion of the œsophagus has been described (p. 1479). The thoracic portion of the oesophagus (usually its lower half) is exposed by a long incision in the line of the eighth or ninth intercostal space. Segments of the posterior ends of the ribs bounding the space are resected, to allow

f wide retraction of the edges of the incision. Access to the upper part of the abdominal avity (for example, to the cardia) is secured by a radial incision in the diaphragm, after it as been temporarily paralysed by picking up and crushing the phrenic nerve as it courses over the pericardium.

ABDOMEN

ANTERIOR WALL OF ABDOMEN

Landmarks.—The configuration of the abdomen varies with the age, sex, obesity, and muscular development of the individual. In the child it is wider above than below, while the reverse is the case in the female adult. It is most prominent in the region of the **umbilicus**, which, in the recumbent posture, is situated below the mid-point between the xiphi-sternal joint and the pubic symphysis, usually a little above the level of the highest part of the iliac crest, and opposite the disc between the third and fourth lumbar vertebræ; but in a person standing upright it sinks to a lower level and is opposite the middle of the body of the fourth lumbar vertebra. In the obese, and especially when the abdominal muscles have lost their tone, the umbilical region becomes prominent and more or less pendulous, so that the umbilicus may come to lie considerably below the normal level. In the child it is relatively lower than in the adult, in consequence of the undeveloped state of the pelvis.

In spare subjects the lower end of the body of the sternum, the xiphoid process, and the costal margin can readily be traced. Below the xiphi-sternal joint and bounded on each side by the seventh, eighth, and ninth costal cartilages, is the **infrasternal angle**, which varies considerably according to the shape of the chest; it is relatively wider in the child than in the adult. The lower border of the curve of the **tenth costal cartilage** is easily recognizable, and is usually the lowest point seen or felt on the costal margin when the body is examined from the front; it also marks the level of the subcostal plane.

The anterior wall is limited below by the groove of the groin and the pubic crest. In a spare muscular subject the recti muscles, the furrows corresponding to the tendinous intersections and the supra-umbilical portion of the **linea alba** can be readily made out. When the outline of the rectus is not visible, the lateral border may be indicated by a line drawn from the tip of the ninth costal cartilage to the mid-point of a line between the umbilicus and the anterior superior iliac spine, and from there to the pubic tubercle. In the angle between the lateral border of the rectus and the ninth costal cartilage there is a slight triangular depression which, on the right side, overlies the fundus of the **gall-bladder**. Between the lower part of the lateral border of the rectus and the bulging above the anterior part of the iliac crest caused by the lower muscular fibres of the external oblique, there is another slight triangular depression which corresponds to the inferior and narrow part of the aponeurosis of the external oblique muscle.

Inferior Epigastric Artery.—This artery may be mapped out by a line drawn from the mid-inguinal point towards the umbilicus. The vessel, together with the medial third of the inguinal ligament and the lower part of the lateral border of the rectus, bounds a triangle known as the **inguinal triangle.** As the inferior epigastric artery passes upwards and medially to disappear behind the conjoint tendon and the lateral border of the rectus, it lies behind the spermatic cord immediately medial to, and below, the deep inguinal ring. The floor of the inguinal triangle is formed throughout by the fascia transversalis, superficial to which, over the medial half or so of the triangle, is the conjoint tendon.

Inguinal Canal and Hernia.—Close above, and almost parallel to, the medial half of the inguinal ligament is the **inguinal canal**, which is traversed by the **spermatic cord** (Fig. 1218); the cord can be felt to emerge at the superficial inguinal ring immediately above the pubic tubercle. The **inguinal rings** are fully described in the section on Muscles. The **superficial inguinal ring** is triangular in shape, with its apex directed upwards and laterally, and its base at the pubic crest. It is to be

noted that the neck of an *inguinal hernia* lies above the pubic tubercle, whereas the neck of a *femoral hernia* emerges below the medial part of the inguinal ligament, lateral to the pubic tubercle. The **deep inguinal ring** is nearly 1·3 cm. above the *mid-inguinal point*—that is, a point on the inguinal ligament midway between the pubic symphysis and the anterior superior iliac spine.

An **oblique inguinal hernia** leaves the abdomen at the deep inguinal ring and traverses the whole length of the inguinal canal; its coverings are therefore the same as those of the spermatic cord, and the neck of the sac lies lateral to the inferior epigastric artery. A **direct inguinal hernia**, on the other hand, instead of traversing the whole length of the inguinal canal, pushes before it that part of its posterior wall which is formed by the floor of the inguinal triangle. The neck of the sac therefore is medial to the inferior epigastric artery. If a direct hernia makes its way through the medial part of the inguinal triangle, it derives a covering from the conjoint tendon as well as from the fascia transversalis; if through the

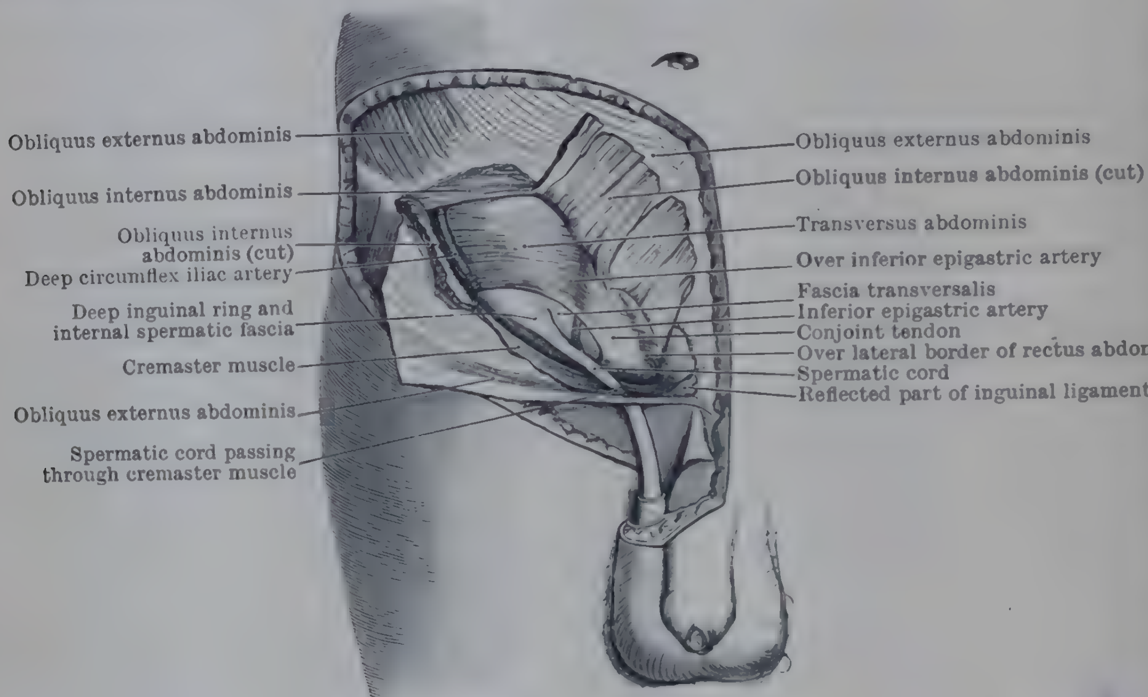

FIG. 1218.—DISSECTION OF GROIN TO SHOW STRUCTURES RELATED TO INGUINAL HERNIA.

lateral part of the triangle, the lateral edge of the conjoint tendon curves round the medial side of the neck of the sac. To relieve the constriction at the neck of the sac, in the case of an *oblique inguinal hernia*, the edge of the knife is directed upwards and laterally to avoid the inferior epigastric artery; in a *direct hernia* the constriction is divided in an upward and medial direction in order to avoid damaging the artery. In an oblique inguinal hernia there are three coverings or fasciæ: the external spermatic derived from the external oblique aponeurosis; the cremasteric from the internal oblique muscle; and the internal spermatic from the transversalis fascia. The sac of the hernia lies within the last-mentioned covering. In a direct inguinal hernia the coverings are less well defined; it may be impossible to distinguish individual layers, but the tunica propria of the hernia is derived from the fascia transversalis. The extraperitoneal fat which covers the outer surface of the hernial sac is sometimes hypertrophied to such an extent as to amount to a fatty tumour.

In a large number of children, at birth, the **vaginal process** of peritoneum which connects the tunica vaginalis testis with the abdominal peritoneum, is still patent, especially on the right side. Should the bowel force its way along the patent process, a **congenital inguinal hernia** arises. In the majority of the cases of congenital inguinal hernia it will be found that the tunica vaginalis testis has been shut off by closure of the lower part of the vaginal process, only the upper part remaining patent and forming the sac of the hernia.

In the child the persistence of a patent vaginal process can almost invariably be detected if the spermatic cord is rolled between the finger and thumb; for after the va

deferens and spermatic vessels have slipped away from one's grasp, the edge of the sac can be felt to follow them. In regard to the operation for the cure of inguinal hernia, it should be borne in mind that in the acquired form the *hernia produces the sac*, whereas in the congenital variety the *sac is the cause of the hernia*; it follows, therefore, that in the operation for *acquired* hernia the closure of the canal is as important as the removal or obliteration of the sac, while in a *congenital* hernia the most essential part of the operation is the closure of the neck of the sac, and, as the muscular and fascial layers of the walls of the canal are often well developed (especially in children), they should be interfered with as little as possible. A patent vaginal process may persist during adult life without any bowel descending into it; on the other hand, years after birth, bowel may suddenly enter it. In practically all oblique inguinal herniæ which develop suddenly in children as well as in adolescents and young adults, the *sac* is congenital.

Hydrocele.—In the ordinary form of hydrocele the fluid is confined to the tunica vaginalis testis; but, when the upper portion of the processus vaginalis remains patent, the hydrocele may extend upwards into the inguinal canal, and it may or may not communicate with the general peritoneal cavity (*infantile hydrocele*). In the condition known as *encysted hydrocele of the cord* the patent vaginal process is shut off both from the tunica vaginalis testis and from the peritoneal cavity.

Distribution of Sensory Nerves.—A knowledge of the segmental distribution of the sensory fibres of the lower intercostal nerves to the anterior abdominal wall enables us to appreciate the significance of the so-called girdle-pain often associated with lesions of the spinal cord and the nerve-roots. In tuberculous disease of the vertebral column, for example, the girdle-pain may be an early symptom, and when present it affords a valuable guide to the situation of the disease in the vertebral column. The seventh thoracic nerve supplies the skin at the level of the epigastric fossa, the eighth and ninth that between it and the umbilicus, the tenth that at the level of the umbilicus, the eleventh and twelfth and the ilio-hypogastric (from first lumbar) that between the umbilicus and groin (Fig. 918, p. 1059).

ABDOMINAL INCISIONS

Before the abdominal cavity is dealt with reference must be made to some anatomical points connected with the more typical incisions employed when the abdomen is opened.

Incisions in Median Plane.—Median incisions through the linea alba have the advantage of being comparatively bloodless and rapid of execution, of dividing no motor nerves, and of enabling the surgeon to expose a wide area of the abdomen. Unless special precautions are taken, however, they are more liable to be followed by a ventral hernia.

Above the umbilicus the linea alba is comparatively broad, so that the edges of the recti are separated by a distinct interval, which may be of considerable width in obese subjects and multiparous women. Deep to the linea alba is the transversalis fascia, which is so thin and adherent that the two structures form practically a single layer. The extraperitoneal fat, which forms a comparatively thick stratum, must not be mistaken for omentum. The peritoneum presents itself as a thin, bluish, semi-transparent membrane. If it is necessary to prolong the incision downwards below the level of the umbilicus, in order to avoid the round ligament of the liver, it should pass to the left of the umbilicus. If, in closing a median supra-umbilical incision, the surgeon merely sutures the edges of the stretched linea alba without opening into the rectal sheaths, a hernia may result. To ensure against it, the medial borders of the recti are exposed by opening into their sheaths along each edge of the wound. In closing the wound, the deepest suture includes on each side the posterior wall of the rectal sheath along with the split linea alba, the transversalis fascia, and the peritoneum. That gives a substantial "first line of defence". The next suture takes up some of the fibres of the medial edges of the recti, along with the anterior wall of their sheaths. The skin is sutured separately. By this procedure the edges of the recti are brought into actual contact and a double-layered linea alba is fashioned—one layer behind the margins of the recti and the other in front of them.

Below the umbilicus the medial edges of the recti are practically in contact, and an incision between them therefore opens into the rectal sheath on both sides.

Infra-umbilical median incisions, if carried as low as the pubic symphysis, may damage the anterior wall of the bladder unless special precautions are taken; this applies more especially in children, for in them the bladder extends up out of the pelvis. The bladder should therefore be emptied before the abdomen is opened by a low median incision; in suprapubic cystotomy, on the other hand, the bladder is intentionally filled so as to elevate the peritoneum well above the symphysis. Below the peritoneal layer is the **retropubic space**, occupied by a pad of extra

peritoneal fat which must be separated by blunt dissection before the bladder-wall is actually exposed. In opening the bladder, the veins which ramify on its surface are avoided. Above the pubes the fascia transversalis recedes a little from the recti, leaving an interval, filled with areolar tissue, which must not be mistaken for the retropubic space.

Incisions through Recti.—In **longitudinal incisions through the rectus** the superior epigastric artery will be encountered above the umbilicus, and the inferior epigastric below it. Incisions must be kept close to the medial margin of the muscle, to preserve its nerve supply. **Above the level of the umbilicus** the posterior wall of the rectus-sheath is well developed; and when the wound is closed this wall is included in the same suture as the transversalis fascia and the peritoneum, the three together forming a most efficient line of closure. The higher and more lateral the incision through the rectus is made, the more will the posterior wall of the sheath be found to be made up of muscular fibres of the transversus abdominis muscle. **Below the level of the umbilicus** the posterior wall of the sheath is much thinner and ceases to be a definite layer, usually appearing to end in a slightly thickened arched band, called the *arcuate line*, about midway between the umbilicus and the pubes. Below that level, therefore, the "deep closure" of a laparotomy wound through the rectus is less secure than it is at a higher level. It is all the more important, therefore, to see that the edges of the anterior wall of the sheath are accurately sutured.

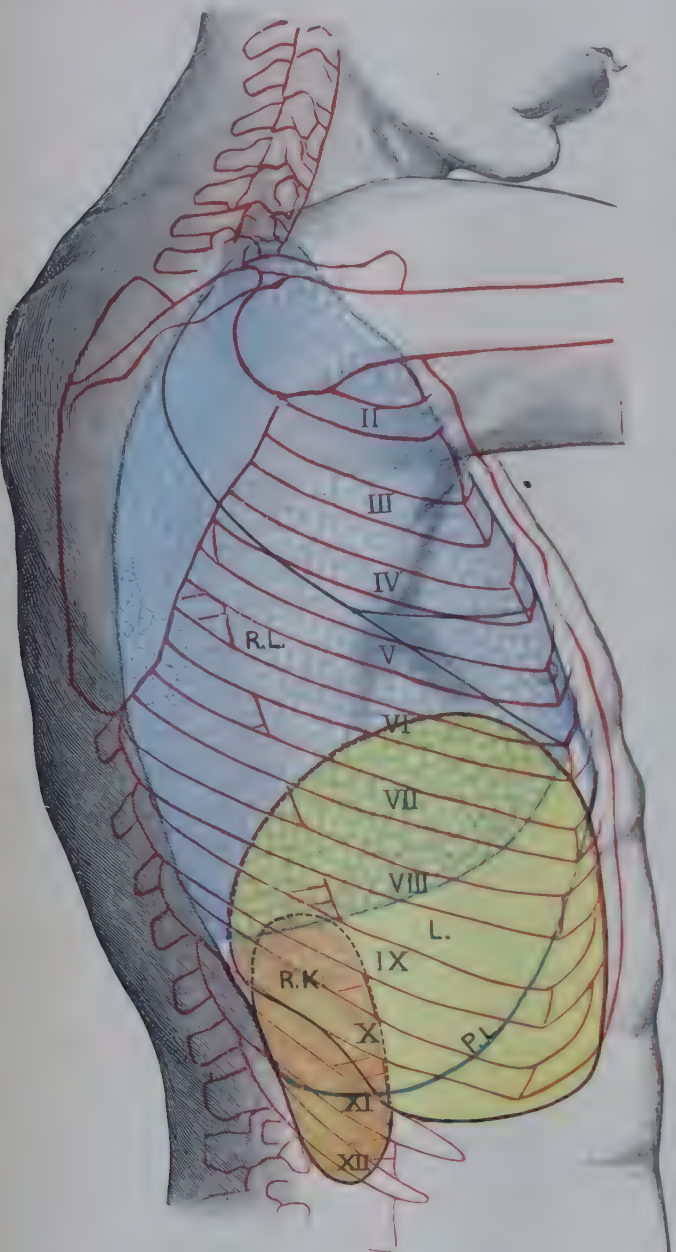

FIG. 1219.—RIGHT LATERAL ASPECT OF TRUNK, SHOWING SURFACE TOPOGRAPHY OF VISCERA.

R.L. Right lung. R.K. Right kidney.
L. Liver. P.L. Pleura.

Incisions which imply Retraction of Rectus.—A vertical incision to one or other side of the median line opens the rectus-sheath, the muscle is separated and retracted laterally, and the posterior wall of the sheath and peritoneum are opened in the line of the skin incision. When the incision is closed, the tier of sutures in the peritoneum and posterior layer of rectus sheath is separated from that in the anterior layer by a "shutter" of muscle. This is the most generally used form of abdominal incision.

Transverse Incisions.—Incisions which divide the upper segments of the rectus muscles transversely give good access, and since they are parallel to the nerves, are not followed by muscular weakness.

Subcostal Incisions.—Incisions from the midline to the ninth costal cartilage, about 4 cm. below and parallel to the costal margin, give good access on the right side to the biliary apparatus, and on the left side to the spleen.

Incisions in Iliac Region.—To reach the cæcum and vermiform appendix on the right side and the pelvic colon on the left side (colostomy), it is customary, by using what is known as the "gridiron incision", to split the three abdominal muscles in the direction of their fibres. The external oblique is split in the direction of the skin-incision, which is made obliquely from above downwards and medially. After retracting the edges of that muscle the fibres of the internal oblique and transversus muscles are split horizontally. The abdomen is then opened by division of the transversalis fascia and peritoneum. If a comparatively large opening is required, the ascending branch of the deep circumflex iliac artery, which runs upwards between the internal oblique and transversus muscles a little medial to the anterior superior iliac spine, is divided and ligatured, while the ilio-hypogastric and ilio-inguinal nerves are to be avoided. If it is necessary to extend the incision in a medial direction, the lateral part of the anterior wall of the sheath of the rectus is opened and the rectus pulled medially; the inferior epigastric artery, now exposed, is pushed aside or ligatured before the opening in the fascia transversalis and peritoneum is enlarged.

If they are made parallel to the nerves of the abdominal wall, long oblique incisions, partly muscle-splitting and partly muscle-cutting, give wide access to structures in the flanks.

ABDOMINAL CAVITY

Divisions of Abdominal Cavity.—The cavity of the abdomen is divided into three zones by two imaginary planes:—

(1) The *subcostal plane*, which passes through the lowest point on the rib margins seen from the front (usually the lower edge of the tenth costal cartilage) and corresponds to the level of the upper border of the third lumbar vertebra.

(2) The *intertubercular plane*, which passes through the tubercles of the iliac crests (the highest part of the crests seen from the front) at the level of the centre of the fifth lumbar vertebra.

Each zone is divided into three regions by a pair of vertical planes, each of which passes through the mid-inguinal point and the ninth costal cartilage near its tip. The upper zone is thus divided into a *right* and *left hypochondrium* and an *epigastrium*, the middle zone into *lumbar* and *umbilical* regions, and the lowest zone into *iliac* and *suprapubic* regions.

A useful line of reference is that which corresponds to the *transpyloric plane* (Addison). This plane is midway between the upper margin of the sternum and the upper margin of the pubic symphysis, and for easy reference may be said to be a hand's breadth below the xiphi-sternal joint. It is at the level of the lower border of the first lumbar vertebra, and receives its name from the fact that it passes through the pylorus. (See p. 602 and Fig. 514.)

Peritoneal Cavity.—This cavity may be regarded as a large and complicated lymph-sac which is intimately related to the abdominal viscera, and more especially to the gastro-intestinal canal. Inflammatory infections of the peritoneum are therefore almost always secondary to lesions of the viscera. The healthy peritoneum is endowed with great absorptive and reparative properties, and, when irritated, has the power of throwing out an abundant exudation, the cell-elements of which are actively phagocytic.

The reflexion of the peritoneum and its relations to the various organs have been fully described in the Section on the Digestive System.

The attachment of the **transverse mesocolon** to the posterior abdominal wall is at the level of the second lumbar vertebra. The attachment, which ascends slightly as it passes from right to left, crosses the head of the pancreas, after which its attachment follows the lower border of the body of the pancreas. The *peritoneal compartment above that attachment* is roofed in by the diaphragm, and includes the upper part of the great sac of peritoneum, and, posteriorly, the larger portion of the lesser sac. The organs related to that area of the peritoneum are the liver with the bile-ducts and gall-bladder, the stomach and part of the duodenum, the spleen, the pancreas, the upper parts of the kidneys, and the suprarenal glands. Suppuration connected with any of those organs is liable to spread upwards under the cupola of the diaphragm, producing what is known as *subphrenic abscess*.

The attachment of the **mesentery** of the **small intestine** extends from the left side of the second lumbar vertebra downwards to the right iliac fossa. The attachment may be mapped out on the surface by a line drawn from a point 2·5 cm. below the transpyloric line, 2·5 cm. to the left of the median plane, to the intersection of the intertubercular and right vertical planes.

Compartments of Peritoneal Cavity.—From the surgical point of view the peritoneal cavity may be arbitrarily divided into **four great compartments**: namely, a supracolic, a right infracolic, a left infracolic, and a pelvic. All these divisions communicate freely with one another behind the anterior abdominal wall, as well as along the gutter-like channels in the loins. It is along those gutters that pus readily makes its way from the upper part of the abdomen downwards into the pelvis; on the other hand, the pus may ascend from the pelvis along the same channels, especially when the patient is in the recumbent posture.

The highest (subphrenic) region of the **supracolic compartment** is further sub-

divided into a right and left portion by the falciform ligament; and the **lesser sac** may be looked upon as a diverticulum of the right subdivision.

The subphrenic lymph-plexus communicates, by means of lymph-vessels which pierce the diaphragm, with the subpleural plexus on its upper surface; hence, pus confined under tension in either of the subphrenic spaces is apt to give rise to secondary infection of the corresponding pleural cavity. By adhesions of the transverse colon and greater omentum to the anterior abdominal wall, the supracolic compartment of the peritoneal cavity may become more or less completely shut off from the rest of the abdomen. Suppuration in the right half of the supracolic compartment is generally secondary to leakage from an ulcer of the first part of the duodenum or to disease of the gall-bladder and bile-ducts; the left half of the space is more usually infected from the stomach. The supracolic compartment of the peritoneal cavity may be drained through the anterior abdominal wall, or preferably by resecting the twelfth rib through an incision over it, and inserting the drainage tube in the angle between the bed of the rib and the lateral border of the sacro-spinalis muscle.

The **right infracolic compartment** is above and to the right of the mesentery. It is bounded laterally by the cæcum and ascending colon, and superiorly by the right and middle thirds of the transverse colon and the corresponding part of its mesocolon. At its right lower angle are the ileo-cæcal junction and the vermiform appendix; at its right upper angle is the right flexure of the colon; and at its left upper angle is the third part of the duodenum, crossed by the superior mesenteric vessels. In rare instances the third part of the duodenum may be compressed between those vessels and the vertebral column. The condition is named *duodeno-mesenteric ileus*.

The organs related to that compartment are—in addition to the parts of the large intestine already mentioned—coils of small intestine, the lower third of the right kidney, the right ureter, the third part of the duodenum and the lower half of the second part. Suppuration in connexion with the organs in that area may extend upwards along the colon into the sub-diaphragmatic region, or downwards into the pelvis. Drainage of the area is established through a wound in the right iliac fossa, the drainage material being placed medial to the ascending colon.

The **left infracolic compartment** is below and to the left of the mesentery; it narrows as it passes upwards, and reaches a higher level than the right infracolic compartment. Inferiorly, it is directly continuous with the peritoneal cavity of the true pelvis. Above, it is bounded by the left third of the transverse colon and its mesocolon, and, still farther back, by the inferior surface of the body of the pancreas; laterally, it is bounded by the descending colon. At its right upper angle is the duodeno-jejunal flexure, lying immediately to the left of the vertebral column, on the psoas and below the pancreas. At its left upper angle is the left flexure of the colon, while at its left lower angle is the junction of descending with pelvic colon. This compartment of the peritoneal cavity, in addition to containing the majority of the coils of the small intestine, is related to the lower third of the left kidney, the left ureter, the lower part of the abdominal aorta and vena cava, and the inferior mesenteric and common iliac vessels. Drainage of the compartment may be established through the left iliac fossa, or by a tube introduced down to the bottom of the pelvis—into the recto-vesical pouch in the male, and into or through the recto-vaginal pouch in the female.

On account of the oblique manner in which the mesentery is attached to the posterior abdominal wall, it follows that, in order to examine the organs related to the right infracolic compartment of the abdomen, the surgeon must push coils of small intestine downwards and to the left, while to investigate the left infracolic compartment he must displace them upwards and to the right.

ABDOMINAL VISCERA

Liver.—The *inferior margin of the liver* extends from a point a finger's breadth below the right costal margin at the side of the trunk to the fifth left intercostal space below the nipple in a line dropped from the middle of the

clavicle; in the infracostal angle it passes from the tenth right costal cartilage to the eighth left and crosses the median plane at the transpyloric plane; in this region the position can be determined by light percussion and occasionally by palpation. The *highest part of the liver*, which corresponds also to the highest part of the right arch of the diaphragm, reaches, during expiration, to the level of the fourth right intercostal space opposite the nipple or in the mid-clavicular line. To the right of the median plane the superior surface of the liver is too far removed from the anterior wall of the chest, and overlapped by too thick a layer of lung substance, to be accurately determined by percussion. *Behind the sternum* the superior surface is opposite the xiphi-sternal joint. To the left of the median plane the upper limit of the liver cannot be determined by percussion, since it merges into the cardiac dullness. The base or **right lateral surface** extends from the level of the seventh rib to the level of the eleventh rib in the mid-axillary line, and is separated by the diaphragm from the lower part of the right lung and pleura.

The **falciform ligament**, at its attachment to the liver, is a little to the right of the median plane.

By dividing the *round ligament*, which passes backwards and upwards in the free margin of the falciform ligament, the surgeon is enabled to rotate the liver backwards around its transverse axis so as to expose more of its inferior surface; that procedure is sometimes taken advantage of in cases in which there is unusual difficulty in reaching the cystic and hepatic ducts or the bile-duct. The ligament is sutured before the abdominal wall is closed.

The **anterior surface** of the liver may be reached through a median incision which extends downwards from the xiphoid process, or by an oblique incision a finger's breadth below and parallel to the right costal margin. To obtain free access to the **superior surface,** the eighth and ninth costal cartilages of the right side are divided; the seventh cartilage should, if possible, be avoided, for the pleural cavity may be opened into. Division of the round and falciform ligaments allows of greater downward displacement of the liver. To reach the upper part of the **lateral surface** of the right lobe, portions of the seventh and eighth ribs in the mid-axillary line are removed, and both the pleural and peritoneal cavities are traversed.

Gall-Bladder.—The relation of the fundus of the **gall-bladder** to the surface of the body is subject to considerable variation. Normally it is situated behind the angle between the ninth costal cartilage and the lateral border of the right rectus; exceptionally, it is pendulous and suspended from the liver by a more or less distinct mesentery; or it may be elongated and drawn downwards by adhesion to the duodenum or colon. When displaced downwards it is liable to be mistaken for a movable kidney, but may be distinguished from it by the fact that although it may be pushed backwards into the lumbar region it returns at once to its habitual position, immediately behind the anterior abdominal wall, as soon as the pressure is discontinued.

The **cystic duct** is enclosed in the right end of the upper border of the lesser omentum. It is about 3·8 cm. in length, and is sharply bent upon itself close to its origin at the neck of the gall-bladder. It joins the common hepatic duct at a very acute angle. The passage of a probe along the *normal* duct is made difficult by the marked flexure at its commencement, and also by the folded condition of its mucous membrane; these features explain the frequency with which calculi become impacted at the neck of the gall-bladder.

In excising the gall-bladder, the cystic artery and duct are ligated and divided before proceeding to detach the organ from the liver; by this routine, bleeding is lessened and the difficult part of the operation is carried out before the field is obscured by blood from the under surface of the liver.

The outline of the normal gall-bladder is demonstrable on X-ray examination after the oral administration of the compound salt sodium tetra-iodo-phenol-phthalein (Pl. LX, p. 649). The procedure is employed in the investigation of cases of gall-stones and infections of the gall-bladder. A calcified gall-bladder may be visible in an ordinary radiograph (Pl. LII, p. 609).

Bile-Duct.—The bile-duct is about 8·8 cm. in length. Its *upper third* lies in the lesser omentum, close to the right, free border. That is the most accessible part of the duct, and, when cutting into it, it is drawn forwards by the finger introduced

lies immediately behind the duct. The *middle third* of the duct lies a little to the right of the gastro-duodenal artery behind the first part of the duodenum about two finger-breadths from the pyloro-duodenal junction. The *lower third* of the duct, which passes downwards and to the right, is intimately related to the back of the head of the pancreas; in about two out of three bodies it is so embedded in the substance of the gland that it cannot be freed by blunt dissection. Close to its termination the duct is joined by the main pancreatic duct, the two opening separately, but close together, into an *ampulla* which pierces the wall of the duodenum obliquely and opens on the summit of a small papilla situated at the middle of the medial wall of the second part of the duodenum. When a calculus becomes impacted in the ampulla there is retention of the pancreatic secretion as well as of the bile. Frequently, however, the pancreas has an accessory pancreatic duct which opens into the duodenum at a higher level than the main duct.

The surgeon may reach a calculus in the ampulla either by opening the duodenum from the front (trans-duodenal route) or by freeing the duodenum and gaining access to the bile-duct from behind (retro-duodenal route). In the latter instance an incision is made, lateral to the right border of the second part of the duodenum, through that portion of the peritoneum which passes upwards and to the right from the upper layer of the transverse mesocolon over the upper part of the second part of the duodenum on to the anterior surface of the right kidney. By blunt dissection directed medially behind the duodenum, the duodenum, along with the adjacent part of the head of the pancreas, can be separated from the kidney and vena cava, and folded over towards the left. As the bile-duct is freed from the back of the head of the pancreas a vein of considerable size will be encountered; this vein returns the blood from the pancreatico-duodenal system of arteries; it lies close to the bile-duct as it ascends behind the head of the pancreas to open into the commencement of the portal vein. Of the lymph-glands related to the bile-passages it is to be remembered that one lies at the neck of the gall-bladder, another at the junction of the cystic and hepatic ducts, while a third lies close to the termination of the bile-duct. When these glands are enlarged and indurated, care must be taken not to mistake them for impacted gall-stones. On account of the very free anastomosis between the lymph-vessels of the gall-bladder, bile-ducts, and pancreas, infective inflammatory processes readily spread from one organ to the other.

Stomach.—The stomach lies almost entirely in the left hypochondrium and in the left half of the epigastrium. The **cardiac orifice**, which is 2·5 cm. below and to the left of the œsophageal opening in the diaphragm, is about 10 cm. from the surface, and corresponds, on the anterior surface of the body, to a point over the seventh left costal cartilage 2·5 cm. from the median plane. The **pylorus** lies behind the quadrate lobe of the liver in the transpyloric plane, usually a little to the right of the median plane; when the stomach is *empty* the pylorus generally lies in the median plane, when *distended* it may reach 5 to 7·5 cm. to the right of the median plane. Passing from the upper to the lower border of the pylorus at its junction with the duodenum is the **prepyloric vein**. This vein is a useful visible guide to the position of the pylorus. Another guide is the ring-like thickening of the pyloric sphincter, which projects into the commencement of the duodenum and can be readily palpated through the duodenal wall. The highest part of the **fundus of the stomach** corresponds to the left vault of the diaphragm, and lies at the level of the fifth rib in the mid-clavicular line, a little above and behind the apex of the heart. The **greater curvature** crosses behind the left costal margin opposite the tip of the ninth costal cartilage. The lowest part of the great curvature, situated generally in the median plane, is a little above the level of the umbilicus. The **lesser curvature** and the adjacent part of the anterior wall of the stomach are overlapped by the left lobe of the liver.

Radiography of Stomach.—Radiographs taken after an "opaque meal" show that the form and position of the stomach in the living subject differ considerably from those which it presents in the cadaver—see also p. 620 and Pls. LII, LIII, LIV, pp. 609, 612, 613.

In the cadaver, owing to loss of muscular tone, the stomach presents itself as a more or less empty pear-shaped bag with collapsed and flaccid walls.

In the living subject, the form and position of the stomach are found to vary, not only according to the amount of food it contains, but also according to whether the patient occupies the erect or the recumbent posture (Fig. 530, p. 622). The most

the motor activity of the stomach is obtained by "screen" examinations and radiographs taken with the patient in the erect posture. When examined in that way after the stomach is partly filled with an "opaque meal", it is seen to have a distinctly J-shaped form (Pl. LII). The stem of the J, which represents the **body of the stomach**, lies immediately and entirely to the left of the vertebral column. The **fundus**, which is slightly more expanded than the body, reaches up to the left cupola of the diaphragm; it is represented in the radiograph as a dark semilunar area, the horizontal lower margin of which corresponds to the upper limit of the meal. That dark semilunar area is due to the presence of air which has been swallowed and which naturally rises to the highest part of the cavity. The **cardiac orifice** is seen to lie opposite the left side of the disc between the tenth and eleventh thoracic vertebræ. The shadow of the **pyloric portion of the stomach**, after crossing the left side of the vertebral column opposite the third and fourth lumbar vertebræ, ascends as the **pyloric canal** to join the duodenum to the right of the median plane opposite the second (not infrequently the third) lumbar vertebra. The **pylorus** itself is represented by a narrow streak of barium when the pyloric sphincter is contracted. The lowest portion of the **greater curvature**, which lies at or a little to the left of the median plane, reaches, in the erect posture, down to the level of the fourth lumbar vertebra or even lower.

As more food enters the stomach its capacity is increased by expansion of the organ and downward extension of its greater curvature. The normal tonic action of the gastric muscle is able to hold up the meal against the action of gravity to the level of the cardiac orifice. When, as not infrequently happens, the normal muscular tonicity of the stomach is lost, the barium is no longer held up against the action of gravity, but at once sinks to the most dependent part of the stomach, where it lies as in a flaccid sac, and gives rise to a crescentic shadow which may reach down almost, or even quite, to the level of the pubes.

In gastroptosis, and in general visceroptosis, the stomach may extend downwards without any great loss of its tonicity (Pl. LIV, Fig. 2, p. 613).

During a "screen" examination after an opaque meal, the peristaltic movements of the stomach can be seen to pass in distinct wave-like indentations from left to right along the greater curvature, and to increase in force as they approach the pylorus (Pl. LVI, p. 621). When the stomach is hypertrophied and dilated, as a result of pyloric obstruction, the peristaltic waves are at first more pronounced but in a short time they disappear and the organ takes on the atonic appearance described above. In the infant and young child the stomach is flask-shaped rather than fish-hook or J-shaped, and its axis is less vertical than in the adult (Pl. LV, Fig. 1, p. 620). The elongated form of the adult stomach is acquired as a result of the erect posture. Occasionally the axis of the adult stomach inclines more towards the horizontal and has a shape more like the horn of a steer (steer-horn stomach—Pls. LIV, Fig. 1, p. 613, and LV, Fig. 2).

It must be remembered that the only really fixed part of the stomach is the region of the cardiac orifice, and the form and position of the organ may therefore be considerably influenced by the condition of the neighbouring organs. For example, it may be displaced downwards and to the left by enlargement of the liver, upwards by distension of the intestines, and to the right by distension of the left colic flexure.

Ulcer of Stomach.—Perforation of an ulcer on the *anterior wall* of the stomach leads to extravasation into the greater sac of the peritoneum; and if the perforated ulcer is on the *posterior wall*, extravasation takes place into the lesser sac. The close relation of the splenic artery and its branches to the posterior wall of the stomach explains the severe hæmorrhage which is sometimes caused by a posterior gastric ulcer. The surgeon may reach the posterior wall of the stomach through the greater omentum near the stomach or, after throwing the greater omentum and transverse colon upwards, by traversing the transverse mesocolon; by the former route the posterior wall of the stomach is reached through the anterior wall of the lesser sac, by the latter through its posterior wall.

Operations on Stomach.—In partial resection of the stomach the main vessels are ligated at an early stage of the operation. The arteries are the right and left gastrics at the lesser curva-

ture, the gastro-duodenal behind the first part of the duodenum, and the right and left gastro-epiploics at the greater curvature. If the operation is for cancer, the left gastric is ligated as near the cardiac orifice as possible, in order that the whole chain of lymph-glands along the lesser curvature may be removed. The glands that lie behind the first part of the duodenum in relation to the gastro-duodenal artery and head of the pancreas also are removed, as well as those along the right half of the greater curvature in relation to the right gastro-epiploic artery. If the disease has spread to the retroperitoneal lymph-glands around the cœliac artery, *i.e.*, above the pancreas, the chances of a permanent recovery are very remote.

In the classical "no-loop" **gastro-enterostomy operation**, a longitudinal opening in the commencement of the jejunum is anastomosed by suture to an opening in the posterior wall of the stomach near the greater curvature. To bring the surfaces of the two organs in contact, surgeons are in the habit of protruding the posterior wall of the stomach through an opening made in the transverse mesocolon on the proximal side of the arch formed by the middle and left colic arteries. Another plan is to make an opening also into the lesser sac through the greater omentum a little below the gastro-epiploic vessels, and then to bring the jejunum into contact with the posterior wall of the stomach by drawing it (the jejunum) upwards through the opening in the transverse mesocolon. By that plan the posterior wall of the stomach along with the jejunum can be protruded through the opening in the greater omentum; they can then easily be delivered out of the abdominal cavity. Another advantage is that the transverse colon can be replaced into the abdominal cavity while the anastomosis is being made. When the posterior wall of the stomach and transverse colon are held down by adhesions, a long loop of jejunum is brought up in front of the greater omentum and transverse colon and anastomosed to the anterior wall of the stomach.

Duodenum.—The duodenum is the widest, thickest, and most fixed part of the small intestine. For descriptive purposes it is divided by anatomists into four parts. From the surgical standpoint it may with advantage be divided into a supracolic and an infracolic portion—above and below the attachment of the transverse colon. To expose the supracolic portion, the greater omentum and the transverse colon are pulled downwards; to expose the infracolic portion they are thrown upwards along with the transverse mesocolon.

The **first part** lies medial to the gall-bladder, overlapped by the quadrate lobe of the liver. As regards its **blood-supply**, it occupies the frontier zone between the cœliac and superior mesenteric vascular areas, and the vessels which supply it vary considerably in their size and mode of origin. The peculiarity of its blood-supply may partly account for the relative frequency with which that portion of the intestine is the seat of ulceration.

The first 2·5 cm. of the duodenum possesses some degree of mobility, being surrounded by the same two layers of peritoneum as invest the stomach. Beyond that it is in direct contact posteriorly and inferiorly with the pancreas, while descending behind it are the bile-duct and the gastro-duodenal artery. When an ulcer of the first part perforates, extravasation takes place, in the first instance, into the supracolic compartment of the peritoneum, thence into the recess between the liver and kidney, and subsequently down along the ascending colon into the right iliac fossa—hence the possibility of mistaking the condition for an acute appendicitis. Perforation of the ulcer into the peritoneal cavity is often prevented by the duodenum becoming adherent—especially to the pancreas, to the gall-bladder, or to the omentum.

If the finger is passed upwards, backwards, and to the left, immediately above the first part of the duodenum and behind the free border of the lesser omentum, it will pass through the opening into the lesser sac. Another method of finding the opening is to pass the finger along the under surface of the gall-bladder from the fundus towards the neck.

The **second part** of the duodenum descends from the neck of the gall-bladder to the level of the third lumbar vertebra. The transverse colon crosses it about its middle, while posteriorly it lies in front of the hilum and medial border of the right kidney, from which it is separated by loose areolar tissue. The procedure necessary to free that portion of the duodenum has been referred to already (p. 1499).

The **third part** of the duodenum crosses the inferior vena cava and the aorta about 2·5 cm. above a line joining the highest part of the iliac crests; the upper part of the right ureter is behind its commencement.

The **fourth part** ascends on the left psoas opposite the third and second lumbar vertebræ.

The X-ray shadow of the first part of the duodenum usually takes the

directed towards the pylorus (Pl. LII, p. 609). Owing to the fact that th opaque meal is held up for a short time in the cap, the shadow is denser than th caused by the other divisions of the duodenum, which are rapidly traversed by th meal; and as the first 2·5 cm. of the duodenum contains no circular folds of mucou membrane the outline of the cap is smooth and nearly symmetrical. In duoden ulcer the outline of the cap is generally distorted—owing partly to fibrosis an partly to the spasm which the ulcer sets up.

Duodeno-Jejunal Flexure.—This flexure is 2·5 cm. below the transpyloric plan and the same distance to the left of the median plane, and it is the landmark whic the surgeon makes for when he wishes to identify the commencement of the jejunu (Fig. 568, p., 669 and Pls. LIII, LIV, Fig. 1, p. 612). To find the flexure, the great omentum and the transverse colon are thrown upwards, and the finger is passed alon the lower layer of the transverse mesocolon to the left side of the vertebral column. Th flexure lies in the angle between the left psoas major and the inferior surface of the bod of the pancreas. With the finger in that angle the commencement of the jejunum ma be hooked forward a little to the left of the superior mesenteric vessels at the root the mesentery.

Peritoneal Recesses.—There may be one or more small peritoneal recesses in th neighbourhood of the end of the duodenum. The one that is surgically the mo important is the **paraduodenal recess**, which is a little to the left of the fourt part of the duodenum, with its mouth looking towards the right. An intern hernia may develop in it; and should strangulation occur, the incision to relieve is made in the lower margin of the mouth to avoid the inferior mesenteric vein, fo the vein first ascends in the peritoneal fold which forms the anterior margin an then curves medially in the upper margin (see also p. 632).

Jejunum and Ileum.—To expose the coils of the jejunum and ileum completel the greater omentum is turned upwards along with the transverse colon and th greater curvature of the stomach. On account of the oblique attachment of th mesentery, the greater number of the coils lie in the left infracolic peritone compartment, where they extend upwards to the left of the vertebral column a far as the attachment of the transverse mesocolon and the inferior surface of th pancreas; here they lie in front of the lower part of the left kidney, in the ang of the left colic flexure.

The only certain means which the surgeon has of distinguishing the uppe from the lower coils of small intestine is by their relation to the duodeno jejunal flexure and the ileo-cæcal junction. The lower coils of the ileum lie in th true pelvis, and the *terminal portion of the ileum*, which is attached by the lowes part of the mesentery to the floor of the right iliac fossa, crosses the brim of th pelvis, and ascends along the medial side of the cæcum to reach its openin into the large intestine. The terminal loop of the ileum may be hooked up b the finger passed along the medial side of the cæcum downwards over the media border of the right psoas major and the external iliac vessels into the true pelvis.

To bring out a loop of the upper jejunum in the operation of jejunostomy, the abdomen i opened through the left rectus muscle at the level of the umbilicus or a little above it. Th duodeno-jejunal flexure is then identified and a catheter is introduced into the jejunum, an the bowel itself is then sutured to the edges of the opening in the divided peritoneum.

The **diverticulum ilei**, which is due to persistent patency of the proximal portio of the vitello-intestinal duct, is situated on the anti-mesenteric border of the ileum, usuall from 60 to 90 cm. above the ileo-cæcal junction; its average length is 5 cm. Its termina tion is usually free, but it may be adherent either to the anterior abdominal wall, to th mesentery, or, more rarely, to one of the adjacent viscera. When its termination i fixed it may give rise to strangulation of the intestine.

Cæcum.—The cæcum occupies the right iliac region from the anterior superio iliac spine to the brim of the pelvis (Pls. LVII and LVIII, p. 648). **When empty**, it generally more or less completely overlapped by small intestine, and frequentl also by the greater omentum. **When partly distended**, the cæcum comes in contac with the anterior abdominal wall immediately above the lateral half of the in guinal ligament. **In the normal condition** it is completely clothed with peritoneun

and can, therefore, along with the vermiform appendix, be readily delivered out of the abdomen. In chronic constipation associated with intestinal atony, the cæcum is thin-walled and dilated; and stretching of its attachments to the posterior abdominal wall results in abnormal mobility so that it may sink into the pelvis and rest upon the pelvic floor.

The position of the **ileo-colic valve** corresponds, on the surface of the body, to the lower medial angle between the intertubercular and right vertical lines, and the orifice of the vermiform appendix is 2·5 cm. lower. It is to be noted that the lower end of the ileum protrudes into the cæcum, and that its circular muscular fibres are prolonged into the flaps of the ileo-colic valve. Both of those anatomical arrangements favour the occurrence of intussusception. In infants, other predisposing causes are: (1) the striking disproportion in size of the lumen of the large and small intestines; (2) the greater mobility of the cæcum; and (3) the frequent presence of a mesentery to the ascending colon.

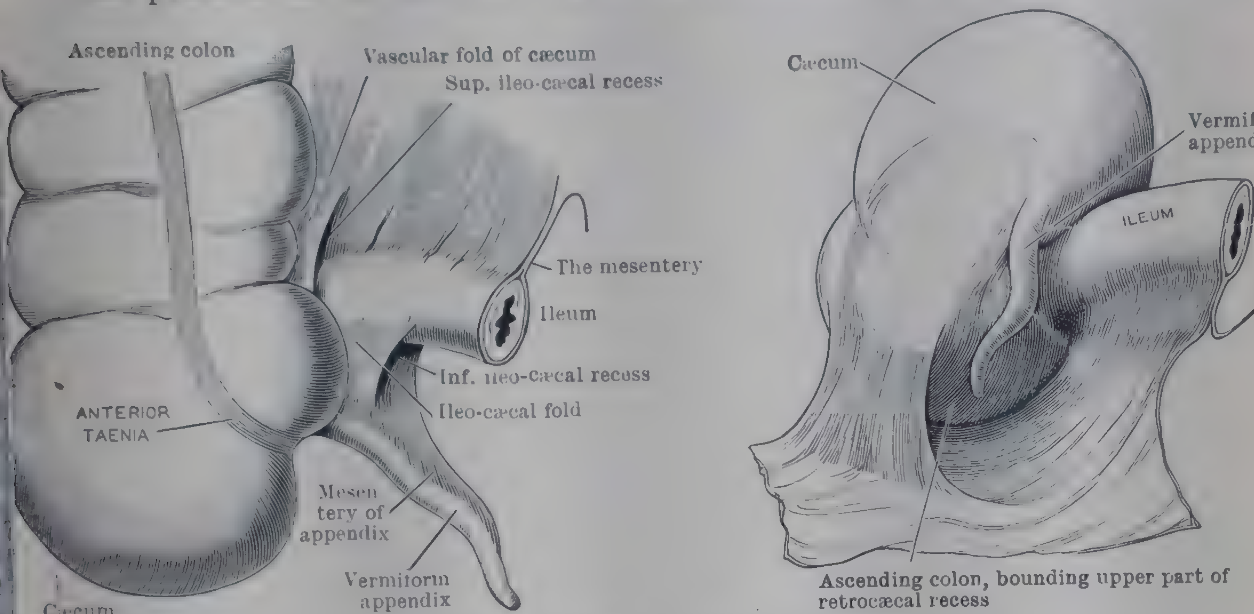

Fig. 1221.—Ileo-Cæcal Region and Recesses.

Vermiform Appendix (Pl. LVII, p. 648).—The vermiform appendix springs from the postero-medial aspect of the cæcum 2·5 cm. below the ileo-cæcal junction; and it is provided with a small but well-formed mesentery derived from the posterior layer of the lowest part of the mesentery of the ileum. That portion of the posterior layer of the mesentery sometimes develops a band-like thickening which, by dragging upon the lower end of the ileum, produces the kink to which attention was directed by Arbuthnot Lane. The vermiform appendix is supplied by one artery; it occupies the free border of its mesentery and gives off several branches to the organ. In amputating the vermiform appendix, the artery is ligated on the proximal side of its first branch in order to control the blood-supply to the stump of the appendix. The fact that the vermiform appendix is supplied by a single artery predisposes it to gangrene should the vessel become thrombosed, or should the circulation in it be interfered with as

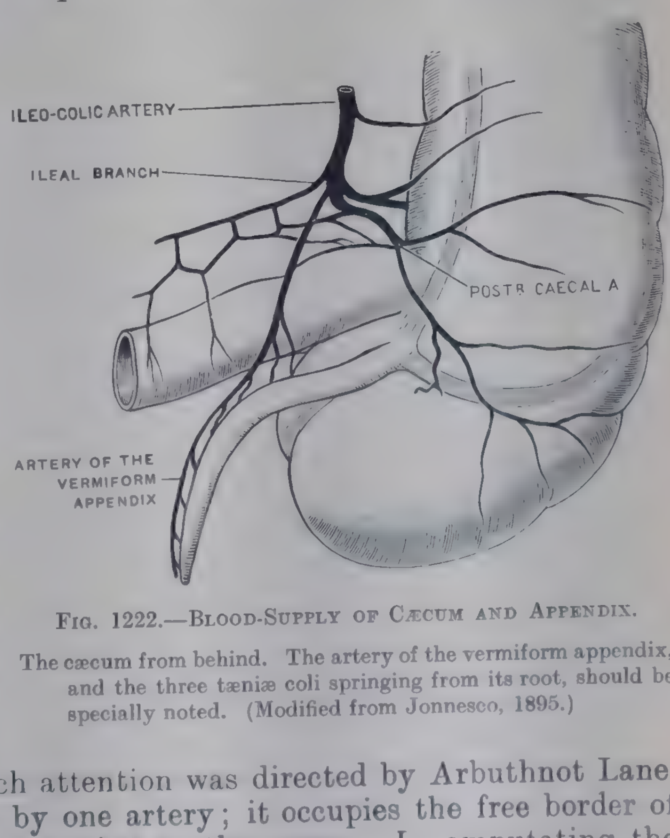

Fig. 1222.—Blood-Supply of Cæcum and Appendix.

The cæcum from behind. The artery of the vermiform appendix, and the three tæniæ coli springing from its root, should be specially noted. (Modified from Jonnesco, 1895.)

The vermiform appendix will generally be found to pass either upwar medially behind the lower end of the ileum, or downwards and medially ov external iliac vessels into the pelvis; less frequently it ascends in the recess the caecum (Fig. 1221). When an inflamed appendix occupies the last-men situation a retrocaecal abscess may result. The abscess may perforate the po wall of the caecum, or it may ulcerate through the posterior peritoneum; latter case the suppuration may spread upwards, in the loose, fatty extraper tissue behind the colon, into the lumbar and perinephric regions; and it may even the under surface of the diaphragm and form a subphrenic abscess. caecum remains undescended, the appendix lies in relation to the pyloro-du junction, the neck of the gall-bladder, and the lower half of the right k When it dips downwards into the pelvis it may become adherent to the colon, the rectum, or the bladder, or, in the female, to the uterine tube ovary.

To find the vermiform appendix, the caecum is pulled out of the wound, and if the p normal the appendix will be delivered along with it; but, if the caecum and appendix are down by adhesions, it is identified by following the anterior taenia coli to its root.

Ascending Colon.—The ascending colon, after crossing the iliac crest, l the fascia covering the quadratus lumborum and the adjacent aponeurotic or the transversus abdominis. Between the bowel and the fascia there is a qu of loose, fatty areolar tissue which may be the seat of an abscess; the source which such an abscess may arise are—(1) the ascending colon, (2) a ret vermiform appendix, (3) the right kidney. The areolar tissue is directly conti above with a thin layer that lines the lower surface of the diaphragm suppurative process may therefore extend upwards and give rise to a subp abscess. The ascending colon is occasionally completely clothed with perito and it may even be provided with a mesocolon. A mesocolon is almost inva present in infants who develop ileo-caecal intussusception; after the intussus has been reduced, the mesentery of the ileum is seen to be continuous, throu ascending mesocolon, with the transverse mesocolon.

In order to resect the caecum and ascending colon, the surgeon frees them by divid peritoneum along its line of reflexion from the colon on to the side-wall of the ab The colon, along with the posterior peritoneum medial to it, is then stripped, fr lateral side towards the median plane, off the quadratus lumborum, the psoas, and th part of the right kidney. While that is being done, the branches of the ileo-colic an colic vessels, which pass laterally to supply the gut, are secured, and the lymph-vess associated lymph-glands are removed along with the bowel. As the peritoneum is strip care must be taken not to injure the important structures which lie behind it, name duodenum, the ureter, and the testicular or ovarian vessels.

The **right colic flexure** lies between the lower part of the right kidne the liver, immediately to the right of the gall-bladder, opposite the tenth cartilage—just below the level of the transpyloric plane. It is separated fro kidney by a quantity of loose areolar tissue; therefore, after the peritoneum its right side is divided, it is an easy matter to dissect it from the kidney.

Transverse Colon.—The transverse colon crosses the abdomen immed above the level of the umbilicus and below the greater curvature of the st (Pls. XLVIII, p. 538, LVII and LVIII, p. 648). In cases of visceroptosis i form a U-shaped or V-shaped loop that extends down to the level of the pub

The transverse colon receives its blood-supply from the arch formed b middle and left colic arteries. The arch lies in the posterior wall of the sac between the two layers of the transverse mesocolon.

In resecting portions of the stomach for malignant disease, the surgeon removes the which lie in the greater omentum in relation to the right gastro-epiploic vessels. At th of the operation care must be taken not to endanger the blood-supply of the transvers by injury to the middle colic artery.

The **left colic flexure** is more acute and more fixed than the right flexure it is at a higher level as well as deeper. A tumour that originates in the f is generally under cover of the left costal margin, and it is therefore diffic palpate it.

To expose the left colic flexure, the omentum is turned upwards along with the transverse olon and the body of the stomach. To free it for the purpose of resection, the surgeon must vide: (1) the phrenico-colic ligament, which attaches it to the diaphragm opposite the eleventh b; (2) the left border of the greater omentum, which attaches it to the stomach; and (3) the ft portion of the transverse mesocolon, which attaches it to the pancreas.

Descending Colon.—The *upper part* of the descending colon, like the ascend-ng, is deeply placed in the lumbar region and is related to the lower half of the teral border of the left kidney. It is less frequently provided with a mesocolon han is the ascending colon.

The *lower part* (iliac colon) begins at the iliac crest, and ends at the inlet f the pelvis by joining the pelvic colon. It has no mesocolon, and is connected the fascia covering the iliacus and psoas major muscles by loose areolar tissue. owards its termination it turns medially immediately above and parallel to the guinal ligament, and at its junction with the pelvic colon it lies in front of the sticular (or ovarian) and external iliac vessels. Although, as a rule, it is entirely verlapped by coils of small intestine, it can frequently be felt by firm palpation at e lateral part of the left iliac fossa, because its muscular wall is comparatively hick and generally is contracted.

Pelvic Colon (Pls. LVII and LVIII, p. 643).—The pelvic colon, in con-equence of having a well-developed mesocolon, is a freely movable loop which, hough usually confined to the true pelvis, may, when distended, rise well up into e abdomen. It is the section of the large intestine which is opened for the urpose of making an artificial anus in malignant disease of the rectum.

The pelvic colon varies considerably in length, the average being 40 cm. It is latively longer and of greater calibre in the child than in the adult. It is the part the large intestine especially involved in the condition known as **megalocolon**—a ngenital abnormality in which the large intestine is greatly dilated and its walls ypertrophied.

When the pelvic colon is thrown upwards and to the right, its mesocolon is read out and is seen to be attached in an inverted V-shaped manner to the sterior wall of the pelvis. At the apex of the Λ there is occasionally a small ritoneal pouch, called the **recess of the pelvic mesocolon**, situated in front of the eter as it crosses the termination of the common iliac artery to enter the pelvis. hat recess is one of the situations at which an internal retroperitoneal hernia ay originate. The mouth of the recess looks downwards and to the left, while ove and to its right there is a branch of the lower left colic artery. The recess a guide to the position of the left ureter (p. 647).

It is to the proximal part of the pelvic colon that the divided lower end of the um is anastomosed in the short-circuiting operation of **ileo-sigmoidostomy**.

In the operation of transplanting the ureters into the large intestine r incontinence of urine—the result of epispadias in the female, and of ectopia sicæ in either sex—the left ureter is implanted into the proximal part of the lvic colon and the right ureter into its distal part.

In the operation of abdomino-perineal excision of the rectum, division of the achments of the pelvic mesocolon is the first step. The colon is then divided; its oximal end is brought out through a small opening in the left iliac fossa (*colostomy*); distal segment is passed through the floor of the pelvis, and removed with the tum by a perineal incision. Further, the mobility of the pelvic colon is such that er the whole descending colon is resected and the left colic flexure is freed, the vided ends of the bowel can be sutured together without undue tension.

Kidneys.—The kidneys lie behind the peritoneum; they are higher up than often supposed, and they are not so far away from the vertebral column as is en depicted; hence it is that, unless enlarged, the kidneys can seldom be felt rough the abdominal wall. The right kidney as a rule is a little lower than left, as well as a little farther away from the median plane. The hilum of the ht kidney is 5 cm. from the median plane; that of the left rather less. For actical purposes the **hilum** of the kidney may be regarded as opposite a point the anterior abdominal wall a finger's breadth medial to the tip of the ninth

first and second lumbar vertebræ—that is, a little below the transpyloric line. The position of the other parts can be judged from the situation of the hilum.

A great part of the upper half of the anterior surface of the **right kidney** is covered with peritoneum and can be felt by the hand passed upwards behind the right lobe of the liver and pressed backwards. Its lower half is felt immediately below the right lobe; and the small part of it that is covered with peritoneum lies in the angle of the right flexure of the colon. The second part of the duodenum overlaps the medial border. When the right kidney is excised by the abdominal route, the peritoneum is divided lateral to the ascending colon and right colic flexure, and these structures, along with the second part of the duodenum, are stripped off the organ in a medial direction, until the hilum and the renal vessels are exposed.

The **left kidney** is crossed transversely, about its middle, by the body of the pancreas and the splenic vessels. To palpate the suprapancreatic portion, the

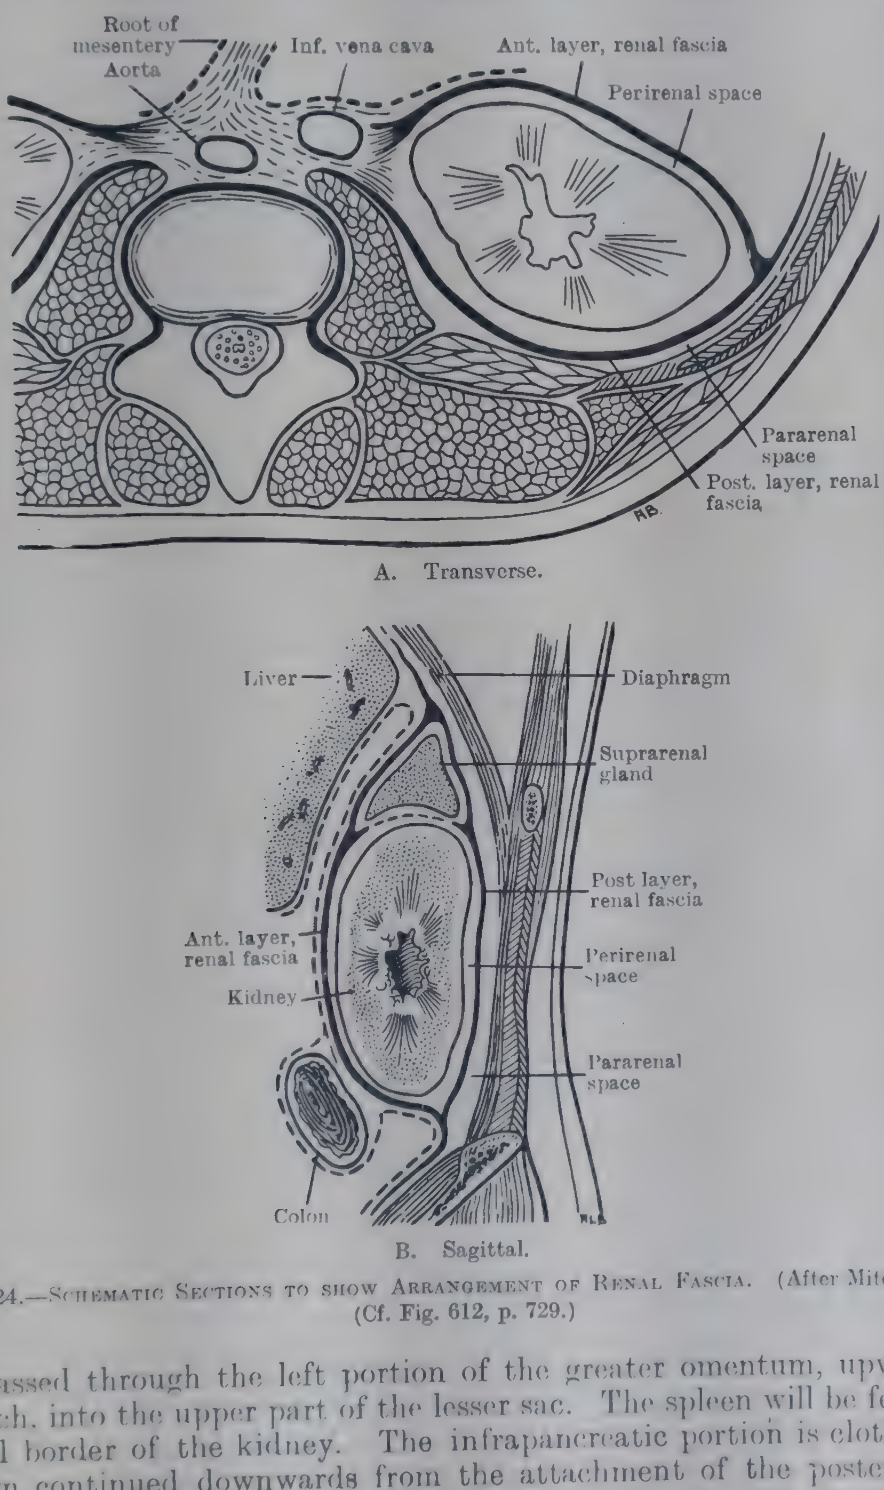

Fig. 1224.—Schematic Sections to show Arrangement of Renal Fascia. (After Mitchell, 1950.) (Cf. Fig. 612, p. 729.)

hand is passed through the left portion of the greater omentum, upwards behind the stomach, into the upper part of the lesser sac. The spleen will be felt to overlap the lateral border of the kidney. The infrapancreatic portion is clothed with the peritoneum continued downwards from the attachment of the posterior layer of the transverse mesocolon; coils of jejunum overlie it; the descending colon may overlap its lateral border; and, underneath the peritoneum, it is crossed by

branches of the upper left colic vessels. To palpate this part of the left kidney the hand is passed deeply into the upper part of the left infracolic peritoneal compartment as far as the angle of the left flexure of the colon, and pressed backwards. When the left kidney is excised by the transperitoneal route, the surgeon frees the left colic flexure and the descending colon by dividing the peritoneum, and he chooses the lateral side in order to avoid the branches of the left colic artery.

The kidney is surrounded by a variable quantity of **renal fat**, and is enclosed with its fat in an ill-defined sheath of **renal fascia**. The sheath is a continuation of the fascia transversalis. At the lateral margin of the kidney the fascia splits into two layers (anterior and posterior renal fasciæ). The anterior layer passes in front of the kidney and merges into the mass of connective tissue that surrounds the great vessels, while the posterior layer passes behind the kidney, blends with the fascia of the psoas, and is attached to the intervertebral discs close to the medial border of that muscle (Mitchell, 1950). The two layers remain separate for some distance, or are only weakly united, below the kidney, and it is int[o] that downward extension of the fascial compartment that the kidney descend[s] in the condition known as **movable kidney**. The posterior layer also fuses with the connective tissue around the aorta and inferior vena cava: and the attachment of both layers around these vessels forms a kind of septum which prevents a perinephric abscess from extending across the median plane to the opposite side (see also p. 728) The suprarenal gland is enclosed in the renal fascia, separate from the kidney by a thin fascial lamina only, and above the gland the two layers are firmly united to each other and to the diaphragmatic fascia (Fig. 1224). Fat lying between the renal fascia and the kidney is described as *perirenal fat*, and outside the renal fascia there is a second layer of fat sometimes spoken of as the *pararenal fat.*

The lower pole of the kidney may receive a special blood-supply either directly from the aorta or from the renal artery.

The branches of the renal artery are distributed to the cortex of the kidney in an anteri[or] and a posterior group; therefore, in splitting the kidney substance to reach the pelvis of th[e] ureter, the incision is made along the frontier line between the two vascular areas, viz., abo[ut] 1·3 cm. behind and parallel to the lateral border of the kidney.

Ureters.—Each ureter is about 25 cm. in length. It lies behind the peritoneum on the psoas major muscle, and it descends almost vertically about 4 cm. from th[e] median plane. At the level of the pelvic brim it crosses the origin of the extern[al] iliac artery and then passes backwards and downwards into the true pelvis in fro[nt] of the internal iliac artery.

The diameter of the ureter is not uniform. Its intravesical portion has th[e] smallest lumen, and it is there that calculi are most likely to become impacte[d]. A second narrowing occurs at or a little below the origin of the ureter proper fro[m] its pelvis, and a third where it crosses the brim of the pelvis.

The ureter has a fairly thick muscular wall, and its rich blood-supply favou[rs] rapid healing. Its abdominal portion is supplied by the renal and testicular (or ovarian) arteries; its pelvic portion by the vesical and the middle rectal arteries. B[y] their anastomoses they form a continuous and slightly tortuous chain which [is] generally visible through the peritoneum along the whole course of the tube.

The outline of the pelvis of the ureter and the relations of it and of the uret[er] proper to the skeleton may be demonstrated by X-rays after injection of the lum[en] by a radio-opaque fluid such as sodium iodide ("*retrograde pyelography*", Pl. LX[X], p. 744).

Similar but less well-defined appearances are obtained by the intraveno[us] injection of a radio-opaque substance excreted by the kidneys ("*excreti[on] urography*" or "*descending pyelography*", Pl. LXXI, Fig. 1, p. 745)—see p. 155[…]

The shape of the normal pelvis of the ureter and the arrangement of [the] major and minor calyces vary considerably (Pls. LXX, LXXI). The shadow[s] opposite the tips of the transverse processes of the first and second lumbar verteb[ræ] —the upper calyces generally overlapping a portion of the twelfth rib.

The radiographic shadow produced by an opaque catheter in the ureter crosses the tips of the transverse processes of the lumbar vertebræ and then descends to a point opposite the lower end of the sacro-iliac joint; from there the shadow descends with a curve, almost parallel to the shadow of the side of the pelvic brim, and ends opposite a point a little above and medial to the pubic tubercle. Laterally the shadow reaches almost to that caused by the ischial spine (Fig. 1225). The ureter is occasionally double throughout, or it may be bifid above or below. When the kidney is prolapsed, the abdominal portion of the ureter acquires a tortuous outline.

Normally the pelvis of the ureter can contain about 7 c.c. of fluid without discomfort to the patient. Its wall, like that of the ureter proper, is very distensible; it is therefore capable of great expansion in cases of gradually increasing urinary obstruction (hydronephrosis); and, for the same reason, incisions into these structures heal rapidly because the edges of the wound fall into apposition. To avoid branches of the renal vessels, incisions into the pelvis of the ureter are made horizontally through its posterior wall.

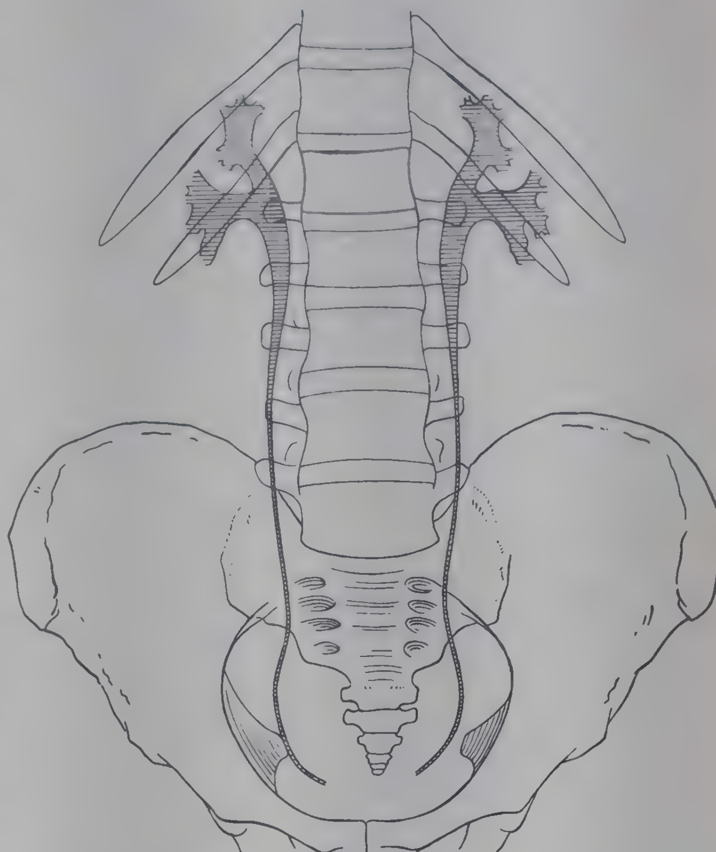

Fig. 1225.—Outlines of Pelves of Ureters and of Ureters proper in relation to the Skeleton. (Drawn from radiograph; cf. Pls. LXX, LXXI, p. 744.)

Pancreas.—The *head of the pancreas* occupies the curve of the duodenum and is at the level of the second lumbar vertebra. The *neck* is opposite the first lumbar vertebra, in the transpyloric plane, and the body lies partly above that plane. The relations of the pancreas to the transverse mesocolon and to the neighbouring viscera have been sufficiently referred to already.

After opening the abdomen in the median line, the pancreas is exposed by passing through the greater omentum near the greater curvature of stomach. Access to the organ through either the lesser omentum or the transverse mesocolon is more limited and therefore less satisfactory.

A pancreatic cyst gives rise to a tumefaction of the abdomen either in the epigastrium or in the umbilical region, depending on whether it pushes the lesser omentum before it and develops between the liver and stomach, or whether it extends forwards below the stomach. In severe contusions of the abdomen the pancreas may be ruptured against the vertebral column.

Vessels of Abdomen.—The commencement of the **abdominal aorta** and the **cœliac artery** are situated one finger's breadth above the transpyloric plane. The **abdominal aorta** bifurcates a little to the left of the median plane, on a level with the highest part of the iliac crest, and about 1·3 cm. below the level of the umbilicus.

The **inferior vena cava** lies immediately to the right of the aorta; its most important surgical relation is the right ureter, which is to the right of it and may lie close to its right side.

The **common** and **external iliac arteries** may be mapped out by a line drawn, with a slight lateral curve, from a point opposite the bifurcation of the aorta to the mid-inguinal point; the upper third of the line corresponds to the common iliac artery, the lower two-thirds to the external iliac.

In ligaturing the lower part of the common iliac artery or the upper part of the exter iliac, the close relation of the ureter and the ovarian vessels must be remembered: in ligat of the lower part of the external iliac in the male, the testicular vessels and the vas defer have to be avoided.

The common **iliac veins** lie in a plane posterior to their arteries; but the l vein, as it crosses the fifth lumbar vertebra, is also below and to the right of artery, and it ends behind the right artery by uniting with the right vein form the inferior vena cava.

The fact that the end of the left common iliac vein is *behind* the right comm iliac artery has long been regarded as a sufficient explanation for the greater f quency with which thrombosis of the femoral vein is met with on the left side th on the right: but a probable contributory factor is the close relation of the colon the left external iliac vessels, for a loaded colon, exerting pressure on them, m retard the blood-flow in the vein.

The great vessels on the posterior abdominal wall, along with the adjace lymph-vessels and lymph-glands, lie in the extraperitoneal fat, and therefore witl the general fascial envelope of the abdomen. Abscesses which originate from retroperitoneal lymph-glands are, therefore, like perinephric abscesses, extrap toneal but intrafascial; abscesses of vertebral origin, whether lumbar, iliac, psoas, are extrafascial. Abscesses connected with the vermiform appendix primarily intraperitoneal; occasionally they ulcerate through the parietal pe toneum and burrow in the extraperitoneal fat.

MALE PERINEUM AND PELVIS

The male perineum is a heart-shaped space, the osseous boundaries of which the same as those of the outlet of the pelvis. A line drawn transversely across perineum between the anterior part of the tuberosities of the ischium crosses median plane immediately in front of the anus and divides the space into anterior or urogenital triangle and a posterior or anal triangle.

Urogenital Triangle.—This triangle is divided into a superficial and a d compartment or pouch by the perineal membrane.

The **superficial perineal pouch** contains the root of the penis, which gives rise a longitudinal fullness on the surface. Anteriorly, the surface of the triangle continued on to the scrotum, while on each side a distinct groove separates it fr the medial surface of the thigh. The **perineal body** (central point) is the comm tendon of the perineal muscles, mingled with fat and continuous with the mid of the posterior border of the perineal membrane: it lies a finger's breadth front of the anus. In front of it, about 2·5 cm. from the centre of the anus the posterior end of the **bulb of the penis.**

The pouch is bounded below by the membranous layer of the superficial fas which is attached posteriorly to the posterior border of the perineal membrane on each side to the margin of the pubic arch. Anteriorly the membranous fa passes on to the scrotum, the penis, and spermatic cord, to become continuous w the membranous layer of the superficial fascia on the front of the abdomen.

When the urethra is ruptured distal to the perineal membrane, the course infiltration of the extravasated urine is determined by the attachments of membranous layer of fascia; at first, therefore, the urine is confined within superficial pouch, but it gradually travels forwards on to the lower par the anterior abdominal wall; it is prevented from passing into the front of thigh by the attachment of the membranous fascia of the abdomen to the fa lata a little distal to the inguinal ligament.

The **deep perineal pouch** is the interval between the perineal membrane the fascia of the pelvis. The most important structures in the pouch are membranous part of the urethra surrounded by its sphincteric muscle, the bu urethral glands, the dorsal nerve of the penis, the internal pudendal vessels, the artery to the bulb.

The **membranous part of the urethra** lies 2·5 cm. behind the lower border of pubic symphysis. When that portion of the urethra is ruptured, the extravas

urine, after filling the deep pouch, may reach the superficial pouch by bursting through the perineal membrane where the vessels pierce it; or it may penetrate the fascia of the pelvis, infiltrate the perivesical areolar tissue and the retropubic space, and ascend on the anterior abdominal wall between the fascia transversalis and the parietal peritoneum.

The **bulbo-urethral glands** lie immediately behind the membranous part of the urethra, separated from the bulb of the penis by the perineal membrane. The **internal pudendal vessels** and the **dorsal nerve** lie just within the margin of the pubic arch. The **artery to the bulb** runs transversely and medially 0·5 cm. in front of the posterior border of the perineal membrane.

Male Urethra.—The male urethra measures about 20 cm. from the external to the internal orifice; the narrowest point is at the external orifice; a second narrowing occurs at the perineal membrane. It is behind these narrow points that a calculus is apt to become impacted. The *most dependent part* of the urethra is the portion in the bulb, and it is there that stricture is most frequently encountered. The membranous part of the urethra, situated between the perineal membrane and the fascia of the pelvis, is surrounded by the sphincter urethræ muscle, which, when thrown into spasm, may firmly grip an instrument as it is passed into the bladder. *Rupture of the urethra* from a fall on the perineum generally involves the portion in the bulb. A *false passage* made during the passage of an instrument generally traverses the floor of the urethra at the perineal membrane; to prevent that injury the point of the instrument is directed upwards, and at the same time the handle is depressed as soon as the instrument is felt to encounter the resistance of the perineal membrane. When the *prostate is hypertrophied* the prostatic part of the urethra is elongated, and its internal orifice may look directly forwards; and if the lateral lobes are unequally enlarged it may deviate to one side. Patients with prostatic hypertrophy are seldom able to empty the bladder completely, on account of the dependent well which is formed behind the enlarged middle lobe.

From the clinical point of view surgeons speak of an "anterior urethra", situated distal to the membranous portion, and a "posterior urethra", situated proximal to it. The anterior urethra is the least sensitive portion of the canal, but the posterior urethra is highly sensitive and more vascular; and when its mucous membrane is injured toxic agents may be rapidly absorbed by the abundant blood-vessels and lymph-vessels of its submucous tissue. The anterior urethra is shut off from the posterior urethra by the tonic contraction of the sphincter urethræ muscle.

Viewed with an endoscope the mucous membrane of the anterior urethra is seen to be smooth and glistening and to have a pale yellowish-pink colour. The mucous membrane of the posterior urethra is of a redder colour. The opening of the prostatic utricle is seen as a small slit-like orifice on the most prominent part of the urethral crest, while immediately on each side of it is the minute orifice of the ejaculatory duct. In the floor of the sulcus on each side of the crest are the minute openings of the majority of the prostatic ducts.

Cystoscopic Examination of Bladder.—In a cystoscopic examination of the bladder special attention is paid to the **trigone**, as most of the pathological lesions are associated with that region. The **internal urethral orifice** is at its inferior angle: and at its supero-lateral angles there are the small oblique, slit-like **orifices of the ureters**, each surrounded by a very slight lip-like elevation of the mucous membrane. At the base of the trigone the mucous membrane is raised into a smooth *transverse ridge* which stretches between the ureteric openings with a slight forward convexity. The ridge is caused by a bundle of transverse muscular fibres continuous with the longitudinal fibres of the ureters. The distance of the ureteric orifices from each other is rather more than 2·5 cm., and their distance from the internal urethral orifice is slightly less than 2·5 cm.

The urine is ejected into the bladder intermittently at intervals of a minute or so. During each ejection the ureteric orifice is seen to pucker up, and, as it relaxes the gush of urine takes place in the form of a characteristic whirl "resembling an injection of glycerine into water". The **mucous membrane** of the trigone is closely connected with the subjacent muscular wall, and is therefore smooth; whereas

over the rest of the bladder it is thrown into folds owing to the looseness of the submucous tissue. Further, the mucous membrane of the trigone has a pink tinge, while over the rest of the bladder it is of a pale straw colour. This contrast is due to the difference in the number and arrangement of the blood-vessels. Over the trigone they are larger, more numerous, and form so close a network that, when the surface is inflamed, the dilated, congested vessels form a continuous vascular layer. Over the rest of the bladder one sees, here and there in the mucous membrane, small segments of fine vessels giving off a cluster of short branches, the finer anastomoses of which are not visible when the mucous membrane is healthy.

The form and shape of the trigone in women may be distorted by prolapse of the bladder, by alterations in the size and position of the cervix uteri, and by the presence of fibroids. In the male, distortion is usually due either to the enlargement of the prostate or to disease of the seminal vesicles.

When the normal bladder is comfortably filled, the bladder walls appear almost smooth, but when the bladder contracts the delicate muscular trabeculæ become visible through the mucous membrane. When the bladder is hypertrophied as the result of urethral obstruction the muscular trabeculæ become greatly hypertrophied, and stand out prominently, even when the bladder is full. The spaces between the trabeculæ may become so deeply pitted as to lead to the formation of little pockets known as **false diverticula**.

Prostate.—With the body erect the **base** of the prostate is in a horizontal plane at the level of the middle of the pubic symphysis, while its **apex** is 1·3 cm. behind and below the lower border of the symphysis. It follows, therefore, that the vesical orifice and the base of the prostate are within easy reach of the finger introduced through a suprapubic cystotomy-incision. The **anterior surface** of the prostate is about 2 cm. behind the pubes, to which it is connected by the pubo-prostatic ligaments. Above those ligaments is the *retropubic space*, occupied by fatty tissue which passes upwards in front of the anterior wall of the bladder, between the umbilical arteries, as far as the umbilicus, while laterally it extends on each side, between the peritoneum and pelvic fascia, as far back as the internal iliac arteries. The **posterior surface** of the prostate is related to the part of the rectal ampulla immediately above the anal canal, and is therefore accessible to palpation *per rectum*. Between the rectum and the posterior part of the fascial sheath of the prostate there is a layer of loose areolar tissue which is taken advantage of in the operation of excision of the rectum and when the posterior surface of the prostate is exposed in the operation of perineal prostatectomy. The areolar tissue between the rectum and the prostate is traversed by a fibrous sheet, called the *recto-vesical septum*, which extends in a coronal plane from the floor of the recto-vesical pouch of peritoneum to the perineal body and is the remains of the walls of the lower part of the recto-vesical pouch, which originally extended down behind the prostate. The **lateral surfaces** of the prostate cannot be felt through the rectum; they are related to the anterior parts of the levatores ani, from which they are separated only by the fascial sheath of the gland.

The *prostatic substance* is made up of branching tubular glands supported by a fibro-muscular stroma. The gland tissue is most abundant in the posterior and lateral parts of the organ; anteriorly the stroma is more abundant and extends backwards from the capsule to the urethra to form a sort of anterior commissure. By the term "*capsule*" of the prostate is understood the immediate or proper envelope of the gland; that envelope consists of parallel layers of fibro-muscular tissue continuous with the stroma of the organ and forming part of it. In some instances it is so thin that the gland tissue reaches almost to its surface, while in other instances it is so thick as to deserve to be regarded as the cortical portion of the gland. By the term "*sheath*" of the prostate is meant the fibrous envelope derived from the pelvic fascia; the veins of the *prostatic plexus* lie between the lamellæ of the sheath.

In what is known as "**senile**" **hypertrophy** of the prostate the organ may be uniformly enlarged, or the enlargement may affect chiefly one or other of the lateral lobes, or the posterior lobe, which may project into the bladder. The intravesical overgrowth may take the form of a more or less pedunculated projection, situated behind the internal

urethral orifice, or it may surround the orifice as a prominent ring-like elevation. As the intravesical growth enlarges, it makes its way towards the bladder within the ring of the sphincter vesicæ, and, having pushed the internal longitudinal fibres of the bladder before it or having separated them, it comes ultimately to be separated from the cavity of the bladder by mucous membrane only. In the operation of *suprapubic prostatectomy* the surgeon tears through the mucous membrane that overlies the prostate at its highest point. His finger then finds the plane of separation between the true capsule and the

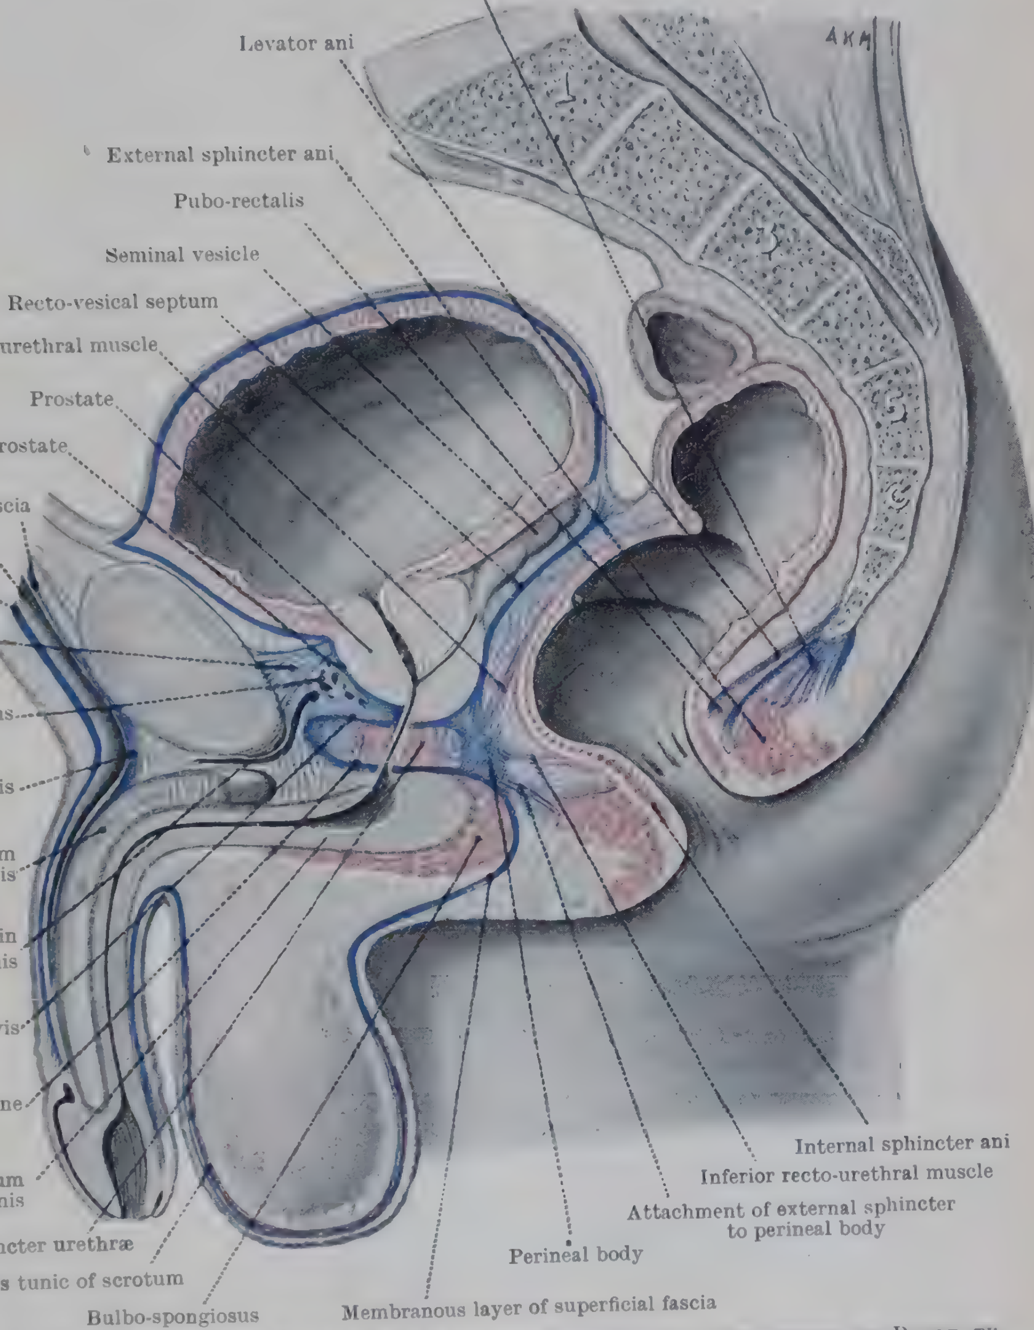

FIG. 1226.—SAGITTAL SECTION OF MALE PELVIS SHOWING POSITION AND RELATIONS OF PROSTATE.
The fascial structures are coloured blue.

hypertrophied tissue of the gland and completes the enucleation of the gland. As the sheath is markedly thicker and denser in the hypertrophied than in the normal prostate, the enucleation can be accomplished without injuring the veins of the prostatic plexus, for they are protected by such of the outer fibres of the capsule as may be left behind. The cavity, left behind after removal of the prostate, contracts at once owing to the natural shrinking of the fascial sheath and approximation of the bladder, rectum, and the two levatores ani at the sides.

In *perineal prostatectomy* the posterior surface of the prostate is exposed through a horseshoe-shaped incision whose convexity reaches forwards to a point immediately behind the bulb; at the sides, the incision sinks into the ischio-rectal fossæ, its extremities ending at the anterior part of the ischial tuberosities. After reflexion of the skin and

subcutaneous tissue, the incision is carried through the perineal body. The bulb, the superficial transverse perineal muscles, and the perineal membrane are then drawn forwards, and the fibres of the recto-urethral muscle (which connect the anterior wall of the rectal ampulla with the sphincter urethræ) are divided; that allows the anal canal and the lower end of the rectum to be pulled backwards. The dissection is now carried in a forward direction, between the anterior borders of the levatores ani, towards the prostate, so as to strike the loose non-vascular tissue which intervenes between the posterior part of the prostatic sheath and the thin fascia outside the muscular coat of the rectum. The posterior surface of the prostate is reached through an incision in its fascial sheath. The prostate, along with its capsule and the urethra, may either be enucleated entire from the sheath, or the capsule may be incised as well as the sheath, and the adenomatous masses removed separately. The operation is greatly facilitated if the prostate is pulled down into the wound by a special retractor inserted into the bladder through a median incision into the floor of the membranous part of the urethra.

In *retropubic prostatectomy* (Millin, 1947), the prostate is approached through a suprapubic incision, the bladder being displaced downwards and backwards. The anterior and lateral aspects of the prostate are displayed. In turn, the prevesical fascia, the true capsule of the prostate and the false capsule are incised. This exposes the adenomatous mass, which is enucleated by dissection with a finger. The incisions in the true capsule and in the prevesical fascia are then closed by suture.

Epididymis, Spermatic Cord, and Scrotum.—The **epididymis**, which can be felt as an elongated curved body applied vertically to the posterior margin of the testis, is especially involved in gonorrhœal and tuberculous infections. Occupying the posterior part of the spermatic cord is the **vas deferens**, which, when grasped between the finger and thumb, feels like a piece of whip-cord. The testicular veins form a **pampiniform plexus** in the substance of the cord; a varicose condition of these veins is known as *varicocele*. Besides the testicular artery, the testis receives its blood-supply from the artery to the vas deferens and the artery to the cremaster muscle. The marked swelling which attends *œdema and hæmatoma of the scrotum* is due to the loose and delicate character of the areolar tissue which intervenes between the dartos muscle and the subjacent external spermatic fascia.

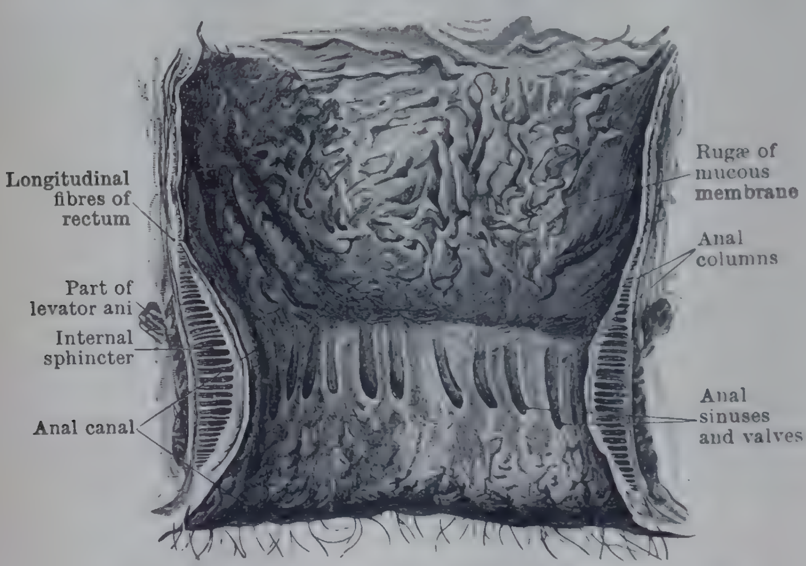

FIG. 1227.—INTERIOR OF ANAL CANAL AND LOWER PART OF RECTUM.

The anal columns were more numerous in this specimen than usual.

Anus and Anal Canal.—The **anus** is situated about 4 cm. in front of and below the tip of the coccyx. The skin around the orifice is pigmented and thrown into radiating folds. The painful linear crack or ulcer, known as *fissure of the anus*, generally occupies one of the furrows at the posterior margin of the anus. The skin of the anus is provided with large sebaceous and sweat glands which are occasionally the site of small and very painful *anal abscesses*.

In a *rectal examination* the finger, before it reaches the cavity of the rectum traverses the **anal canal**. That canal is directed from below upwards and forward from the anal orifice to the ampulla of the rectum and is about 3·5 cm. in length.

Internal haemorrhoids are developed from the veins in the upper part of the anal canal and invest 2·5 cm. of the rectum. The first to appear (*primary haemorrhoids*) are in association with the veins accompanying the three terminal branches of th

superior rectal artery: therefore they occupy left lateral, right postero-lateral and right antero-lateral positions on the circumference of the anus.

In the upper half of the anal canal the mucous membrane is thrown into longitudinal ridges called *anal columns*. At the lower end of the grooves between the columns there are little flaps, called *anal valves*, which bound small pockets called the *anal sinuses* (Fig. 1227). Fissure of the anus is generally caused by the tearing downwards of an *anal valve* during the passage of a scybalous mass.

Ischio-Rectal Fossa (Fig. 1228).—The apex of the **ischio-rectal fossa** is at the origin of the levator ani from the obturator fascia; it is directed upwards

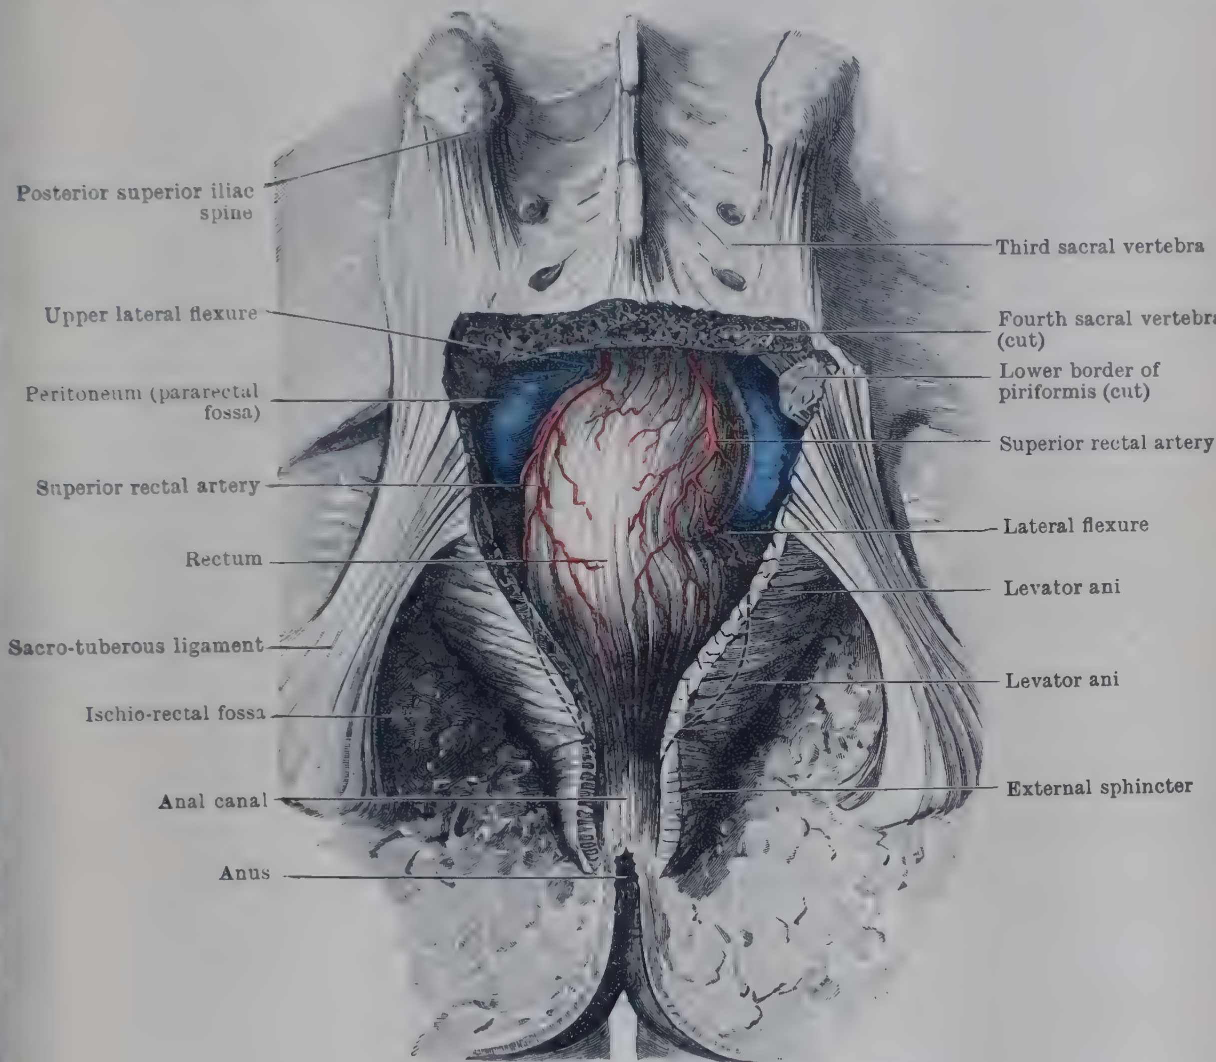

FIG. 1228.—DISSECTION OF RECTUM FROM BEHIND.
From a formalin-hardened male body, aged thirty.

towards the pelvis and is 6 cm. from the surface. The fossa is bounded medially by the levator ani covered with fascia (anal fascia); and laterally by the obturator internus muscle covered with the obturator fascia.

An abscess in the ischio-rectal fossa is usually the result of an infective process in the lower part of the rectum or anal canal, the fossa being infected by way of the lymphatics accompanying the inferior rectal vessels. When the abscess is opened surgically, or bursts through the skin of the fossa, it may continue to discharge because of a communication with the bowel (*fistula-in-ano*). In other cases the cutaneous opening communicates with the cavity of a *submucous* rectal abscess, or with an abscess (*pelvi-rectal*) which starts in the areolar tissue surrounding the upper part of the rectum, perforates the levator ani muscle, and so reaches the ischio-rectal fossa and breaches the skin over it.

Lymphatic Drainage.—The *lymph-vessels* from the skin of the anus pass along the perineo-femoral grooves to the most medial glands of the groin—both superficial and deep inguinal. Those from the region of the white line end in glands which lie in front of the internal iliac artery, while those from the mucous membrane of the upper part of the anal canal and the rectum traverse a few minute glands placed between the muscular and fascial coats of the rectum, along the superior rectal vein

and its two branches, and pass thence to the sacral glands which lie medial to the anterior sacral foramina.

The distribution of lymph from the ano-rectal segment is arranged in three "pedicles"—inferior, middle, and superior. The inferior pedicle collects lymph from each lateral half of the anus; it passes to the inguinal glands, and in a lesser degree to the lateral sacral glands and to the common iliac glands that lie on the sacral promontory. The middle pedicle drains that portion of the rectum which extends from the level of the third transverse fold to the ano-rectal junction. It follows the courses of the middle rectal, the lateral sacral, and median sacral arteries, and it passes into the external and internal iliac and the median common iliac glands. The superior or abdominal pedicle drains the rectum from the level of the third fold upwards; its course corresponds to that of the superior rectal and inferior mesenteric arteries. Three groups of vessels constitute it, the division being according to their relative lengths. The short group lies to the right of the superior rectal artery and opens into a rectal gland at the bifurcation of that vessel. The group of vessels of medium length is found to the left of the superior rectal artery and terminates in a gland which lies immediately below the origin of the lowest left colic artery. The long group also lies to the left of the superior rectal artery and passes into glands that lie below the inferior mesenteric artery at the level of the origin of the upper left colic artery.

Digital Examination of Rectum.—In making a *rectal examination*, the finger is carried forwards from the tip of the coccyx so as to enter the anus from behind. The finger is then gently pressed upwards and slightly forwards through the sphincteric region, in the axis of the anal canal, until it reaches the ampulla of the rectum. The horizontal folds of the rectum, three in number, project into the cavity of the bowel in the form of prominent crescentic shelves; the lower fold, which may be large enough to impede the passage of the finger, must not be mistaken for a pathological condition. Through the anterior wall the finger can palpate from below upwards the bulb of the penis, the membranous part of the urethra, the bulbo-urethral glands (when inflamed and enlarged), the prostate, the seminal vesicles, and the back of the bladder. With the left fore-finger in the rectum, an instrument passed into the bladder can be distinctly felt as it traverses the membranous urethra; as it lies in the prostatic urethra it is separated from the finger by the prostate. Hence, when a *false passage* is made through the part of the urethra which lies in the bulb or through the membranous portion, the instrument, if pushed onwards towards the bladder, will be felt immediately outside the rectum between it and the prostate. In the child, owing to the rudimentary condition of the prostate, the instrument is distinctly felt close to the rectum as it lies in the prostatic as well as in the membranous portion of the urethra. When the prostate is not enlarged the tip of the finger can just reach the back of the bladder, which is most distinctly felt when the bladder is full. The seminal vesicles, indistinctly felt when healthy, may be readily palpated when enlarged and indurated from disease. Through the side-wall of the rectum may be palpated the ischio-rectal fossa, the bony wall of the pelvis, and, when enlarged, the internal iliac lymph-glands; through the posterior wall the sacrum and coccyx, and (when enlarged) the lymph-glands in the retrorectal fibro-areolar tissue.

In the child rectal examination enables one to palpate, in addition to the structures in the cavity of the pelvis, those which occupy the lower segment of the abdomen. When the bladder is empty even a small calculus can be readily felt in it by recto-abdominal palpation.

Recto-Vesical Pouch.—The distance of the apex of this pouch of peritoneum from the anus varies considerably according to the degree of distension of the bladder and rectum; when both are empty it reaches to about 5 cm. from the anus; when both are distended it is at least 2·5 cm. higher (Figs. 620, 621, pp. 740, 741).

Examination by Sigmoidoscope.—In introducing the sigmoidoscope into the pelvic colon, the direction of the anal canal and the curve of the rectum must be remembered; as the instrument traverses the anal canal it must be directed forwards as well as upwards; it is then pushed onwards, in a backward and upward direction towards the hollow of the sacrum; and, finally, in order to reach the pelvic colon it is again directed forwards and also a little to the left so as to clear the promontory of the sacrum. The instrument is more difficult to pass in women, on account of the greater abruptness of the curvature of the sacrum.

When examined with the sigmoidoscope the mucous membrane of the rectum is seen to possess a deep red colour; and an excellent view is obtained of the horizontal folds. The most conspicuous fold projects from the right wall about the level of the recto-vesical peritoneal reflexion, *i.e.*, about 7·5 cm. from the anus. The highest fold gives rise to a distinct narrowing which must not be mistaken for a stricture. The pulsations of the left common iliac artery can generally be seen to be communicated, through the pelvic colon, to the postero-lateral wall of the rectum about 10 cm. from the anus.

Removal of Rectum by Perineal Route.—When the rectum and anal canal are removed for malignant disease an incision is carried round the anus and then upwards and backwards over the coccyx and lower part of the sacrum. The *ano-coccygeal body* is divided longitudinally and the *coccyx* is removed after division of the structures attached to its margins, viz., the lower fibres of the gluteus maximus, the coccygeus, and the sacro-tuberous and sacro-spinous ligaments. The **median sacral artery** is ligatured. There is now seen, stretching across the floor of the wound, a well-defined sheet of fascia; this is divided longitudinally and stripped to each side off the posterior surface of the rectum, and the branches of the **middle rectal arteries** are ligatured. Anteriorly, the anal canal is detached from the **perineal body**, after which the anterior surface of the rectum is freed from below upwards from—(1) the sphincter urethræ containing the **membranous urethra**, (2) the **prostate**, (3) the **bladder**, the **seminal vesicles** and the **vasa deferentia.** The procedure is facilitated by the existence of a layer of areolar tissue. In order to reach that tissue, the surgeon, after dividing the perineal body transversely, deepens the incision up to the apex of the prostate. In doing that he divides a band of muscular fibres (**recto-urethral muscle** (Fig. 1226)), which passes from the anterior wall of the lowest part of the rectal ampulla to blend with the muscle-fibres that surround the urethra at the apex of the prostate. It is those recto-urethral fibres which, by pulling forwards the ampulla, bring it into close relation with the urethra; hence it is especially at that stage of the operation that great care must be taken not to open into the rectum or to wound the urethra. After exposing the apex of the prostate he next retracts the anal canal well backwards and defines the anterior borders of the **levatores ani.** Each of those muscles is then divided well above its insertion into the anal canal. The posterior surface of the prostate, covered with recto-vesical septum, is then exposed.

The separation of the rectum upwards along the layer of areolar tissue above mentioned is continued, and the bottom of the **recto-vesical pouch** of peritoneum will be reached. The peritoneum can usually be stripped for some distance off the rectum without risk of opening into the peritoneal cavity. As the rectum is freed on each side, bands of fibro-areolar tissue containing branches of the **middle** and **superior rectal vessels** are divided. If the tumour is situated at the upper part of the rectum, the recto-vesical pouch of peritoneum is freely opened by a transverse incision. The surgeon then sets free the **colo-rectal junction** by dividing the sacral attachment of the **pelvic mesocolon** and securing the superior rectal artery. After dividing the rectum well above the tumour, he closes the opening into the peritoneal cavity by suturing together the anterior and posterior walls of the recto-vesical pouch. Since a permanent colostomy has been established previously, the divided bowel is closed.

When malignant lesions arise in the upper portion of the rectum close to its junction with the pelvic colon a combined abdomino-perineal excision of the rectum may be performed. A preliminary division and mobilization of the bowel is carried out from the abdominal area, the mobilized segment being removed from below, as in the perineal operation.

FEMALE PELVIS AND PERINEUM

Pelvic Organs.—When the abdomen is opened by a median incision from the umbilicus to the pubis, and the pelvis is looked into from above, after displacement of some coils of the small intestine upwards, the **fundus of the uterus**, directed forwards and a little upwards, is seen resting upon the upper surface of the bladder. Behind the uterus is the rectum, and between the two the **recto-uterine pouch**, containing the pelvic colon and the lower coils of the ileum. The **ovary** lies on the side of the pelvis, a little below the level of the brim, closely attached to the upper layer of the broad ligament. When the vermiform appendix hangs into the pelvis its tip may be in close relation with the right ovary—a condition which often leads to a difficulty in distinguishing an inflammation of that ovary from appendicitis. The **round ligament** of each side is seen passing forwards and laterally from the upper part of the border of the uterus to the deep inguinal ring, which lies immediately above and in front of the termination of the external iliac artery. Inferiorly and at the medial side of the round ligament, as it enters the ring, is the **inferior epigastric artery**. If the uterus is pulled upwards the attachments of the **broad ligament** to the floor and side-wall of the pelvis are brought into view, as also are the utero-vesical and recto-uterine peritoneal pouches. The

utero-vesical pouch is a shallow recess; the deepest part of the recto-uterine pouch covers the upper fourth of the posterior wall of the vagina and is in relation, therefore, with the posterior fornix.

The utero-vesical peritoneal reflexion takes place at the junction of the body of the uterus with the cervix. The anterior wall of the cervix is in relation, therefore, with the upper part of the base of the bladder, from which, however, it is separated by a layer of loose areolar tissue. It is the existence of that areolar tissue which enables the surgeon to separate the bladder readily from the uterus in the operation of hysterectomy.

The anterior wall of the vagina is firmly united to the urethra, but its posterior wall can be readily separated from the rectum, because of the interposition of loose areolar tissue between them.

The **ureter** crosses the bifurcation of the common iliac artery and then passes backwards and downwards into the pelvis, where it lies at first on the side-wall immediately below and in front of the internal iliac artery under cover of the peritoneum, through which it can be seen. It then courses medially and forwards in the parametric areolar tissue below the root of the broad ligament. In that position it lies above the lateral fornix of the vagina, about 2 cm. lateral to the upper part of the cervix uteri; finally, immediately before it pierces the lateral angle of the bladder, it inclines medially to lie in front of the upper lateral part of the vaginal wall.

The relation of the parts of the ureters that lie in the pelvis are of special importance in the female as their close relation to the cervix uteri and upper part of the vagina renders them liable to injury, more especially in the operation of hysterectomy performed for malignant disease of the uterus.

Pelvic Vessels.—The **uterine artery**, in the first part of its course, passes downwards and forwards a little anterior and lateral to the ureter. At the level of the upper end of the cervix uteri it takes a medial direction and passes along the root of the broad ligament and crosses above and in front of the ureter from lateral to medial side; it then passes above the lateral fornix of the vagina and finally ascends close to the side of the body of the uterus, and ends by anastomosing with the ovarian artery below the isthmus of the uterine tube.

The **ovarian artery** enters the pelvis between the layers of that portion of the broad ligament known as the **infundibulo-pelvic ligament**; it is there that the vessel may be most readily ligatured in abdominal hysterectomy and in ovariotomy.

The **lymph-vessels** from the lower part of the vagina pass to the inguinal and ano-rectal glands. Those from the rest of the vagina, from the cervix uteri, and from the greater part of the body of the uterus, pass to the internal and external iliac and the sacral glands. The ano-rectal glands lie on the wall of the ampulla of the rectum. The internal iliac glands are situated on the side-wall of the pelvis in close relation to the origins of the branches of the internal iliac artery. The sacral glands form a chain along the medial side of the anterior sacral foramina. Some of the lymph-vessels from the fundus of the uterus, and those from the uterine tube and the ovary, terminate in the glands around the aorta and inferior vena cava: but others from the fundus run along the round ligament to the inguinal glands.

Perineum.—The external genital organs are fully described in the Section on the Urogenital System. The **external orifice of the urethra**, surrounded by a slight annular prominence, is situated about 2·5 cm. posterior to the clitoris, in the smooth triangular, anterior division of the vestibule of the vagina, immediately in front of the vaginal orifice. When a *catheter* is passed the instrument is directed along the forefinger (introduced just within the vaginal orifice with the palmar surface towards the pubic symphysis) to the base of the smooth triangle, where it is tilted slightly upwards so as to bring its point opposite the urethral orifice.

The **greater vestibular glands** are a pair of glands placed at the sides of the posterior third of the orifice of the vagina, on the lower surface of the perineal membrane. Each has a slender duct, nearly 2·5 cm. in length, which opens into the angle between the labium minus and the hymen. Abscesses and cysts not infrequently develop in connexion with these glands.

The **bulbs of the vestibule** are a pair of piriform collections of erectile tissue

situated one on each side of the lowest part of the vagina, between the bulbo-spongiosus muscle and the perineal membrane. Rupture of the bulbs gives rise to the condition known as *pudendal hæmatocele.*

Vagina.—The **cervix uteri** projects downwards and backwards into the upper part of the vagina and is separated from the vaginal wall by a distinct **fornix.** The relations of the fornix are of so much practical importance that for descriptive purposes it is customary to divide it into an anterior, a posterior, and two lateral portions. The **anterior fornix** is shallow, and it is related to the base of the bladder and to the areolar tissue below the utero-vesical pouch of peritoneum. The **posterior fornix** is much deeper; it extends upwards for some little distance in front of the anterior wall of the lowest part of the recto-uterine pouch. The septum between the fornix and the pouch is merely the wall of the vagina; hence the readiness with which the pelvis may be drained by an incision in the posterior vaginal wall.

The **lateral fornix** (Pl. LXXII, p. 745) is below the medial part of the root of the broad ligament. An incision carried through it would therefore open into the para-metric areolar tissue and would expose the uterine artery as it passes transversely to the uterus after crossing the ureter.

Vaginal Examination.—In making a *vaginal examination,* the patient is placed on her back with the thighs well flexed; the index-finger of the right hand is carried along the fold of the buttock towards the median plane, where it will impinge against the posterior part of the **vestibule of the vagina,** and then passed upwards and backwards into the vagina; to make a more thorough examination the middle finger also may be introduced. When the uterus is in its normal position the **vaginal part of the cervix uteri** is felt as a knob-like body projecting downwards and backwards into the upper part of the vagina. In nulliparæ the external os is a small transverse slit, whereas in women who have borne children it is larger and its lips are more or less fissured. Above and behind the cervix is the **posterior fornix,** which is in close proximity to the **recto-uterine** or **recto-vaginal pouch**; the pouch, though normally occupied only by a loop of ileum or of pelvic colon, is the frequent site also of displaced abdominal and pelvic organs, and collections of intraperitoneal effusions and exudations. A loaded rectum can be detected through the vagina by the characteristic way in which the contents can be pitted by the finger. In front of the cervix is the **anterior fornix,** through which the body of the uterus and the base of the bladder may be felt. Through the lower half of the anterior vaginal wall the **urethra** may be detected as a cylindrical, cord-like thickening which may be rolled against the lower border of the symphysis. If the **ureter** is enlarged, the finger, in the anterior part of the lateral fornix, can recognize it by compressing it against the pubic bone.

By the *bimanual examination* the pelvic organs are steadied and pushed downwards towards the outlet of the pelvis by the pressure of the left hand applied above the pelvis, so that they can be more readily reached and palpated by the finger placed in the vagina with its palmar surface directed upwards. The **ovary,** when enlarged, may be felt if fingers are pushed well up into the lateral fornix towards the side-wall of the pelvis. The healthy **uterine tubes** cannot, as a rule, be felt per vaginam.

Rectal Examination.—By rectal examination the finger can palpate, from below upwards, the recto-vaginal septum, the cervix uteri, the posterior fornix of the vagina the floor of the recto-vaginal pouch, and the body of the uterus.

THE BACK

Median Line of the Back.—In the median line of the back is the **vertebral furrow,** which is deepest in the lower thoracic and upper lumbar regions. Over the upper sacral region, where the sacro-spinales muscles are tendinous, there is a flattened area forming an equilateral triangle, the angles of which correspond to the posterior superior iliac spines and the third sacral spine. The **vertebral spines** can be palpated at the bottom of the vertebral furrow; it is possible to identify and count them if it is remembered that the first thoracic is the lower of the two knobs at the root of the back of the neck, that the third thoracic is on a level with the root

of the spine of the scapula, the seventh thoracic with its inferior angle, the fourth lumbar with the highest part of the iliac crest, and the second sacral with the posterior superior iliac spine.

Lateral Region of the Back.—Above the spine of the scapula is the **supra-scapular region,** which is padded by a thick mass of muscle consisting of the supraspinatus and levator scapulæ, covered by the trapezius; shrugging the shoulders brings the two trapezius muscles into relief.

In the **interscapular region** are the trapezius and rhomboid muscles, which are thrown into prominence when they brace back the shoulders.

Below the inferior angle of the scapula the last five ribs can readily be felt lateral to the sacro-spinalis muscle; when the twelfth rib does not reach beyond this muscle, the eleventh rib will be mistaken for it, unless the ribs are counted from the second rib downwards.

The **lower border of the trapezius** is indicated by a line drawn upwards and laterally from the twelfth thoracic spine to the tubercle of the crest of the scapula; the **upper border of the latissimus dorsi** by a line drawn from the seventh thoracic spine horizontally across the inferior angle of the scapula.

The lateral border of the **sacro-spinalis** is indicated on the surface by a shallow groove on the loin about a hand's breadth from the median line. The lateral border of the **quadratus lumborum,** which passes upwards and slightly medially, lies a little lateral to the lateral border of the sacro-spinalis at the iliac crest, and a little medial to it at the twelfth rib.

The Loin.—The anatomy of the muscles and fasciæ which complete the abdominal wall between the last rib and the iliac crest is of importance in connection with operations in the **region of the loin.** The space between the last rib and the iliac crest varies greatly according to the length of the rib, and according to the general shape of the chest and slope of the ribs as a whole. As a rule, the **tip of the twelfth rib** lies about 5 cm. vertically above the middle of the iliac crest. From a surgical point of view the costo-iliac space may be said to be limited medially by the lateral edge of the sacro-spinalis, and, more deeply, by the tips of the lumbar transverse processes; laterally it is bounded by the posterior, free border of the external oblique, and, more deeply, by the line of reflexion of the peritoneum from the colon on to the side-wall of the abdomen. The space is roofed over by the latissimus dorsi, except below, where a narrow, triangular interval is left between its lateral border and the posterior border of the external oblique, the base of the triangle being formed by the iliac crest just behind its middle. This **lumbar triangle** is a weak area through which a lumbar abscess may come to the surface, and through which a lumbar hernia occasionally develops. When the latissimus dorsi and the lower part of the serratus posterior inferior are removed, another triangle is exposed, which constitutes a second weak area in the loin; it is bounded above by the last rib, medially by the sacro-spinalis, and laterally by the posterior muscular fibres of the internal oblique; the floor of the triangle is formed by the aponeurosis of origin of the transversus abdominis muscle; that aponeurosis splits into three layers to form two compartments, the anterior enclosing the quadratus lumborum and the posterior the sacro-spinalis.

Kidneys.—The upper limit of the kidney is indicated by a line drawn transversely across the loin opposite the eleventh thoracic spine, the lower limit by a line on a level with the third lumbar spine. The upper pole reaches to the eleventh rib; the lower, which lies immediately lateral to the tip of the transverse process of the third lumbar vertebra, is 1·3 to 5 cm. above the iliac crest. About a third of the kidney lies above the lower margin of the twelfth rib. The left kidney is usually about 1·3 cm. higher than the right. The most lateral point of the lateral border is 10 cm. from the median plane, while the hilum is about 5 cm. lateral to the median plane in front of the interval between the tips of the transverse processes of the first and second lumbar vertebræ.

The psoas major muscle intervenes between the postero-medial surface of the kidney and the transverse processes, and the kidney is therefore protected from contact with the bony processes in the event of a blow directed from the front. Between the upper end of the kidney and the eleventh and twelfth ribs is the

dia ragm and the costo-diaphragmatic recess of the pleura (Fig. 1214). The relat ons of the pleura to the last rib have been considered already (p. 1485).

Exposure of Kidney.—To expose the kidney by an oblique incision in the loin, the latissimus dorsi and serratus posterior inferior muscles are divided at the medial part of the wound; the posterior fibres of the external and internal oblique muscles are divided at its lateral part; next, the aponeurotic origin of the transversus muscle is split to expose the extraperitoneal fat and the peritoneum as it is reflected from the colon on to the side of the abdominal wall. The peritoneum and the colon are then stripped forwards and medially off the front of the kidney, until the hilum and renal vessels are reached. The sacro-spinalis and quadratus lumborum muscles are pulled well medially; and it may be necessary to divide the lateral fibres of the quadratus muscle.

To expose the upper part of the ureter, the division of the abdominal muscles is extended

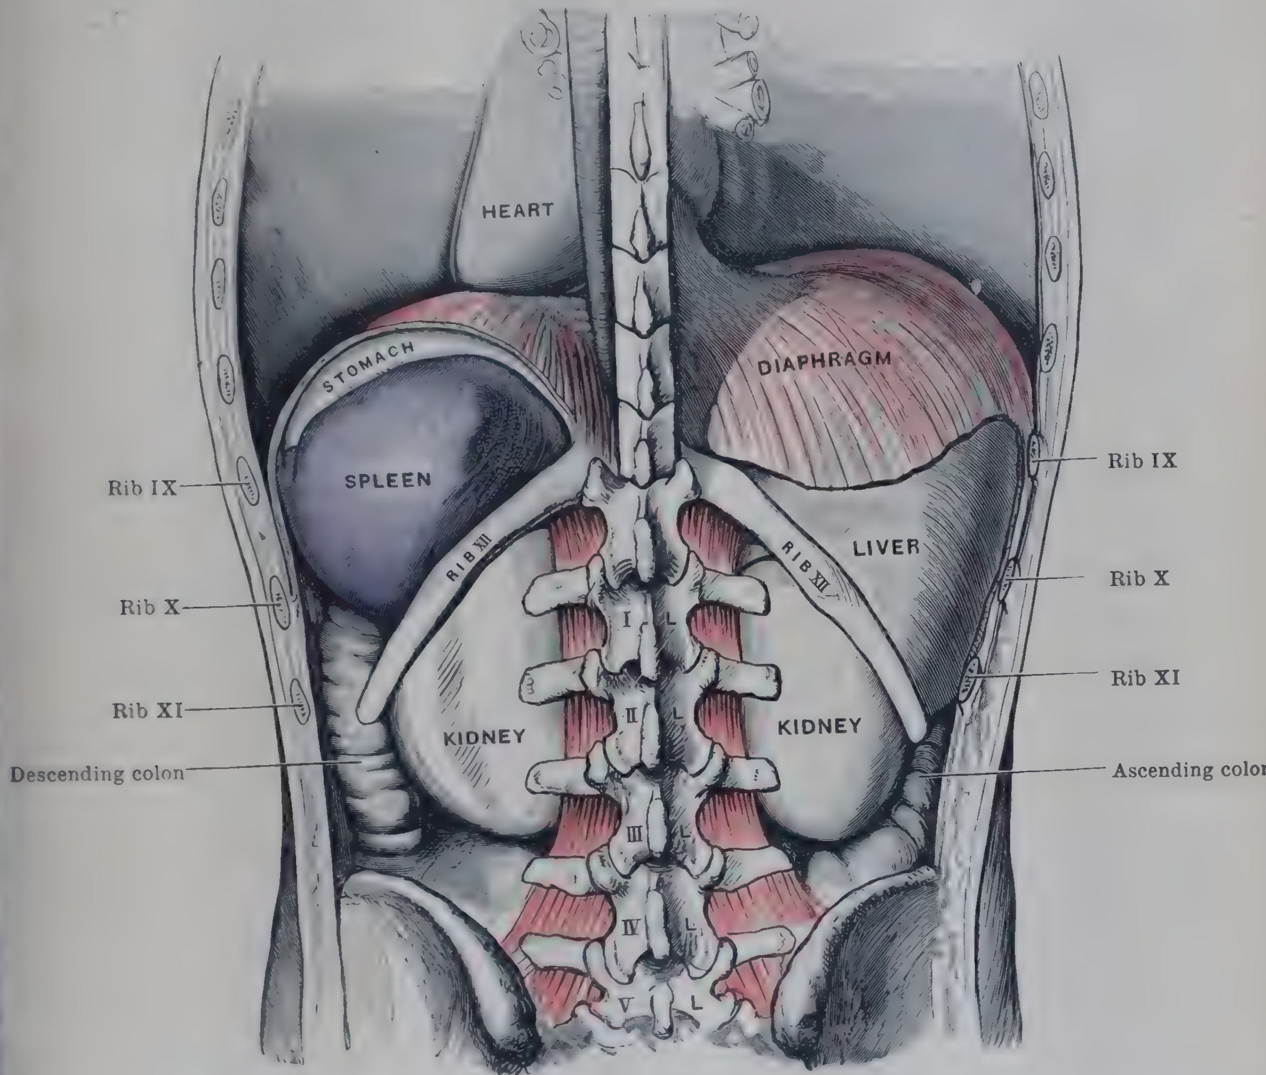

FIG. 1229.—DISSECTION OF SPLEEN, LIVER, AND KIDNEYS FROM BEHIND, IN A SUBJECT HARDENED BY FORMALIN INJECTION.

still farther downwards and forwards into the iliac region. After the peritoneum is stripped off the quadratus and psoas muscles, the ureter will be found clinging to the peritoneum. Care is required to avoid injury to the testicular or ovarian vessels, which cross in front of the ureter from the medial to the lateral side. The ureter is surrounded by a quantity of loose areolar tissue, and, owing to an abundance of elastic fibres in its adventitious coat, is very extensible, so that it can be readily brought to the surface.

To deliver an enlarged kidney out of the loin, it is generally necessary to prolong the incision upwards so as to divide the lateral arcuate ligament; and it may be necessary to resect the twelfth rib also.

The subcostal and the ilio-hypogastric and ilio-inguinal nerves, which lie at first behind and then lateral to the organ, must not be injured; the subcostal nerve should be displaced upwards and laterally, the other two downwards and medially.

The pus of a **perinephric abscess** lies in the renal fat, and is, therefore, within the fascial envelope of the abdomen; the pus in a **psoas abscess**, on the other hand, lies external to the fascia.

A needle passed through the medial extremity of the eleventh intercostal space will transfix **the suprarenal gland.**

96

Diaphragm, Liver, Stomach, and Large Intestine.—Posteriorly the righ **arch of the diaphragm** and the right lobe of the liver extend upwards to the level of the angle of the scapula (eighth rib), while the **left arch** and the **fundus** of the stomach are 2·5 cm. lower (eighth interspace); the central tendon reaches up to the eighth thoracic spine. The **right lobe of the liver** is covered posteriorly by the eighth to the twelfth ribs, and is overlapped by the base of the right lung as far as a line drawn horizontally laterally from the tenth thoracic spine; therefore on the back, the upper limit of the liver cannot be defined by percussion, and its lower limit merges into the dullness of the loin-muscles and kidney.

The **cardiac orifice of the stomach** is opposite a point 2·5 cm. to the left of the ninth thoracic spine. The fundus, overlapped by the ninth to the twelfth ribs extends upwards to the level of the eighth thoracic spine, 2·5 cm. below the inferior angle of the scapula. The **pyloric portion** crosses the median plane opposite the first and second lumbar spines, the **pylorus** itself being situated 2·5 cm. to the right of the first lumbar spine.

Viewed from behind, the **large intestine**, on both sides, overlaps the latera border of the kidney and lies parallel to the lateral border of the sacro-spinali muscle. The peritoneum is reflected from the colon on to the posterior abdomina wall along a line drawn vertically upwards from the middle of the iliac crest The **right flexure** is at the level of the first lumbar spine and the left flexure is little higher.

Spleen.—The *spleen* is situated in the left hypochondrium behind the stomach It varies greatly in size and outline, but a spleen of average size is opposite th ninth, tenth, and eleventh ribs, its long axis corresponding approximately to tha of the tenth rib. Between the upper third of the spleen and the chest-wall (pleur and diaphragm intervening) is the lower part of the left lung, the inferior margi of which crosses the spleen horizontally at the level of the tenth thoracic spin The costo-diaphragmatic recess of the pleura reaches down as far as the inferic angle of the spleen. The upper limit of the spleen cannot therefore be defined b percussion; and when a spleen puncture is done from behind, the needle wi traverse the pleural as well as the peritoneal cavity unless the spleen is enlarge or displaced downwards.

The *lateral end* of the spleen reaches the ninth intercostal space in the mic axillary line. The *medial end* is at the same level as the lower margin of the lun about 3·8 cm. lateral to the tenth thoracic spine. The *highest point* is opposi the ninth rib in the scapular line. The only parts of the splenic outline whic can be defined by percussion are the lateral, crenated part of the upper margi and the lateral end; and it is those parts which may be felt below the cost margin when the organ is considerably enlarged.

To excise the spleen, the abdomen is opened by a vertical incision through the upper half the left rectus muscle a little lateral to the median line. The spleen is drawn forwards into th wound after displacing the stomach and transverse colon downwards and to the right. The sho gastric vessels are secured as they course between the two layers of the gastro-splenic ligame The splenic vessels, which form the main pedicle, lie between the two layers of the lieno-ren ligament. Care must be taken not to injure the tail of the pancreas, which is in relati with the lower part of the gastric surface of the spleen. In a *floating spleen* the two peritone ligaments are elongated to form distinct pedicles.

Pancreas.—The head of the **pancreas** lies opposite the first and second lumbar spine the tail lies at the same level as the left flexure of the colon.

Vertebral Column and Spinal Cord.—The spinal cord usually ends opposi the lower border of the first lumbar spine but may do so one vertebra higher lower; in the infant it reaches the interval between the second and third lumb spines. The *cervical enlargement*, which corresponds to the lower four cervical an the first two thoracic segments, ends opposite the first thoracic spine. The fi lumbar segments are opposite the last three thoracic spines. The fourth cervic segment is opposite the third cervical spine, the eighth cervical segment opposi the interspace between the fifth and sixth cervical spines, the fourth thorac opposite the second thoracic spine, the eighth thoracic opposite the fifth thorac spine, the twelfth thoracic opposite the ninth thoracic spine, the second lumb

opposite the tenth thoracic spine. The sacral segments correspond to the last thoracic and first lumbar spines (see Figs. 742, 914, pp. 856, 1051).

The nerve-roots which arise below those of the first lumbar, and form the cauda equina, are arranged in a right and a left bundle, with a median space between them. The highest roots occupy the most lateral position in the cauda, and the lowest are nearest the filum terminale.

To expose the spinal cord by the operation of laminectomy, the surgeon, after separating the muscles from the spines and laminæ, removes certain of the spines along with their

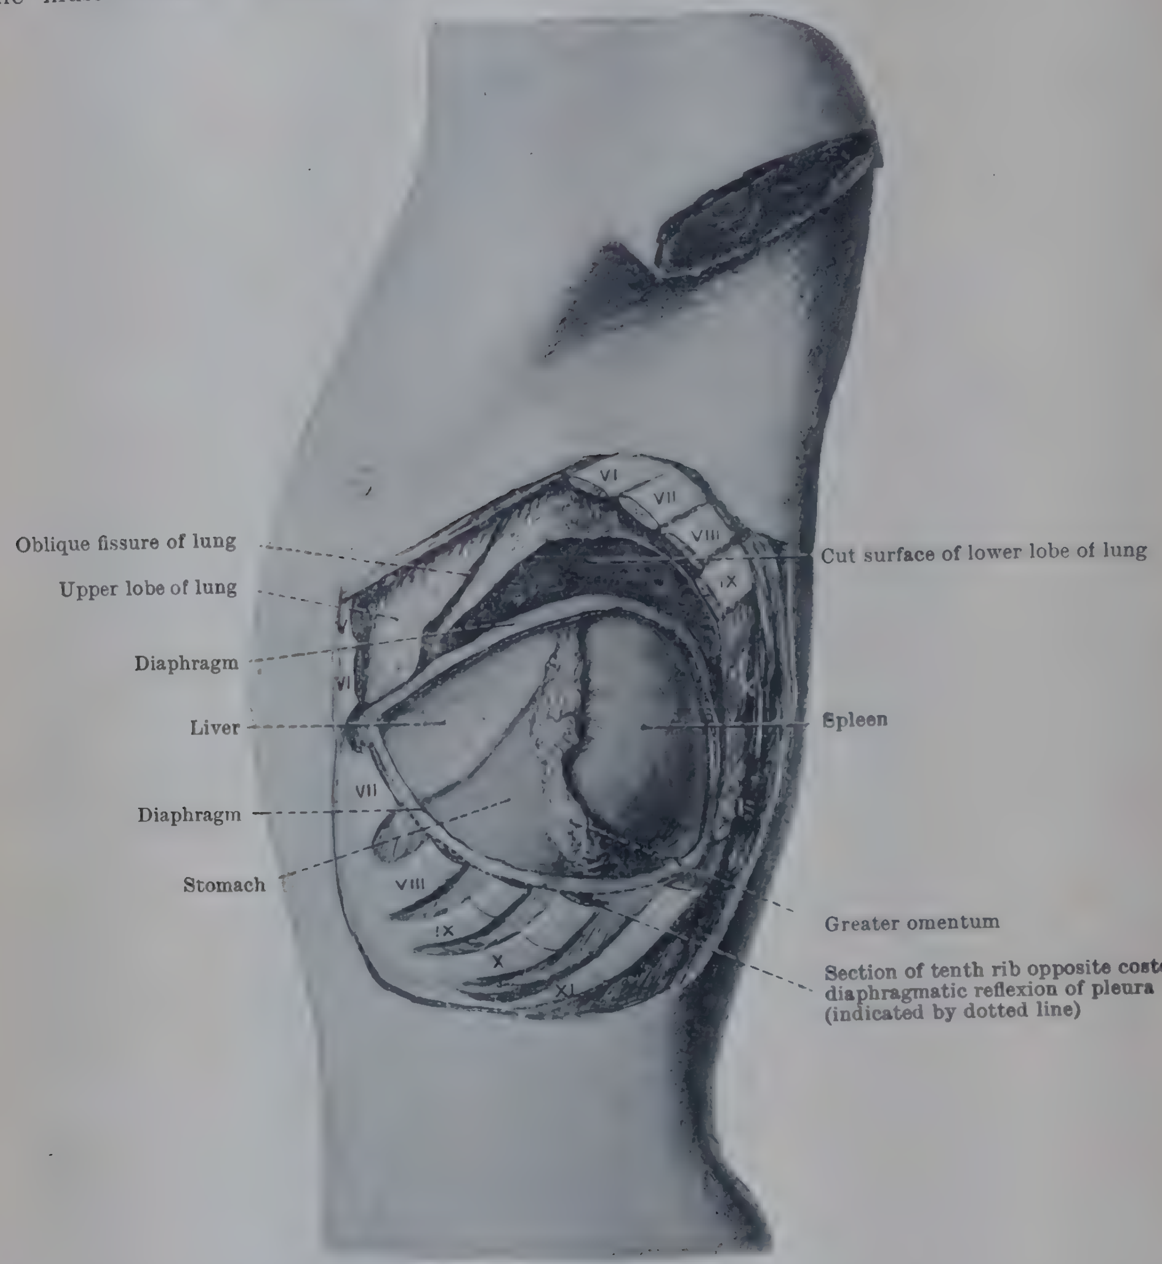

FIG. 1231.—DISSECTION OF LEFT HYPOCHONDRIUM TO SHOW RELATIONS OF SPLEEN TO SIDE-WALL OF CHEST, DIAPHRAGM, AND ADJACENT VISCERA. Portions of several ribs and a part of the base of the left lung have been removed ; and a window has been made in the diaphragm down almost to the level of the costo-diaphragmatic reflexion of the pleura.

supraspinous and interspinous ligaments. The next step is the removal of the corresponding laminæ. That is not difficult in the cervical region, for there they are comparatively slender and do not overlap. In the thoracic region there is more difficulty owing to the greater size of the laminæ and to their imbricated arrangement ; in the lumbar region the difficulty arises from the greater depth at which the laminæ lie and their greater thickness. The bleeding comes mainly from (1) the plexus of veins on the backs of the vertebral arches, and (2) from the plexus which occupies the fatty tissue outside the dura mater. After the dura and arachnoid mater are incised, cerebro-spinal fluid escapes. The anterior and posterior nerve-roots are now exposed and are seen to be separated by the denticulate ligament, which ends below in a fork-like manner opposite the first lumbar vertebra. As the first lumbar posterior root rests on the "fork", the ligament serves as a guide to that nerve. Tumours which arise outside the spinal cord, but within the dura, are classified according to their relationship to the anterior and

posterior nerve roots and to the denticulate ligament. The classification is therefore anterior, antero-lateral, postero-lateral, and posterior. To reach an anterior tumour one of the teeth of the ligament is divided and the spinal cord (thus freed) may be rotated gently.

The **subdural space** extends down to the level of the second or third sacral spine. In the operation of *lumbar puncture* the needle is introduced into the subarachnoid space below the level of the spinal cord, the puncture being made in the interval between the third and fourth or fourth and fifth lumbar spines. The fourth spine is at the level of the highest part of the iliac crest. The instrument should be directed very slightly upwards. In the adult the distance of the dura mater from the surface is from 5 to 7·5 cm., in the infant 2 cm.

Owing to the shape and arrangement of the articular surfaces of the vertebræ, **dislocations** without fracture are practically confined to the cervical region; they are commonest between the fifth and sixth vertebræ. The dislocation may be unilateral, but it is more frequently bilateral and incomplete. In both instances the spinal cord may be only slightly bruised, and then the paralysis will be only partial. In complete bilateral dislocations the spinal cord is usually completely crushed, and when the lesion is at, or above, the level of the fourth cervical segment (origin of the phrenic nerves) death may ensue rapidly from respiratory paralysis.

Fracture-dislocations of the vertebral column are commonest in the lower cervical region and the thoraco-lumbar region—that is to say, where the movable cervical and lumbar regions join the more fixed thoracic region. The vertebral column above the injury is generally displaced forwards, and the spinal cord is often severely lacerated or completely torn across by the upper end of the portion of the column below the fracture. It is important to remember that, in consequence of the shortness of the cord as compared with the vertebral column, the origins of the spinal nerves are at a higher level than their exits from the vertebral canal. The distance between origins and exits becomes greater the farther down the nerves are—the lowest nerve-roots running almost vertically downwards. The cervical nerves leave the vertebral canal *above* the vertebræ after which they are named (except the *eighth,* which is above the first thoracic vertebra); the thoracic, lumbar, and sacral nerves leave the canal *below* their vertebræ.

To understand the effect of **lesions of the spinal cord**, it is necessary to be familiar with the sensory and motor distributions of the various spinal segments (see Figs. 916, 918, pp. 1055, 1059, and 929, p. 1075). Transverse lesions of the cord *above the fifth cervical spine* (that is, above the disc between the fourth and fifth cervical vertebræ) are quickly fatal, owing to paralysis of respiration, as the phrenic nerves arise mainly from the fourth segment. In transverse lesions of the cervical enlargement the *cutaneous insensibility* does not extend higher than a horizontal line at the level of the second costal cartilage. The diagnosis of the particular segment involved is arrived at by testing the motor and sensory functions of each segment. The sensory areas which correspond to the *lower four cervical* and the *first two thoracic segments* are in the upper limbs, and they are placed in numerical order from the lateral to the medial side of the limb. The sensory area which corresponds to the *second, third,* and *fourth cervical segments* occupies the occipital region of the scalp, the back of the auricle, the masseteric region, the whole of the neck, and the shoulders and upper part of the chest down to a horizontal line at the level of the sternal angle. In a total transverse lesion of the cord in the *thoracic region*, the upper limit of the anæsthesia is horizontal, and reaches the level of the terminations of the anterior primary rami of the nerves that arise from the segment opposite the vertebral injury. The upper limit of the anæsthesia is, therefore, at a much lower level than that of the injured vertebra. For example, a fracture-dislocation at the level of the eighth thoracic vertebra involves the origin of the tenth thoracic nerve, which ends at the level of the umbilicus. The sensory zone that corresponds to the *fifth thoracic segment* is at the level of the nipples, that of the *seventh thoracic segment* is at the level of the xiphoid process, that of the *tenth* at the level of the umbilicus, while that of the *twelfth* reaches down, anteriorly, almost to the pubis. The sensory areas that correspond to the lumbar and sacral segments are seen in Fig. 942, p. 1097. See also Figs. 916, 918, 920; and 945, p. 1102.

Congenital Abnormalities and Postural Errors.—Abnormalities in the ossification of the bodies of the vertebræ are occasionally encountered. In rare cases ossification of the body of the vertebra is confined to one of the twin ossific centres,

with the result that the body of the vertebra is distorted, and, if the error is a pronounced one, deformity of the vertebral column results (*scoliosis* or *kyphosis*).

Abnormal development of the laminæ and spines also occurs, and therein lies the foundation of *spina bifida*. The least serious deformity of this type implies a split or gap between the right and left halves of one or more of the spines, and through the space a band of fibrous tissue establishes continuity between the deep surface of the overlying skin and the posterior surface of the spinal meninges (*spina bifida occulta*). In the more

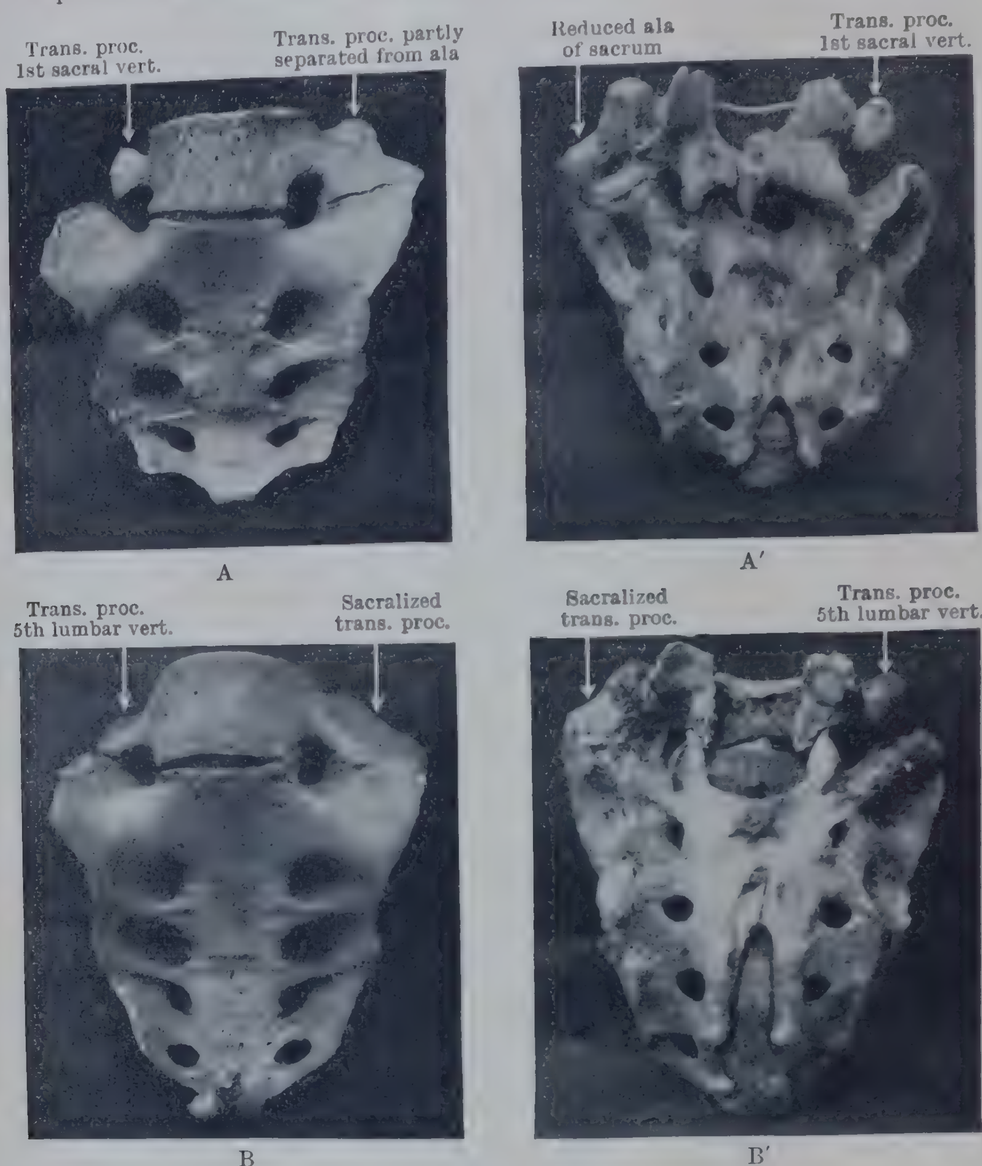

FIG. 1232.—PHOTOGRAPHS OF TWO SACRA SHOWING (A) UNILATERAL LUMBARIZATION OF FIRST SACRAL VERTEBRA AND (B) BILATERAL BUT ASYMMETRICAL SACRALIZATION OF FIFTH LUMBAR VERTEBRA. (Brailsford, 1929.)

Note in B the relation of the right transverse process of the fifth lumbar vertebra to the ala of the sacrum and the almost complete fusion on the left side ; and compare with A.

complete malformations, where the spines are absent and the laminæ rudimentary, a saccular protrusion of meninges and nerve-tissue may appear.

In other instances development is arrested at the stage of the neural groove, so that skin, muscles, spines, laminæ and the posterior part of the spinal cord are absent over a certain area. This is the condition of *myelocele*, and it is incompatible with post-natal existence.

Abnormalities may be encountered in the *articulation between the fifth lumbar vertebra and the first piece of the sacrum*. The normal arrangement is one in which the articular processes lie in the coronal plane, the sacral articular facets being directed backwards. In an appreciable percentage of subjects the articular processes occupy the sagittal plane, with the result that the facets are directed medially. Such a condition results in a lessening of stability at the lumbo-sacral joint, and, in respect of this, leads to various postural disturbances in the lumbar part of the vertebral column and in the sacro-iliac joints.

The transverse processes of the fifth lumbar vertebra are sometimes abnormal in length and in shape (Figs. 1232, 1233). On one or both sides the process may pass downwards to articulate with the sacrum (*sacralization*), or it may extend laterally to impinge upon or to articulate with the posterior portion of the ilium. These irregularities may be responsible for pain, either local or referred, along the distribution of the fifth lumbar nerve, while in some cases they appear to cause a lateral curvature of the lumbar part of the vertebral column. Asymmetrical separation of the first sacral vertebra (*lumbarization*) is less common but simulates sacralization of the fifth lumbar vertebra (Fig. 1232).

The angle of the lumbo-sacral junction in a well-developed adult is 120°. Minor variations are common and are of no significance, but a gross abnormality may lead to pain and to secondary disabilities in related parts. When the angle is notably increased so that the sacrum and the lumbar vertebræ are in relative alignment, or when the angle is notably diminished as the result of backward tilting of the sacrum, an additional strain is thrown upon the sacro-iliac joints, and in a certain number of cases the increased stress results in local or referred pain.

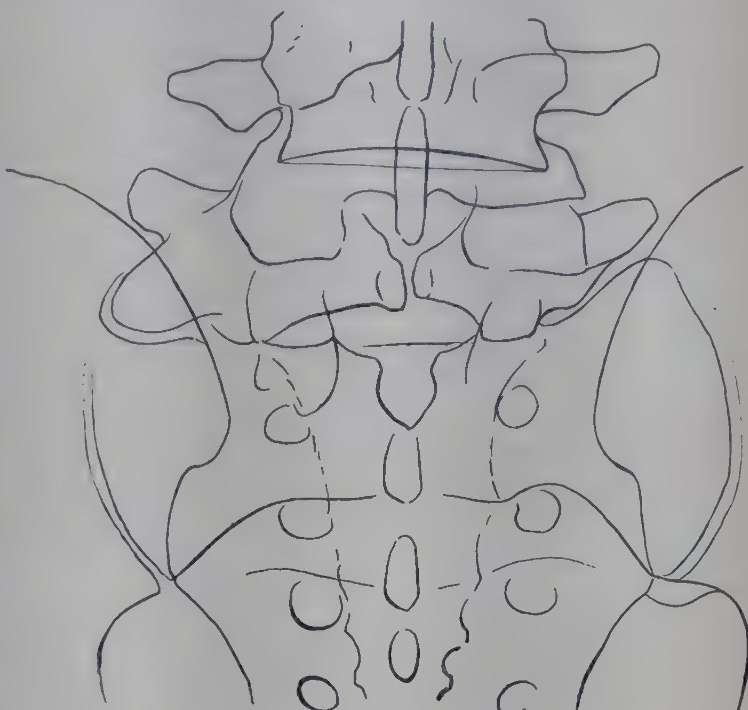

FIG. 1233.—OUTLINE DRAWING OF RADIOGRAPH OF LUMBO-SACRAL AND SACRO-ILIAC REGIONS. Cf. Pl. XVII, p. 272.

On the right side (left in the figure) there is an incomplete "sacralization" of the transverse process of the fifth lumbar vertebra with the development of a bursa at the point of contact.

A forward displacement of the fifth lumbar vertebra upon the sacrum is sometimes encountered, and this condition is given the name of *spondylolisthesis*. It is apt to be associated with local pain, limitation of flexion in the lumbar region, an alteration in gait, and, if the displacement is ex-centric, pressure on the fifth lumbar nerve of the side towards which the displacement is directed may lead to weakness of the muscles supplied by the nerve. The significance of spondylolisthesis is recognized by the obstetrician, because a severe deformity of this character may interfere with parturition.

As a result of trauma, the central part of an intervertebral disc (*nucleus pulposus*) may be forced into the spinal canal, where it presses on the nerve-roots at the corresponding level, giving rise to pain and possibly muscular weakness and wasting. The most commonly affected roots are the fifth lumbar and first sacral, and the clinical picture is that of one type of sciatica.

In addition to these local abnormalities, the orthopædic surgeon recognizes *two general types of bodily habitus* associated with structural variation of the vertebral column—the narrow-backed, long-waisted, slender figure, and the broad-backed, thick-set, heavy one. The former, sometimes classed as the *visceroptotic type* because ptosis of the abdominal viscera is such a frequent accompaniment, is associated with a slender and unduly mobile vertebral column; and, on account of the increased mobility, postural errors are apt to arise. The lumbar part of the column loses its natural lordosis, there is increased backward displacement of the sacrum, the thoracic part of the column becomes unduly straight, while the lordotic curve of the cervical region is increased. The effect of these changes is to throw an undue strain upon the sacro-iliac joints, so that the ligaments which support them are stretched and weakened, and minor degrees of displacement occur at these joints.

In the second type, the back is thick-set and broad, and the movements of the vertebral column tend to be more restricted than is normal. The lumbar vertebræ are broad and massive, the curve of the lumbar lordosis is reduced, and the longitudinal axis of the sacrum tends to come into line with the lumbar bodies. An undue strain is thrown upon the lumbo-sacral joint, and symptoms of this may become apparent. In addition, there is limitation of flexion of the lower portion of the body, so that this movement takes place at

the hip joints rather than in the vertebral area; in the same way the range of lateral movement of the lumbar part of the column is lessened.

UPPER LIMB

SHOULDER, AXILLA, AND BREAST

Landmarks.—The bony landmarks of the shoulder must be systematically examined in all injuries about that region.

Clavicle.—The **sternal end** of the **clavicle** is prominent; its articulation with the sternum is essentially a weak joint, and it is liable to be dislocated, especially from blows on the lateral part of the shoulder which drive the medial end of the clavicle forwards against the anterior sterno-clavicular ligament. The **shaft** of the **clavicle**, subcutaneous throughout, is weakest at the junction of its two curves; it is in that region that the bone is so frequently fractured as the result of force transmitted through it to the trunk. The displacement of the lateral fragment varies according to whether the break takes place medial or lateral to the coraco-clavicular ligament; in the former case the weight of the upper limb, acting through the coraco-clavicular ligament, pulls the lateral fragment downwards; when the fracture is lateral to the ligament, the lateral end of the clavicle swings forwards, but there is no downward displacement. In fractures of the intermediate third of the clavicle the subclavian vessels are protected by the subclavius muscle. The **acromial end** of the **clavicle** is on a plane behind its sternal end, and in that way the clavicle braces the shoulder backwards away from the thorax; therefore, in fractures of the clavicle, both medial and lateral to the coraco-clavicular ligament, the point of the shoulder swings forwards and medially. The groove that corresponds to the **acromio-clavicular joint** runs in the sagittal direction, and can be felt 3 cm. medial to the lateral border of the acromion, immediately lateral to a slight prominence made by the acromial end of the clavicle. When the acromio-clavicular joint is dislocated the clavicle almost invariably overrides the acromion, and the summit of the shoulder presents a conical appearance.

Scapula.—The **tip** of the **acromion** looks directly forwards, and is a finger's breadth lateral to and a little in front of the acromial end of the clavicle. The **lateral border** of the **acromion** can readily be followed to its junction with the spine of the scapula, and the spine can be followed to its root, which is at the level of the third thoracic spine. The **medial border** of the **acromion** and the clavicle meet at an angle into which the point of the finger can be pressed. The **upper angle** of the **scapula**, covered by the trapezius and the supraspinatus muscles, is too deeply placed to be palpated distinctly. The **inferior angle** and the **medial border**, from the root of the spine downwards, form visible prominences which are readily felt; the inferior angle overlies the seventh intercostal space at the level of the seventh thoracic spine; and the medial border is a little medial to the angles of the ribs.

The **tip** of the **coracoid process** may be felt by the finger pressed firmly on the anterior border of the deltoid at a point 2·5 cm. below the junction of the middle and lateral thirds of the clavicle. Medial to the coracoid there is a triangular depression which corresponds to the upper end of the interval between the pectoralis major and deltoid muscles. Behind that triangular depression are the termination of the cephalic vein, a lymph-gland, the first part of the axillary vessels, and the cords of the brachial plexus. By pressing firmly in that situation one can feel the pulsations of the **axillary artery**, and further pressure arrests the circulation in the artery by compressing the vessel against the second rib. The *first part* of the axillary artery may be cut down upon by a longitudinal incision in the interval between the pectoralis major and the deltoid. The **axillary vein** lies in front of the artery as well as to its thoracic side—thus adding to the difficulty of exposing the artery.

Humerus.—The **upper end** of the **humerus**, covered by the deltoid, gives rotundity to the shoulder. The **greater tuberosity** projects beyond the acromion

and is the most lateral bony landmark of the shoulder. When the head of the bone is dislocated, the lateral border of the acromion then becomes the most lateral bony landmark, and the shoulder presents a square contour. The **lesser tuberosity**, small but conical, can be felt through the deltoid. Pointing directly forwards, it is 2·5 cm. lateral to the tip of the coracoid process and a little below its level. In examining the upper end of the humerus for fracture, the tuberosities are grasped between the finger and thumb of one hand, and the flexed elbow is rotated with the other hand. The **head** of the **humerus** has the same direction as the medial epicondyle; its lower part can be palpated through the axilla, the arm being meanwhile abducted to bring the head into contact with the lower part of the capsule. It is through that—the weakest part of the capsule—that the head is driven in the common varieties of dislocation of the shoulder, viz., those due to forcible abduction. The **proximal epiphysis** of the humerus includes the head and both tuberosities (Pl. XV, Fig. 1, p. 268). The capsule is attached mainly to the epiphysis; in children, therefore, separation of the proximal epiphysis takes the place of dislocation. Disease in the upper part of the shaft does not necessarily involve the cavity of the joint. The **bicipital groove** is immediately lateral to the lesser tuberosity; it may be mapped out on the surface by a line, 5 cm. in length, drawn downwards along the axis of the humerus from the tip of the acromion. When there is *effusion into the joint*, the arm becomes slightly abducted, and there is fullness in front, along the line of the long tendon of the biceps. With the elbow at the side, the lower part of the capsule of the shoulder joint is loose and folded upon itself to form a dependent pocket; if, after an injury, the arm is retained too long in that position, the patient may be unable to abduct the arm, in consequence of the formation of adhesions in and around the pouch.

Access to the joint and to the upper end of the humerus, sufficient for excision of the joint or exploration of the bone, is obtained by an incision which begins immediately lateral to the coracoid process and follows the outline of the anterior border of the deltoid muscle downwards and laterally; a short incision parallel to the clavicle laterally from the upper end of the oblique incision may be added. That addition permits the lateral displacement of the anterior half of the deltoid muscle.

Axilla.—The **anterior fold** of the **axilla**, formed by the lower border of the pectoralis major, extends from the fifth rib to the middle of the anterior border of the deltoid. With the arm abducted, the interval between the sternal and clavicular fibres of the pectoralis major is indicated by a slight groove that extends downwards and laterally from the sternal end of the clavicle. The sternal fibres, along with the pectoralis minor, are removed in a complete operation for malignant disease of the breast, the pectoral branches of the acromio-thoracic artery being secured as they cross the interval between the sternal and clavicular portions of the greater pectoral. The **posterior fold** of the **axilla**, formed by the latissimus dorsi and the teres major muscles, is on a lower level than the anterior fold, and leaves the chest a little in front of the inferior angle of the scapula. Between the two folds, and running in the long axis of the limb from the axilla to the middle of the upper arm, is the prominence of the **coraco-brachialis muscle**. The pulsations of the **third part of the axillary artery** may be felt in the furrow immediately behind that prominence.

The axillary fascia resists the spontaneous rupture of an axillary abscess, which, therefore, tends to spread upwards under cover of the pectorals towards the root of the neck. To open the abscess, an incision is made on the medial wall of the axilla, behind and parallel to the lateral thoracic artery, which runs under cover of the anterior wall.

The **axillary lymph-glands** vary greatly in size and number; many are no larger than a pin's head. In women, some of them undergo an adipose functional involution whereby they come to resemble fat-lobules. In health, one or two glands can usually be felt by the fingers thrust upwards and medially behind the anterior fold, the arm being abducted—but only slightly, so as not to stretch the axillary fascia. The *central group*, embedded in the fat immediately deep to the axillary fascia, become inflamed in poisoned wounds of the upper limb. The same group, along with the *pectoral group* (related

to the medial wall of the axilla at the infero-lateral border of the pectoralis minor), are usually the first to become diseased in malignant affections of the breast. When the disease is more advanced the *posterior* (subscapular) and the *apical* (infraclavicular) groups are generally affected as well; and in a considerable number of cases diseased glands are found in the *retropectoral fascia, i.e.*, between the pectoralis major and minor and, above the minor muscle, on the first intercostal space in relation to the superior thoracic artery.

Female Mammary Gland.—The glandular tissue is arranged to form a central portion or *body*, and a peripheral portion made up of branching processes which radiate into the surrounding fat and become continuous ultimately with the fibrous septa of the subcutaneous fatty tissue. The gland has, therefore, no distinct capsule. In the young adult nullipara, the body is compact and well defined, and contains little intramammary fat, and the

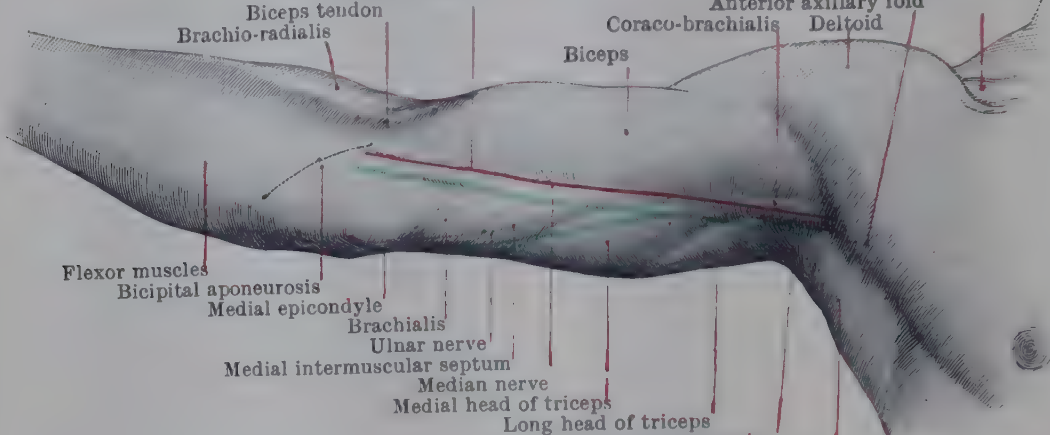

Fig. 1234.—Axilla and Medial Side of Arm and Elbow.

peripheral processes are relatively small. In the multipara, the body contains more fat, and the peripheral processes extend more widely into the surrounding fat.

The parenchyma is prolonged into the peripheral processes and into the loose retromammary areolar tissue and pectoral fascia. The gland has therefore a wide range. Vertically, it extends from the second rib to the sixth costal cartilage at the angle where it begins to ascend towards the sternum; horizontally, from a little medial to the edge of the sternum, opposite the fourth rib, to the fifth rib in the mid-axillary line. The *medial hemisphere* of the gland rests almost entirely on the pectoralis major; at its lowest part it slightly overlies the upper part of the aponeurosis covering the rectus abdominis muscle. The *superior quadrant* of the *lateral hemisphere* rests on the greater pectoral, on the edge of the lesser pectoral, and to a slight extent on the serratus anterior; on the serratus, however, it extends upwards into the axilla as high as the third rib, where it comes into relation with the *pectoral* group of axillary lymph-glands. The *remainder of the lateral hemisphere* rests almost entirely on the serratus anterior, except the lowest part, which overlaps the digitations of the external oblique which arise from the fifth and sixth ribs. It follows, therefore, that *fully one-third of the whole gland lies below and lateral to the axillary border of the pectoralis major muscle.* The surgeon must cut beyond the limits given if he wishes to remove the whole of the mammary tissue.

In operating for malignant disease of the breast, the surgeon removes, in addition to the whole gland and the greater part of the skin over it, both pectoral muscles (with the exception of the clavicular fibres of the pectoralis major), all the axillary lymph-glands, and, as far as possible, all the fat and fascia, including the sheath of the axillary vein. It must be remembered that the distal part of the axillary vein lies immediately under cover of the deep fascia of the lateral wall of the axilla; as the medial wall is cleaned, the nerve to the serratus anterior must not be injured; and as the posterior group of lymph-glands are removed, the nerve to the latissimus dorsi must be avoided,

as it is very important that the action of the latissimus dorsi should be retained when the pectoral muscles have been removed.

UPPER ARM

The anterior and posterior borders of the **deltoid** may be traced from the shoulder girdle to the insertion of the muscle. The surface relations of the anterior border have been referred to already; the posterior border forms a well-marked and important landmark as it crosses the angle between the lateral margin of the scapula and the upper part of the shaft of the humerus. By making an incision along that part of the posterior border of the deltoid, and pulling the edge of the muscle upwards and laterally, the surgeon exposes the **surgical neck** of the **humerus**, and the quadrilateral opening in the posterior wall of the axilla that transmits the **posterior circumflex artery** of the humerus and the **circumflex nerve**; a little lower down is the **radial nerve**. The **coraco-brachialis**, the guide to the upper half of the brachial artery, forms a prominence that occupies the upper half of the *medial bicipital furrow*. Traced downwards the medial bicipital furrow widens out into an elongated triangle. That triangle becomes continuous, distally, with the medial part of the cubital fossa, and is limited posteriorly by the medial intermuscular septum, which may be felt as a cord-like band extending upwards from the medial epicondyle; the floor of the space is formed by the medial part of the brachialis. Within the triangle are the following important structures, enumerated from the lateral to the medial side, viz.: the **brachial artery**, the **median nerve**, the **distal part of the basilic vein**, the **medial cutaneous nerve of the forearm**, and the **supratrochlear lymph-glands**, two or three in number. Extending upwards from the lateral epicondyle to the insertion of the deltoid is the lateral intermuscular septum, which is pierced at the junction of its upper and middle thirds by the **radial nerve**. Between the lateral intermuscular septum and the lateral edge of the biceps there is an ill-defined groove called the *lateral bicipital furrow*, the floor of which is formed by a strip of the brachialis, and, nearer the elbow, by the brachio-radialis and extensor carpi radialis longus.

The posterior compartment of the arm is occupied by the **triceps**, the *long head* of which can be traced upwards to the lateral margin of the scapula, in front of the posterior border of the deltoid and behind the posterior fold of the axilla. The *lateral head* of the triceps, after emerging from under cover of the distal part of the posterior border of the deltoid, is continued obliquely along the lateral side of the upper arm as a well-marked muscular elevation. Above the olecranon is the strap-like tendon of insertion of the triceps, which, when the elbow is fully flexed, forms an admirable posterior splint in fractures immediately above the epicondyles of the humerus.

The **brachial artery**—slightly overlapped in the upper half of the upper arm by the coraco-brachialis and in the lower half by the biceps—can be felt pulsating throughout the whole length of the anterior part of the medial bicipital furrow. To mark the course of the vessel on the surface a line is drawn from the medial border of the coraco-brachialis, at the level of the posterior fold of the axilla, to a point (opposite the neck of the radius) 1·8 cm. below the middle of the bend of the elbow. When the vessel is ligatured, the edges of the coraco-brachialis and biceps muscles, together with the median nerve, furnish valuable guides to the artery, the mobility of which is often a source of trouble in the operation.

The **basilic vein** is superficial to the deep fascia in the lower third of the upper arm, and is visible in the medial epicondylar triangle and the lower part of the medial bicipital groove. The **cephalic vein** ascends in the superficial fascia over the lateral surface of the biceps to reach the interval between the deltoid and pectoralis major.

The surface guide for the **median nerve** is the same as that for the brachial artery. The **ulnar nerve** is indicated superficially by a line drawn from the lateral wall of the axilla, immediately behind the prominence of the coraco-brachialis, to the back of the medial epicondyle; in the proximal half of the upper

arm the nerve lies close behind the brachial artery under cover of the basilic vein; in the distal half it lies a little behind the medial intermuscular septum, partially embedded in the fibres of the medial head of the triceps. The course of the **radial nerve** is traced by first marking the point where it pierces the lateral intermuscular septum, viz., the junction of the upper and middle thirds of a line drawn from the insertion of the deltoid to the lateral epicondyle; from that point a line is drawn obliquely downwards and forwards to the front of the lateral epicondyle, and then onwards to the lateral side of the lower end of the radius. To map out the nerve as it lies in its spiral groove on the humerus, a line is drawn from the same point obliquely upwards across the prominence of the lateral head of the triceps to the junction of the posterior fold of the axilla with the arm. In fractures of the humerus in the neighbourhood of the insertion of the deltoid, the nerve is not infrequently lacerated, or it is so involved in the callus as to produce the condition known as "*drop-wrist*"—the result of paralysis of the extensor muscles of

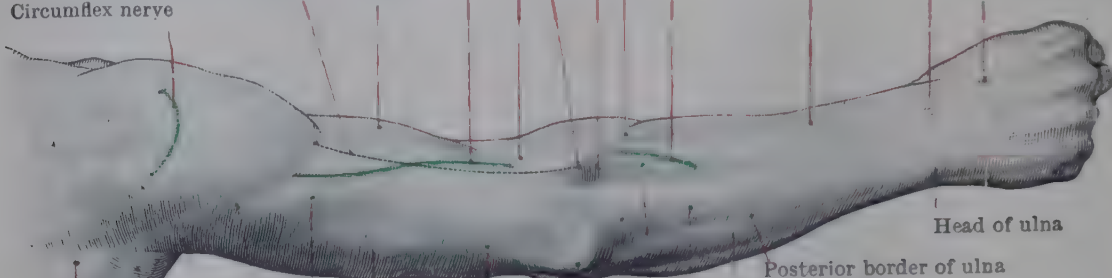

FIG. 1235.—BACK OF UPPER LIMB.

the forearm. To cut down on the nerve, the incision is begun a little below the point where it pierces the lateral intermuscular septum, and carried obliquely upwards and slightly backwards through the lateral head of the triceps.

The **shaft** of the **humerus**, nowhere subcutaneous, is most readily palpated in the region of the insertion of the deltoid, upwards along the lateral head of the triceps, and downwards behind the lateral supracondylar ridge. The **surgical neck** is the portion that intervenes between the tuberosities and the attachments of the muscles inserted into the lips and floor of the bicipital groove; it is related to the lateral wall of the axilla, and is on a level with the junction of the upper and middle thirds of the deltoid. The circumflex vessels and nerve are at the same level.

The shaft may be cut down upon with least injury to soft parts:—(1) In its *upper third, in front*, by an incision which extends downwards through the anterior fibres of the deltoid, parallel to the bicipital groove and a little lateral to it; the sheath of the biceps will thus be avoided, and the anterior circumflex artery will be the only vessel divided. (2) In the *upper third, behind*, by an incision through the posterior fibres of the deltoid, the bone being reached immediately lateral to the origin of the lateral head of the triceps, and the radial nerve thus avoided; the circumflex vessels and nerve will be exposed at the upper part of the wound. (3) In the *lower third*, by an incision which extends upwards from the back of the lateral epicondyle a little to the medial side of the lateral intermuscular septum.

The entire humerus, together with the shoulder joint and the elbow joint, may be exposed by an incision which begins at a point immediately lateral to the coracoid process and then follows the cephalic vein to the bend of the elbow. The incision is continued into the upper third of the forearm. Exposure of the upper third of the humerus and the shoulder joint

is achieved by lateral displacement of the deltoid; to get at the middle and lower thirds of the humerus the brachialis muscle is split a finger's breadth lateral to the biceps.

ELBOW

In injuries at the elbow, the diagnosis rests mainly upon the relative positions of the bony points, which are therefore of great importance. The **epicondyles** of the humerus are both subcutaneous and on the same level, the medial being the more prominent (Pl. XI, p. 256). In the extended position of the elbow the tip of the **olecranon** is on a level with a line joining the epicondyles; when the forearm is flexed the olecranon descends (Pl. XII, p. 257), and when full flexion is reached it lies 2·5 cm. distal to the epicondyles and in a plane in front of the posterior surface of the lower end of the humerus. The **head** of the **radius**, which lies nearly

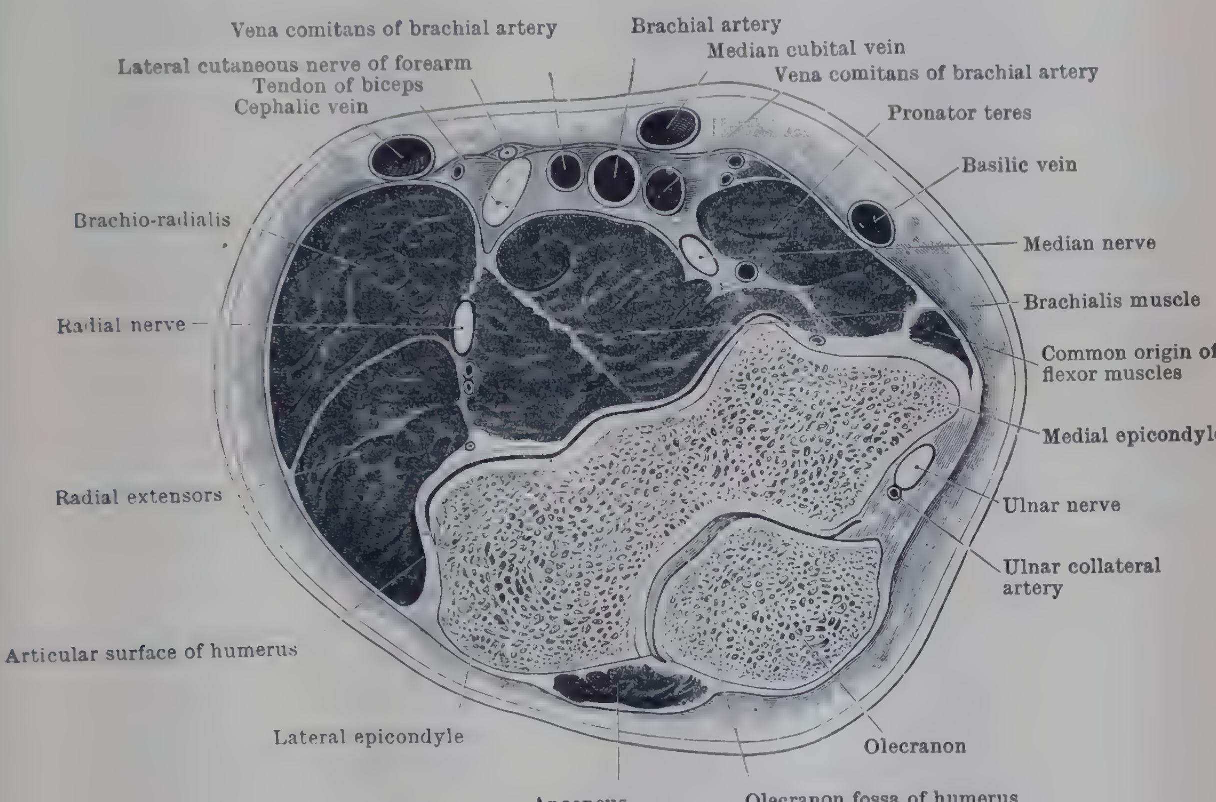

Fig. 1236.—Transverse Section through the Bend of the Elbow.

2·5 cm. below the lateral epicondyle, is felt best from behind; the thumb is placed on it while the semiflexed forearm is being alternately pronated and supinated. On the lateral part of the back of the extended elbow there is a distinct dimple which overlies the **radio-humeral joint**; that dimple, along with the hollows on each side of the olecranon, becomes effaced by synovial thickenings and effusions into the joint. The **coronoid process** is too deep to be felt distinctly. The **distal epiphysis** of the humerus includes the articular portion and the lateral epicondyle; it is therefore almost entirely intracapsular, and, because of that, foci of disease in its neighbourhood soon invade the cavity of the joint. The medial epicondyle ossifies as a separate epiphysis which unites with the distal end of the diaphysis (Pls. XIII, XIV, p. 260). In interpreting radiographs of the elbow in children of six years and older, care must be taken not to mistake this centre of ossification for a fracture; and after twelve years the same caution applies to the lateral portion of the main distal epiphysis of the humerus (Pl. XIII). In the commonest dislocation of the elbow, viz., with backward displacement of both bones of the forearm, the normal relative position of the bony points is lost, whereas in a transverse fracture above the epicondyles the normal relations are maintained. In the child the head of the radius is relatively smaller than in the

adult and is less firmly kept in position by the annular ligament; it is liable therefore to be partially dislocated—giving rise to the condition known as "*pulled elbow*".

To evacuate pus from the elbow joint a vertical incision is made over the back of the joint immediately lateral to the olecranon.

The **median vein** is seen to bifurcate into the median basilic and median cephalic veins 1 cm. below the middle of the bend of the elbow; opposite the same point, but behind the deep fascia, is the **bifurcation** of the **brachial artery**. The **median basilic** and **median cephalic** veins diverge as they ascend one on each side of the biceps tendon; the larger of the two veins, viz., the median basilic, is usually selected for the operations of venesection and transfusion. In the absence of a median vein (as in Figs. 1117, 1237), a **median cubital vein**, which passes from the cephalic to the basilic vein, takes the place of the median basilic vein. When the elbow is flexed, the **biceps tendon** can be traced vertically through the middle of the cubital fossa almost to its insertion. Passing downwards and medially from the medial edge of the tendon is the **bicipital aponeurosis**, which separates the median cubital vein from the brachial artery. If the finger-tip is insinuated behind the medial edge of the aponeurosis it will rest on and feel the pulsations of the brachial artery. The **median nerve** descends through the space a little medial to the brachial artery. The **radial nerve** descends in front of the capitulum of the humerus under cover of the brachioradialis. The **ulnar nerve** can be rolled beneath the finger on the back of the medial epicondyle; its position renders it liable to injury in severe fractures about the elbow; and when the joint is excised care must be taken not to injure the nerve.

FOREARM AND HAND

The upper half of the **radius** is deeply placed, but the lower half is easily palpated. The anterior border of its lower end is felt as a prominent transverse ridge about 2·5 cm. above the thenar eminence; immediately below the ridge is the **wrist joint** (radio-carpal). The **tip** of the **styloid process**—1 cm. lower than that of the ulna—is deeply placed at the lateral side of the wrist in the hollow between the extensor tendons of the first and second phalanges of the thumb. On the middle of the posterior surface of the lower end of the radius is the **dorsal tubercle of the radius**, which intervenes between the extensor pollicis longus and the short radial extensor of the wrist; the tubercle can be distinctly felt, and may be taken as a guide to the upper end of Lister's dorso-radial incision for excision of the wrist. The **posterior border of the ulna** is subcutaneous throughout, and can be felt along the medial side of the extensor carpi ulnaris. Above the wrist, on the ulnar side of the back of the limb, when the forearm is prone, there is the well-marked rounded prominence of the **head** of the **ulna**, and in front of it the **styloid process**—on the ulnar side of the limb; the deep groove between the two is occupied by the tendon of the extensor carpi ulnaris.

The **carpal bones** are built up so as to form an arch, converted by the **flexor retinaculum** into a tunnel for the transmission of the flexor tendons. At each end of the arch the two bony points to which the retinaculum is attached furnish important landmarks. Those bony points are: *laterally*, the tubercle of the scaphoid and the crest of the trapezium; *medially*, the pisiform and the hook of the os hamatum. The **tubercle** of the **scaphoid** is felt immediately above the thenar eminence, close by the radial side of the flexor carpi radialis; 1 cm. below the tubercle is the **crest** of the **trapezium**, felt deeply in the medial part of the thenar eminence. At the upper end of the hypothenar eminence, and crossed by the crease which separates the forearm from the hand, is the **pisiform bone**, above which is the tendon of the flexor carpi ulnaris descending to be inserted into it. The **hook** of the **os hamatum** is felt deeply in the radial part of the hypothenar eminence, and a full finger's breadth below and lateral to the pisiform.

The bases of the **first**, **third**, and **fifth metacarpals**, all of which can be readily

identified on the back, furnish a sufficient guide to the line of the carpo-metacarpal joints. At the base of the **third metacarpal** there is a tubercle, called its *styloid process*, which can be felt projecting upwards from its dorsal surface at a point 2·5 cm. vertically below the dorsal tubercle of the radius. The metacarpal styloid process marks the insertion of the extensor carpi radialis brevis—the favourite site for the development of a "*ganglion*", which in many cases can be ruptured by sudden firm pressure against the tubercle. Anteriorly, the **carpo-metacarpal joints** correspond to the distal border of the flexor retinaculum.

The **first row of knuckles** are the heads of the metacarpal bones. Anteriorly, the **metacarpo-phalangeal joints** are 2 cm. above the edge of the web of the fingers; posteriorly, the joints are immediately distal to the knuckles. A well-marked crease crosses obliquely over the front of the metacarpo-phalangeal joint of the thumb. The first and the terminal **interphalangeal joints** are opposite the most distal of the various creases that overlie the joints.

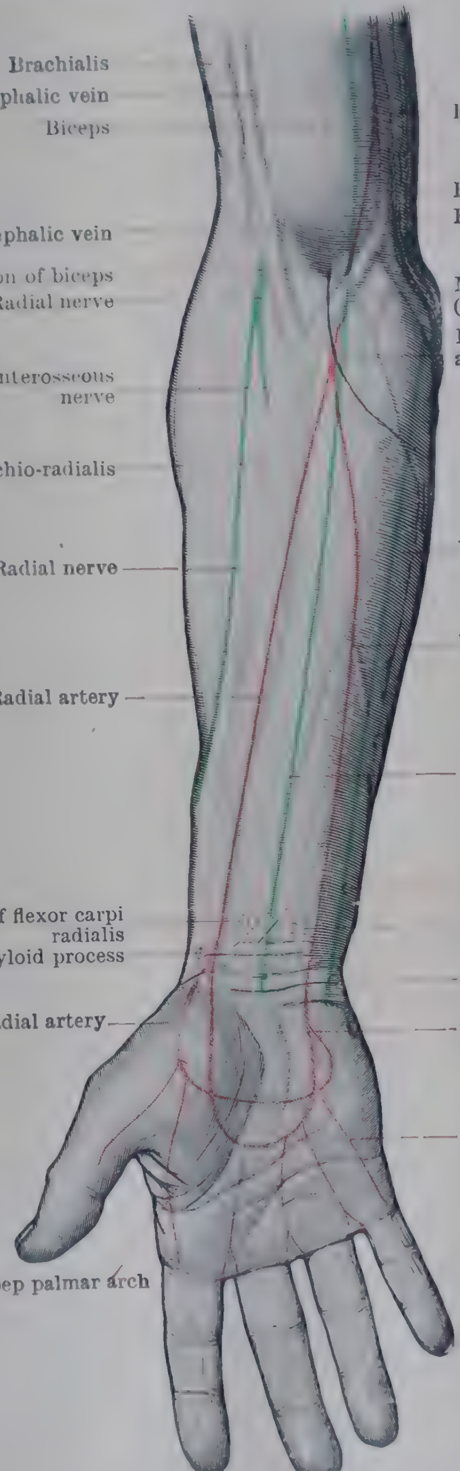

FIG. 1237.—FRONT OF ELBOW, FOREARM, AND HAND.

The most important *muscular* landmarks on the front of the forearm are the brachio-radialis, the flexor carpi radialis, and the pronator teres. The **brachio-radialis** is thrown into prominence when it flexes the semiprone forearm against resistance. At the junction of the upper and middle thirds of the forearm the **pronator teres** passes under cover of the brachio-radialis; between the two is the radial artery. The tendon of the **flexor carpi radialis** forms a prominent landmark descending along the middle of the front of the forearm towards the tubercle of the scaphoid; the tendon of the **palmaris longus**, when present, is seen at its medial side.

On the back of the forearm the intermuscular septum between the radial extensors of the wrist and the extensors of the fingers corresponds to the proximal part of a line drawn from the lateral epicondyle of the humerus to the dorsal tubercle of the radius. The **posterior interosseous nerve**, at the point at which it emerges from the supinator muscle, will be found at the bottom of that septum, 5 cm. below the head of the radius; below that point the septum is the best line along which to cut down upon the posterior surface of the radius. Winding

across the lower third of the back of the forearm there is an oblique prominence caused by the **abductor pollicis longus and extensor pollicis brevis muscles.**

If the front of the hand, the fingers being extended, is inspected, it is apparent that the palm may be divided into three areas—(1) the thenar eminence formed by the small muscles of the thumb, (2) the hypothenar eminence in association with the muscles of the little finger, (3) the hollow of the palm. Between the thenar and hypothenar areas, there are certain spaces filled with areolar tissue which are

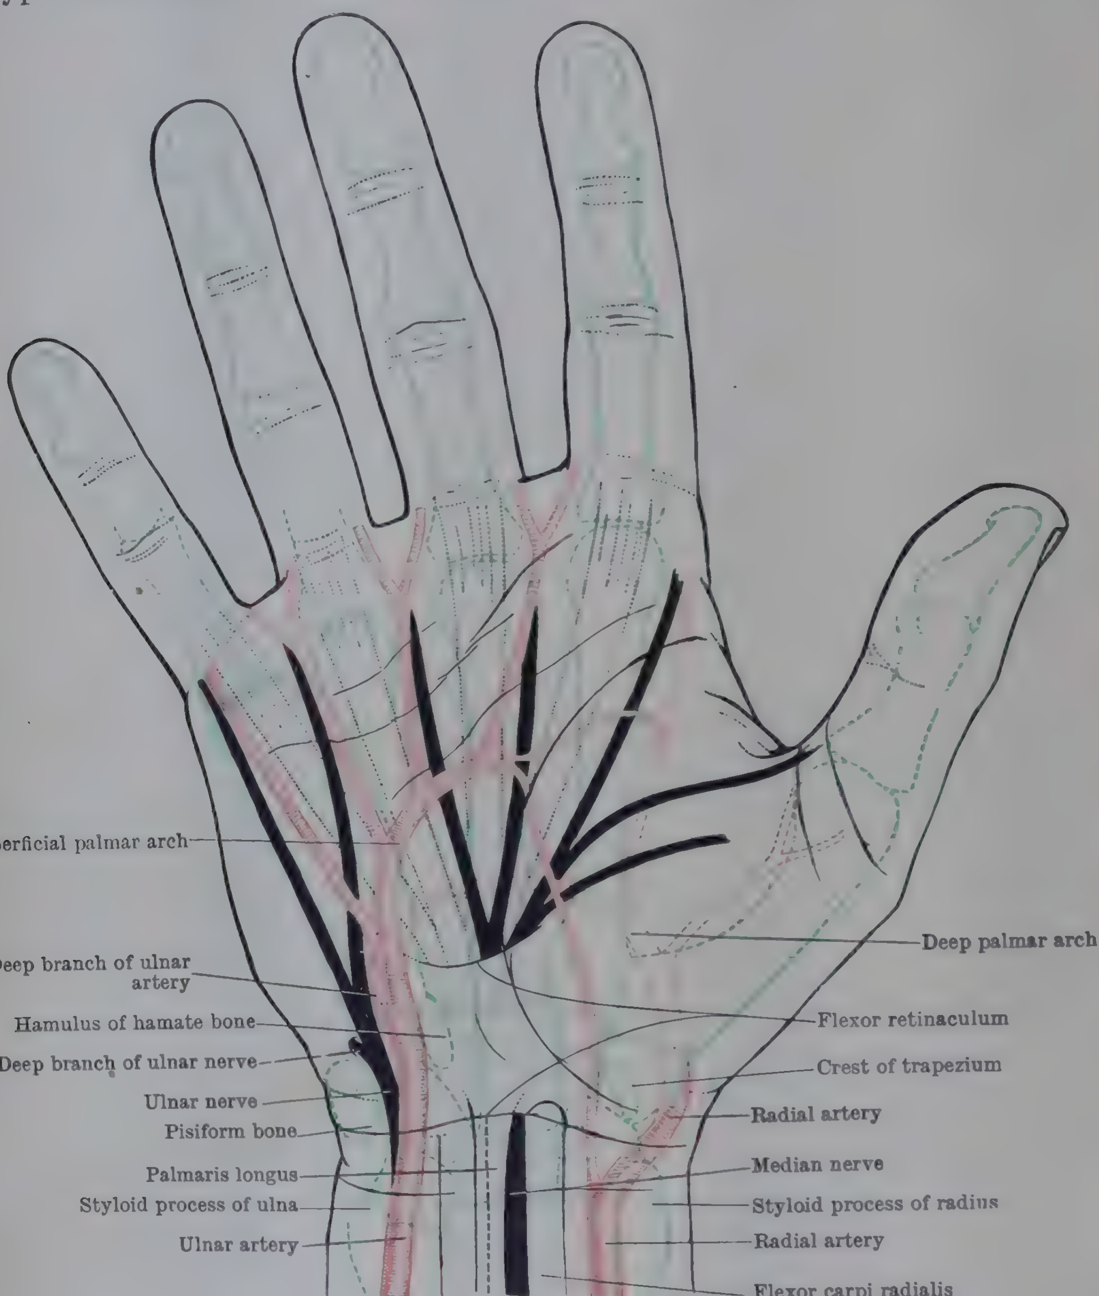

FIG. 1238.—PALM OF HAND. Cf. Pl. LXXXII, p. 1297.

of importance in connexion with acute pyogenic infections—they are the lateral and medial mid-palmar spaces (Fig. 1240).

The *lateral mid-palmar space* lies to the ulnar or medial side of the flexor pollicis longus tendon. Its anterior boundaries are the short muscles of the thumb, the overlying deep fascia, the flexor tendons of the index finger, and the first two lumbrical muscles; posteriorly lie the transverse and oblique heads of the adductor pollicis, and a portion of the first dorsal interosseous muscle. It is separated from the medial mid-palmar space by a fibrous septum, while the tendon of the flexor pollicis longus lies to its radial side. Deep to the flexor tendons of the third, fourth, and fifth digits is the *medial mid-palmar space*—bounded posteriorly by the interosseous muscles and metacarpal bones, medially by the hypothenar muscles, and laterally by a fibrous septum which extends from

the fascia behind the deep flexor tendon to the origin of the transverse head of the adductor.

The synovial flexor sheaths of the palm and of the digits (Fig. 437, p. 511) are of surgical importance in consequence of their liability to suppurative inflammation. The **common flexor sheath** begins 3·8 cm. above the flexor retinaculum and extends downwards behind it to a little beyond the middle of the palm. The **digital flexor sheaths** extend from the bases of the distal phalanges to the level of the distal

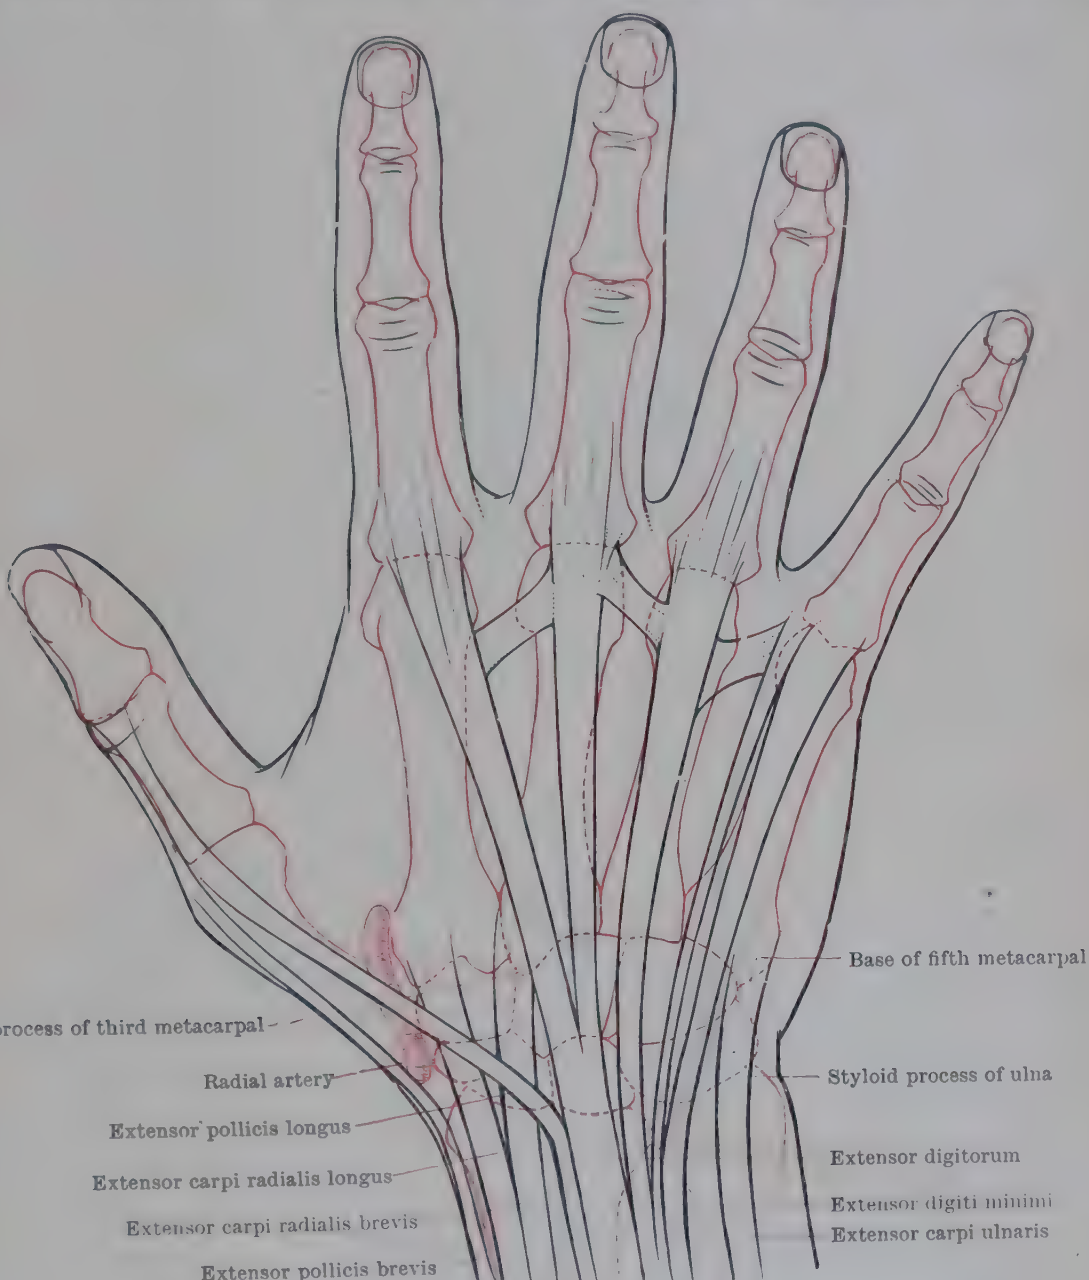

FIG. 1239.—BACK OF HAND.

transverse crease of the palm opposite the necks of the metacarpal bones, *with the exception of the sheath of the little finger*, which is continuous with the common flexor sheath of the palm. The **sheath of the flexor pollicis longus** extends from the base of the terminal phalanx to a point about 2·5 cm. above the retinaculum ; it sometimes communicates with the common flexor sheath. From the anatomical arrangement it follows that suppuration in the sheaths of the little finger and thumb is specially apt to spread upwards into the palm, and thence behind the flexor retinaculum into the forearm.

The pulsations of the **radial artery** can readily be felt in the lower third of the forearm, midway between the lateral border of the radius and the tendon of the flexor carpi radialis. The course of the vessel is indicated on the surface by a line drawn from the bifurcation of the brachial (1·3 cm. below the middle of the bend of the elbow) to the tubercle of the scaphoid ; above that tubercle and below the

tip of the styloid process, the artery winds to the dorsum of the radial side of the wrist; on the back of the wrist the vessel, after passing deep to the extensor tendons of the thumb, dips into the palm through the upper end of the first interosseous space. Incisions for opening or resecting the wrist are planned so as to avoid the vessel.

The upper third of the **ulnar artery** is deeply placed, and takes a curved course from the bifurcation of the brachial towards the medial part of the front of the forearm; the lower two-thirds of the vessel correspond to the lower two-thirds of a line drawn from the front of the medial epicondyle to the radial border of the pisiform bone. The course of the **ulnar nerve**, in the forearm, corresponds to the whole of that line.

The **median nerve** in the forearm is opposite a line drawn from a point midway between the middle of the cubital fossa and the medial epicondyle to a point midway between the styloid processes; in the lower third of the forearm the line follows the medial border of the tendon of the flexor carpi radialis.

To evacuate pus spreading deeply up the front of the forearm, an incision is

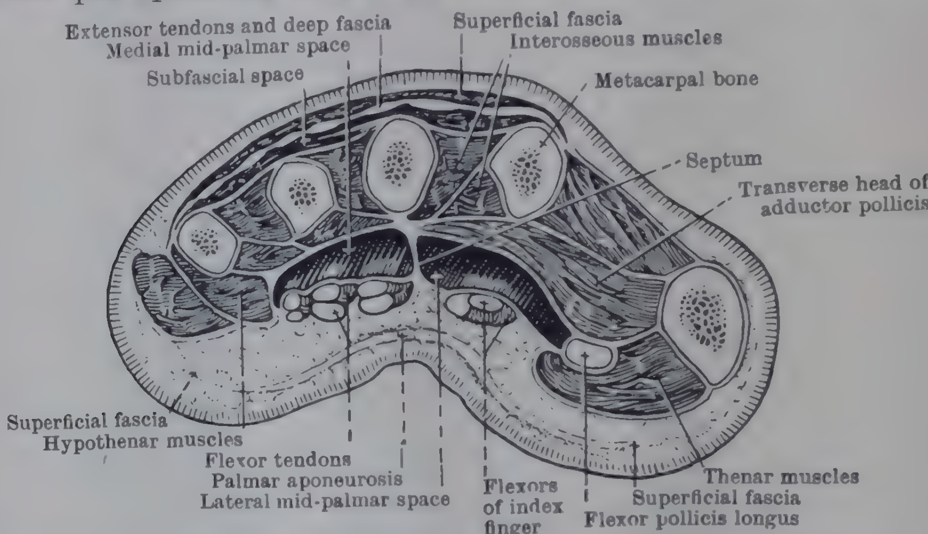

FIG. 1240.—TRANSVERSE SECTION THROUGH HAND TO SHOW THE MID-PALMAR SPACES. (Fifield, 1939.) (Cf. Fig. 438, p. 512.)

made along the anterior border of the lowest part of the radius, and the abscess is drained by Hilton's method. The **radial nerve** winds to the dorsum of the forearm round the lateral border of the radius deep to the tendon of the brachio-radialis, at the junction of the middle and lower thirds of the forearm.

The summit or most distal part of the **superficial palmar arch** corresponds to the mid-point of a line drawn from the middle of the most distal transverse crease of the wrist to the root of the middle finger; a line drawn from the radial border of the pisiform bone across the hook of the hamate bone, and thence in a curved direction downwards and laterally to that point, corresponds to the main part of the arch; the first and fourth digital branches overlie the fifth and third metacarpal bones respectively, and the second and third overlie the fourth and third interspaces respectively. The **deep arch** lies almost transversely, midway between the distal border of the flexor retinaculum and the superficial arch. The **radialis indicis** artery corresponds to the radial border of the index-finger.

The **ulnar nerve** and the commencement of its two divisions lie at the medial side of the superficial palmar arch; the pisiform and the hook of the hamate are therefore the guides to the nerve. The **median nerve** emerges from behind the flexor retinaculum opposite the medial edge of the thenar eminence. It then divides into two portions—the lateral one provides (1) the three digital branches for the supply of the thumb and the radial side of the index finger, and (2) a muscular branch to the three muscles of the thenar eminence. The digital branches to the thumb run along the medial or distal edge of the eminence; incisions for the removal of foreign bodies may therefore be made into the thenar eminence with greater freedom than into the hypothenar eminence. But the muscular branch passes laterally 0·5 cm. below the flexor retinaculum and must be avoided when an incision is made into the thenar space.

When pus forms in connexion with infections of the digits or hand it is encountered in one or other of the following situations: (1) the pulp of the digit; (2) the synovial sheath of the flexor pollicis longus; (3) the lateral mid-palmar space; (4) the medial mid-palmar space; (5) the flexor sheaths of the middle three digits; (6) the flexor synovial sheath of the little finger; (7) the common synovial flexor sheath. For each situation there is an appropriate incision:—Infection of the pulp requires a horse-shoe incision which passes round the periphery of the finger-pulp, so that the distal end of the flap is free. The sheath of the flexor pollicis longus is drained by an incision which extends from the distal crease of the thumb to the ulnar side of the thenar eminence, finishing 3·8 cm. below the distal wrist crease. The lateral mid-palmar space is entered through an incision made immediately dorsal to the edge of the web between the thumb and index finger; a forceps passed through the incision deep to the muscles of the thumb enters the space. The medial mid-palmar space is drained by an incision in the web between the middle and ring fingers. To evacuate the sheath of the little finger, an incision is made along the ulnar border of the palmar surface in the line of the tendon of the little finger and slightly to its ulnar side; from that incision the common sheath also can be explored by forceps pushed upwards, laterally and slightly backwards. A longitudinal incision between the median and ulnar nerves on the proximal side of the superficial palmar arch drains the common flexor sheath directly. To open the digital flexor sheaths, incisions are made along the antero-lateral aspect of the fingers opposite the proximal and middle phalanges.

LOWER LIMB

GLUTEAL REGION

The region of the hip and buttock extends from the iliac crest to the fold of the buttock. The highest point of the **iliac crest**, situated a little behind its middle, is

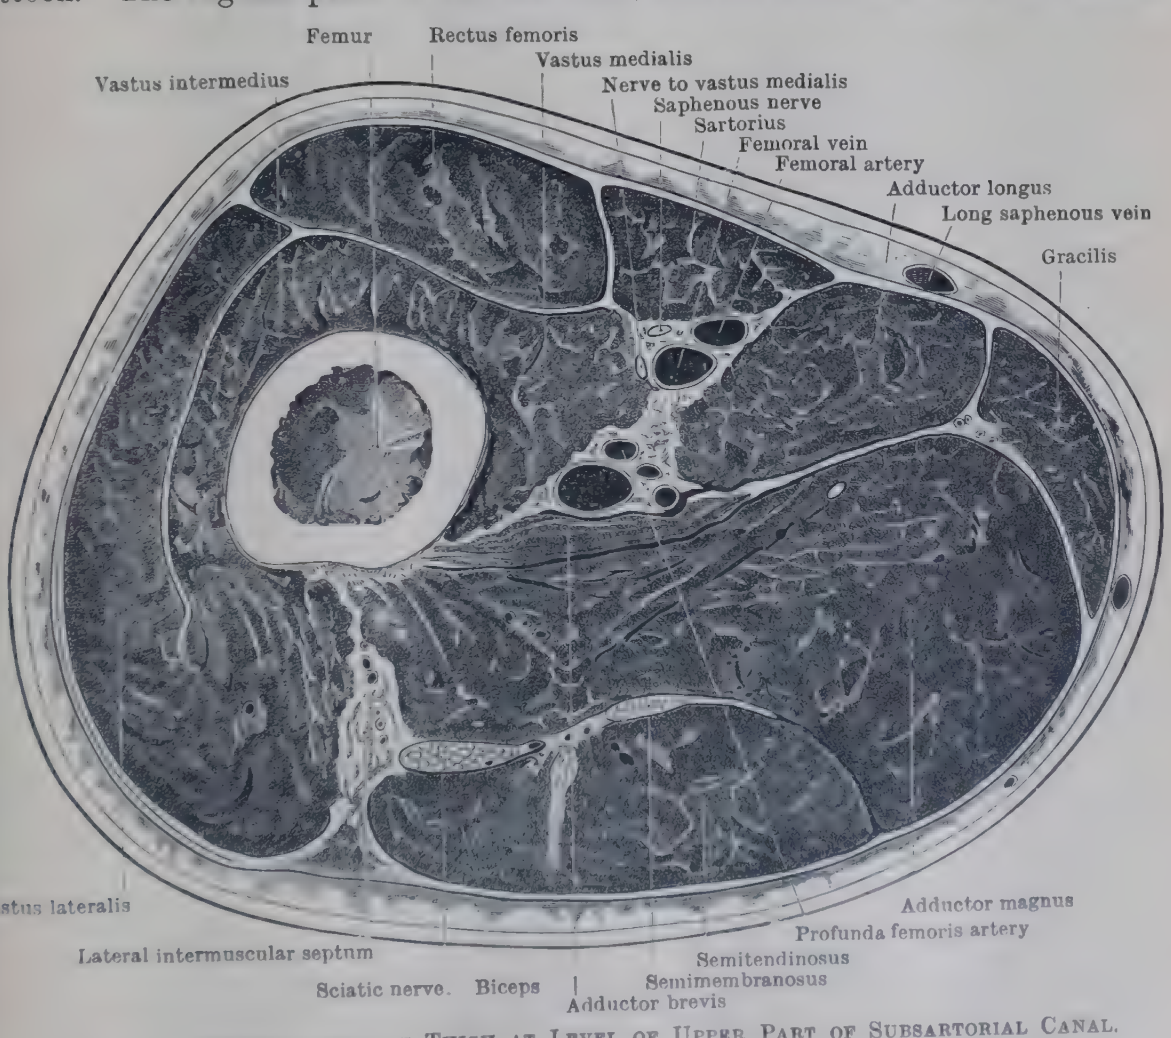

FIG. 1241.—SECTION THROUGH THIGH AT LEVEL OF UPPER PART OF SUBSARTORIAL CANAL.

at the level of the fourth lumbar spine; the **anterior superior iliac spine** is directed forwards, and belongs to the groin, which it limits laterally; the **posterior superior**

spine, situated in the floor of a dimple, is at the level of the second sacral spine and the middle of the **sacro-iliac joint**. Six centimetres above and behind the anterior superior spine there is a prominence on the outer lip of the iliac crest termed the **tubercle of the crest**; it is the most lateral part of the crest, and it has been referred to already. A handbreadth below the tubercle of the crest is the **greater trochanter** —the most lateral bony landmark of the hip. Its anterior and posterior borders are felt best between the fingers and thumb while the limb is slightly abducted to relax the ilio-tibial tract; and, if the thigh is then rotated, it will be noted that the trochanter rotates round the segment of a circle the radius of which is the head and neck of the femur. *Nelaton's line*, drawn from the anterior superior spine to the most

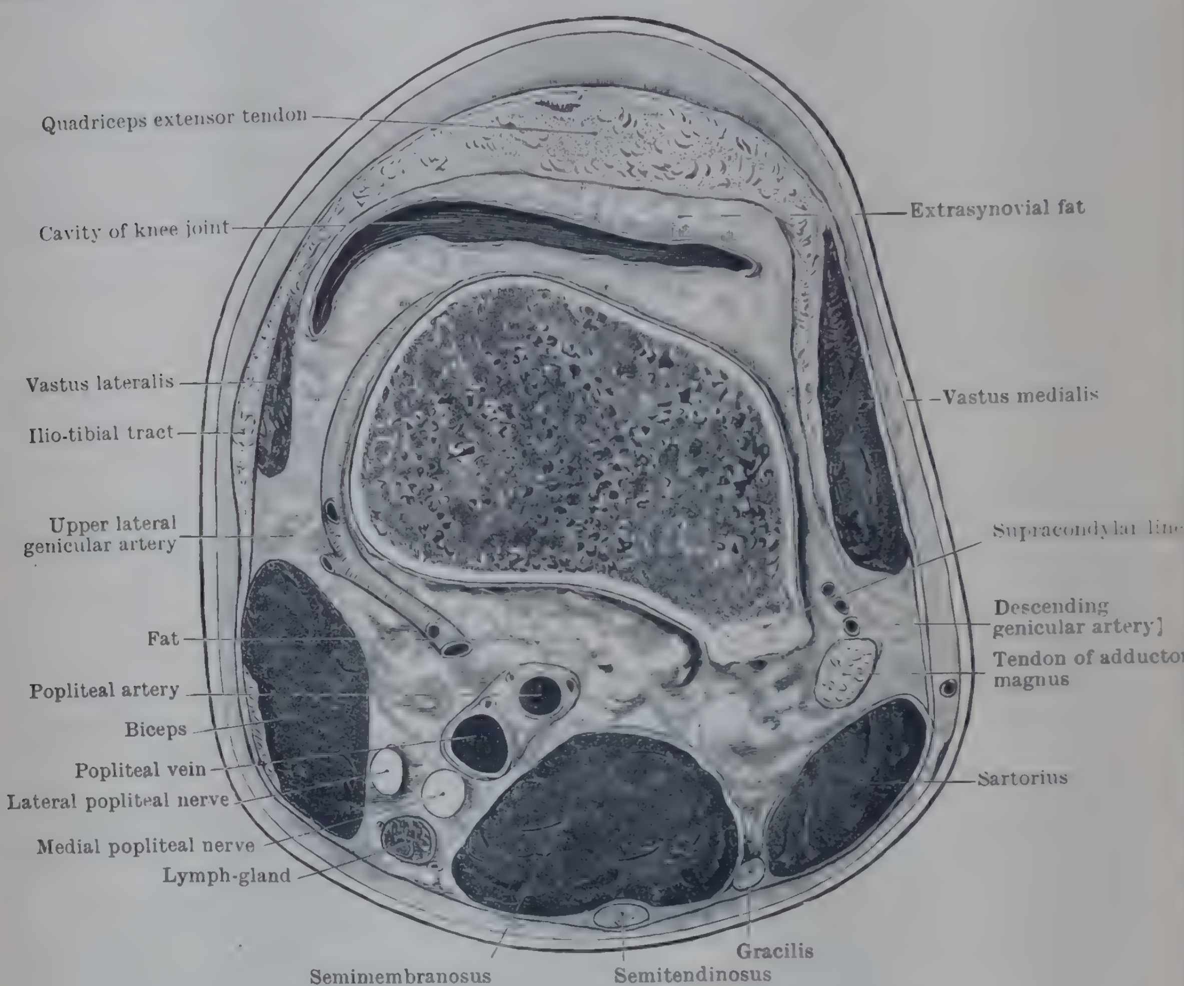

Fig. 1242.—Section through Thigh immediately above Patella.

prominent part of the ischial tuberosity, crosses the hip at the level of the upper border of the greater trochanter; that line is employed to ascertain the presence or absence of upward displacement of the trochanter. John Chiene demonstrated the relative height of the trochanters by stretching two tapes across the front of the pelvis, one between the anterior superior spines, and the other between the antero-superior angles of the trochanters; the lower tape converges towards the upper on the side of the upward displacement. The **ischial tuberosity**, in the erect posture, is overlapped by the lower border of the gluteus maximus; its most prominent part is felt a little above the medial part of the fold of the buttock. If the thigh is rotated medially, the **lesser trochanter** of the femur may be felt by deep palpation above the lateral end of that fold; it corresponds to the interval between the lower border of the quadratus femoris and the upper border of the adductor magnus, and therefore, also, to the level of the **medial circumflex artery** of the thigh.

The **lower border** of the **gluteus maximus**, in its medial half, is a little above the **fold of the buttock**, crosses it about its middle, and is continued downwards and laterally to meet the upper end of the furrow of the lateral intermuscular septum at the junction of the upper and middle thirds of the femur. The medial borders of the right and left great gluteal muscles are separated by the **natal cleft**, which

extends upwards and backwards from the perineum to the level of the third sacral spine, where it opens out into the triangle on the back of the sacrum. Anteriorly the hip is limited by the prominence of the **tensor fasciæ latæ** muscle, which extends downwards and slightly backwards from the anterior part of the iliac crest to join the ilio-tibial tract below the root of the greater trochanter.

The **superior gluteal artery** reaches the gluteal region through the upper part of the greater sciatic foramen, opposite a point at the junction of the upper and middle thirds of a line drawn from the posterior superior iliac spine to the upper border of the greater trochanter.

The **sciatic nerve** enters the gluteal region at a point opposite the junction of the upper and middle thirds of a line drawn from the posterior superior iliac spine to the ischial tuberosity; from that point the nerve passes downwards and slightly laterally on the ischium to a point midway between the ischial tuberosity and the greater trochanter. The **spine of the ischium** and the **internal pudendal vessels** are opposite the junction of the lower and middle thirds of the same line. The vessels and nerves which enter the gluteal region may be exposed by making an incision from the greater trochanter to the crest of the ilium, and continuing it backwards to the posterior superior iliac spine. The origin of the gluteus maximus is divided, and the musculo-cutaneous flap so fashioned is retracted posteriorly to display the region.

BACK OF THIGH AND POPLITEAL FOSSA

The **hamstring muscles**, and especially the tendons of the biceps and semitendinosus, are thrown into prominence when one stands on tiptoe with the knee slightly flexed, or flexes the leg against resistance. When the hamstrings are thrown into action, the line of the **lateral intermuscular septum** of the thigh is indicated by a well-marked furrow that extends from the lower edge of the insertion of the gluteus maximus to the lateral side of the knee; behind that furrow is the **biceps femoris**, and in front of it is the **vastus lateralis**, covered by the ilio-tibial tract. When the **shaft of the femur** has to be cut down upon, the incision that involves the least injury to the soft parts is one made along the whole length of that furrow. The popliteal surface of the femur and deep-seated popliteal abscesses are reached most conveniently through the lower part of the same incision.

The course of the **sciatic nerve** corresponds to the upper half of a line drawn from a point midway between the ischial tuberosity and the greater trochanter to the centre of the popliteal fossa. The nerve enters the thigh under cover of the lateral border of the biceps, whereas the **posterior cutaneous nerve** of the thigh, which takes the same line, descends superficial to the biceps, between it and the fascia lata.

The **lateral popliteal nerve** may be rolled under the finger as it descends along the medial side of the tendon of the biceps and behind the head of the fibula: so close is the nerve to the tendon that, when tenotomy is necessary, the tendon should be divided by the open method rather than subcutaneously.

Abscesses may reach the flexor compartment of the thigh from various sources: (1) from the back of the hip joint; (2) from the pelvis, through the greater sciatic foramen; (3) from one or other of the bursæ under the gluteus maximus; (4) from the front of the hip joint by passing backwards under cover of the tensor fasciæ latæ or by winding backwards below the neck of the femur and through the interval between the quadratus femoris and the adductor magnus; (5) from the iliac fossa behind the inguinal ligament into the femoral triangle, and thence to the back of the thigh by one or other of the routes already mentioned; (6) upwards from the popliteal surface of the femur, the knee, a popliteal gland, or a bursa.

When the knee is extended the **popliteal fascia** is put upon the stretch, and the hollow behind the knee is obliterated; when the knee is flexed the fascia is relaxed, and the fingers may be pressed deeply into the femoral division of the fossa; as a rule, the pulsations of the popliteal artery can be felt. Deep to the **semitendinosus** is the **semimembranosus**, which is still fleshy in its lower part, and bulges into the space to overlap the upper part of the popliteal artery. Between

the semimembranosus and the medial head of the gastrocnemius there is the most important **bursa** in the popliteal region; it not infrequently becomes distended with fluid and then presents usually a more or less sausage-shaped outline; sometimes the bursa communicates with the cavity of the knee joint.

To map out the line of the **popliteal vessels** and the **medial popliteal nerve**, a line is drawn from a point a little medial to the upper angle of the fossa to a point midway between the condyles of the femur, and thence along the middle of the fossa to the level of the lower part of the tubercle of the tibia. The medial popliteal nerve lies immediately under cover of the deep fascia; the artery is separated from the popliteal surface of the femur by a quantity of fat. The popliteal **lymph-glands** lie near the vessels.

FRONT OF THIGH

Between the front of the thigh and the abdomen is the *groove of the groin* in which the **inguinal ligament** can be felt as a tense band stretching from the

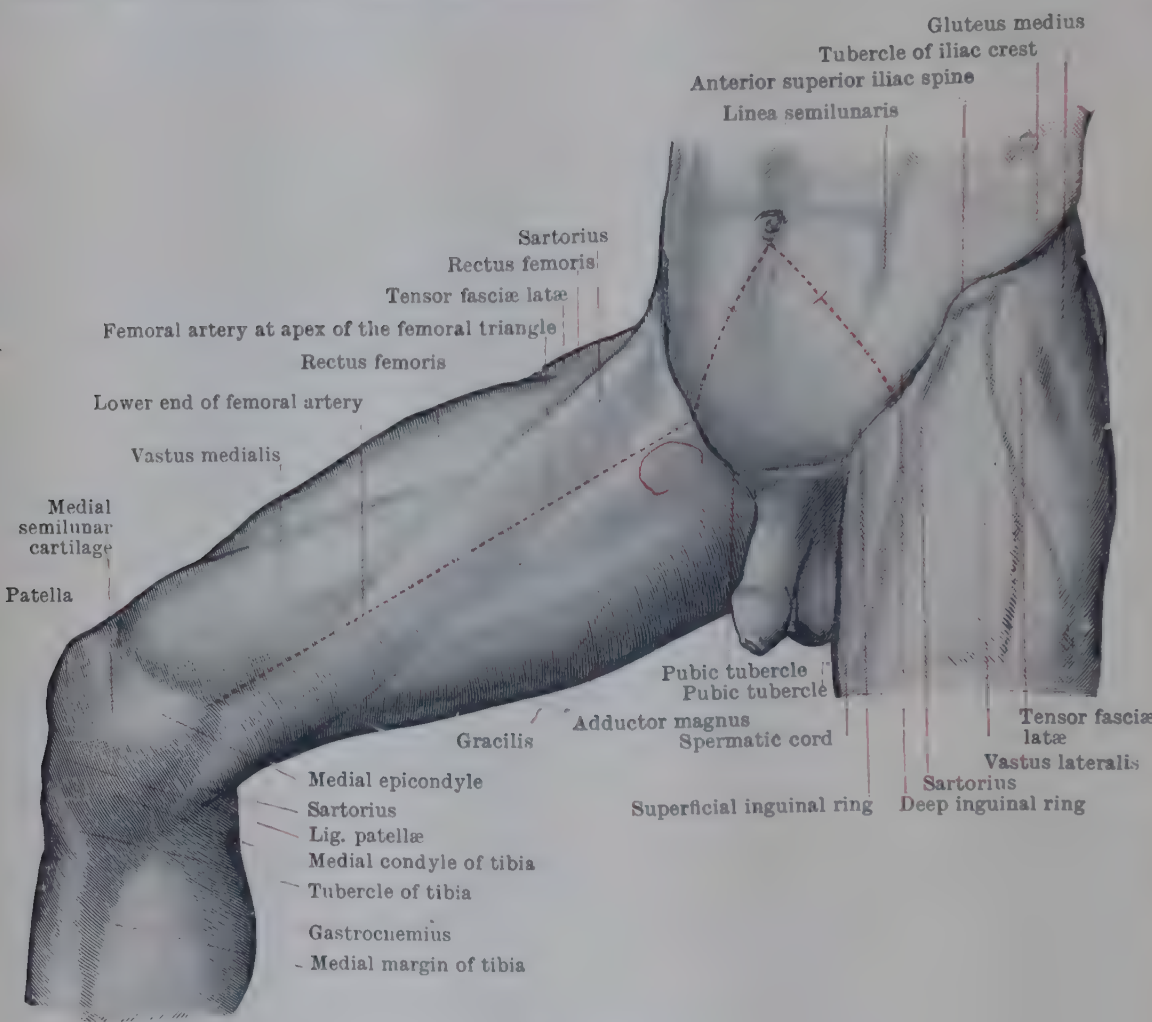

FIG. 1243.—THE THIGH AND GROIN.

anterior superior iliac spine to the pubic tubercle. The **anterior superior spine** looks directly forwards. To make comparative measurements of the two lower limbs a tape is stretched from that spine to the tip of the malleolus, taking care that the pelvis is horizontal, and the limbs are in corresponding positions. The **pubic tubercle**, in a man, is felt about 2·5 cm. lateral to the upper margin of the pubic symphysis, and, in a woman, rather farther from the symphysis—at the upper and lateral part of the mons pubis. Between the tubercle and the symphysis is the **pubic crest**, the two crests together forming a rounded, bony ridge. A line drawn from the pubic tubercle horizontally across the front of the thigh crosses the front of the hip joint at the level of the lower part of the head of the femur. The cord-like **tendon** of the **adductor longus** is readily felt, and a point abou t2·5 cm. below

the pubic tubercle is selected for performing the operation of subcutaneous tenotomy of the tendon.

The centre of the **saphenous opening** is situated 3·8 cm. below and lateral to the pubic tubercle; the opening overlies the medial (hernial) and intermediate (venous) compartments of the femoral sheath; behind the lateral border of the opening is the arterial compartment of the sheath; crossing over the lower border is the terminal part of the long saphenous vein. A femoral hernia makes its way into the thigh behind the upper edge of the opening. The course of the **long saphenous vein** in the thigh is indicated by a line drawn from the adductor tubercle of the femur to the lower part of the saphenous opening.

The **horizontal chain** of superficial **inguinal lymph-glands** can usually be felt a little below the line of the inguinal ligament; when the glands are inflamed the surgeon should not neglect to examine the buttocks and anus as well as the external genitals. The **vertical chain** lies in close relation to the upper end of the long saphenous vein. *Deeper* glands also are met with, behind the cribriform fascia close to the medial side of the femoral vein; and there is generally one in the femoral canal. To clear out the glands in the groin, an incision is made parallel to the whole length of the inguinal ligament and a finger's breadth below it.

To map out the course of the **femoral artery**, the thigh being slightly flexed and rotated laterally, a line is drawn from the mid-inguinal point to the adductor tubercle; rather less than the upper third of the line corresponds to the femoral artery in the femoral triangle, while rather more than its middle third corresponds to the artery as it lies in the subsartorial canal. The seat of election for ligature of the vessel is at the apex of the femoral triangle. To compress the femoral artery, pressure is directed backwards against the ilio-pubic eminence, and not against the head of the femur; in the subsartorial canal, the artery is pressed laterally against the medial surface of the shaft of the femur.

On the lateral side of the thigh the **fascia lata** is thick and strong, but is only loosely attached to the vastus lateralis; hence the tendency of abscesses to travel downwards under cover of it towards the knee. The **sartorius** is the most important muscular landmark of the thigh, and is thrown into prominence when the thigh is held unsupported, flexed, and slightly rotated laterally. In the upper third of the thigh it is the lateral boundary of the femoral triangle; in the middle third it is superficial to the subsartorial canal; and in the lower third it is in front of the medial hamstrings. Lateral and adjacent to the upper part of the sartorius is the prominence of the **tensor fasciæ latæ**, which, as it passes to its insertion, diverges from the sartorius; in the angle between the two the tendon of the rectus femoris may be felt as it overlies the lower part of the front of the capsule of the hip joint.

The medial side of the lower half of the **shaft of the femur** may be conveniently exposed through the vastus medialis where it comes to the surface between the sartorius and rectus muscles; the incision is made along a line that begins at a point midway between the medial border of the patella and the adductor tubercle and extends towards the anterior superior iliac spine.

The front of the **hip joint** may be reached through an incision from the anterior superior iliac spine downwards along either the medial or the lateral border of the sartorius; in the former case the deeper part of the dissection passes between the iliacus and the medial border of the rectus femoris, while in the latter case the joint is reached lateral to the rectus tendon, between it and the anterior borders of the gluteus medius and minimus muscles. The *ascending branch* of the **lateral circumflex artery** of the thigh crosses the capsule parallel to the trochanteric line and immediately above it. The **ilio-psoas** crosses the anterior and the medial part of the capsule; between the psoas and the joint-capsule there is a **bursa** which frequently communicates with the joint through the thin part of the capsule medial to the ilio-femoral ligament; it is by way of that communication that a psoas abscess occasionally gives rise to secondary tubercular disease of the hip joint. One of the commonest situations to meet with an abscess in hip joint disease is in the fatty areolar tissue under cover of the tensor fasciæ latæ; or the pus may pass below and medial to the neck of the femur and thence along the course of the medial circumflex artery to the back of the thigh. *To tap the hip joint*, the puncture is made in the interval between the sartorius and the tensor fasciæ latæ, 5 to 7 cm. below the anterior superior iliac spine; if the instrument is then pushed upwards, medially and backwards behind the tendon of the rectus femoris, it will pass through the capsule a little above the trochanteric line. Regarded from the point of view of **dislocation**, the regions of the acetabular notch and

of the lower part of the capsule are the weak points in the joint; it follows that abduction favours dislocation by bringing the head of the femur into relation with those two weak areas.

When particularly free access to the hip joint is required, as in the open reduction of a congenital dislocation, an angled incision may be employed. The upper limb of the incision runs parallel to the anterior third of the iliac crest and a finger's breadth below it; the vertical or lower limb passes in the plane between the sartorius and the tensor fasciæ latæ to a point below the level of the greater trochanter.

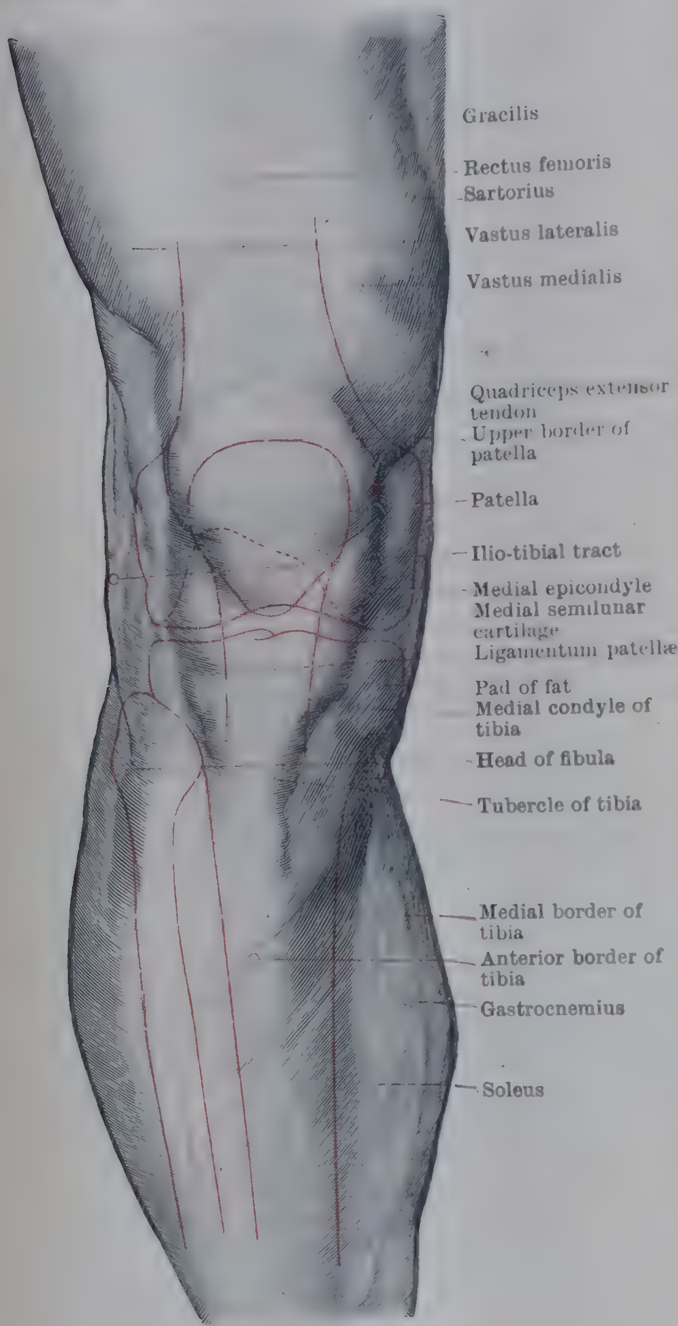

Fig. 1244.—Front of Knee.

THE KNEE

With the knee extended and the quadriceps relaxed, the **patella** can be readily outlined and moved from side to side on the femoral condyles. When the quadriceps is contracted its tendon springs forwards and is felt as a tense band above the patella; and the **ligamentum patellæ**, which has become tense and prominent, may be traced to the tubercle of the tibia. In front of the lower part of the patella and of the upper part of the ligamentum patellæ is the **prepatellar bursa**, into which effusion takes place in the condition known as housemaid's knee. Deep to and on each side of the ligamentum patellæ there is a well-circumscribed pad of fat, palpation of which gives rise to a feeling closely resembling true fluctuation. In extension, only the distal pair of articular facets of the patella are in contact with the patellar surface of the femur (Pl. XXXIV, Fig. 1, p. 371). In semiflexion the middle pair of facets rests on the femur; in that position the medial margin of the medial condyle of the femur, the upper border of the medial condyle of the tibia, and the lower part of the patella are all distinctly visible, and together bound a triangular depression which overlies the line of the joint and contains the anterior part of the **medial semilunar cartilage**; in that triangle the surgeon searches for a displaced or thickened medial cartilage, for a loose body, and for "lipping" of the edge of the articular cartilage in chronic osteo-arthritis. A similar but less well-defined triangle may be felt immediately lateral to the lower edge of the patella. When the quadriceps is thrown into sudden or violent contraction, as in preventing oneself from falling backwards, the patella may be transversely fractured at the moment of partial flexion. In full flexion almost the whole of the patellar surface of the condyles is exposed to palpation, covered, however, by the stretched quadriceps tendon.

The upper part of the medial surface of the medial condyle of the femur is overlapped by the fleshy prominence made by the lower part of the **vastus medialis.** Leading upwards from the medial condyle there is a slight furrow that corresponds to the interval between the lower part of the vastus medialis and the sartorius; at the bottom of the furrow the **tendon of the adductor magnus** can readily be felt

as a tense cord and can be followed to its insertion into the **adductor tubercle** ; the tubercle, situated at the junction of the medial supracondylar line with the upper and posterior part of the medial condyle, marks the level of the **epiphysial cartilage** (Pl. XXIV, p. 297). Anteriorly and posteriorly the epiphysial cartilage lies immediately above the highest part of the articular cartilage.

Disease of the lower part of the shaft of the femur generally invades the popliteal surface of the femur and the popliteal fossa rather than the cavity of the knee joint. In *Macewen's operation for knock-knee*, the incision through which the osteotome is introduced is carried down to the bone through the vastus medialis a little above the medial condyle—keeping a finger's breadth above the patellar surface to avoid injury to the epiphysial cartilage, and the same distance in front of the adductor tendon to avoid injury to the descending genicular vessels.

Below the medial condyle of the femur, the **medial condyle of the tibia** is readily felt, though it is crossed by the tendons of the sartorius, gracilis, and semitendinosus passing to their insertions. Between these tendons and the medial head of the gastrocnemius there is a groove which winds downwards and forwards from the popliteal fossa; an incision along that groove will expose the **long saphenous vein**, the **saphenous nerve** and the saphenous artery.

On the lateral side of the knee is the **ilio-tibial tract**, which, after crossing and obscuring the line of the joint, is attached to the **lateral condyle of the tibia.** By semiflexion of the knee the posterior border of the tract is thrown into relief, and a well-marked furrow intervenes between it and the tendon of the biceps ; the lower part of the shaft of the femur and its popliteal surface may be reached through an incision along that furrow. Under cover of the ilio-tibial tract, as it crosses the line of the joint, are the **lateral semilunar cartilage**, the **lower lateral genicular artery**, and the **lateral ligament of the knee**. The **head of the fibula** and the **tendon of the biceps** passing to be inserted into it become distinctly visible when the knee is semiflexed ; the head of the fibula lies on a level with the tubercle of the tibia, 3·8 cm. behind and a little below the most prominent part of the lateral condyle of the tibia. The termination of the **lateral popliteal nerve** is immediately below the head of the fibula, and is liable to be contused from blows and in fractures of the neck of the fibula.

At the lower part of the knee joint, anteriorly, the **synovial membrane** extends downwards as far as the level of the upper border of the tibia ; posteriorly, it dips downwards for a short distance behind the upper end of the tibia to form a small cul-de-sac, the close relation of which to the popliteal artery must be borne in mind in the operation of excision of the knee. At the upper part, anteriorly, the synovial membrane extends upwards under cover of the quadriceps in the form of a pouch which reaches a level nearly 5 cm. above the articular surface of the femur ; posteriorly, there is no extension of the synovial cavity above the condyles. At the sides of the knee the synovial membrane covers the anterior third of the superficial surface of each condyle.

In **effusion into the knee joint** the hollows become obliterated, the patella is floated up, and fluctuation may be obtained above, below, and on each side of the patella.

In **arthrectomy** of the knee for tuberculous disease, the extra-synovial fat facilitates the separation of the suprapatellar pouch from the lower and anterior part of the shaft of the femur ; to expose the **pouches behind the condyles,** the cruciate ligaments are divided.

THE LEG

The medial surface of the **tibia** is subcutaneous throughout ; hence, the seat of a fracture of the shaft is, as a rule, easily felt, and the lower end of the upper fragment is apt to perforate the skin. The skin over the lower half of this surface is the commonest seat of varicose and callous ulcers, which are frequently prevented from healing by adhesion of the floor of the ulcer to the periosteum.

The **shaft of the fibula** is on a plane behind that of the tibia, and, with the exception of the triangular subcutaneous surface, is deeply placed among the muscles. To examine the fibula, the surgeon stands on the opposite side of

the patient and manipulates the bone along the line of the intermuscular septum between the peronei and the muscles of the calf.

The greater fullness of the antero-lateral surface of the leg, as compared with its medial surface, is due to the presence of the **extensor** and **peroneal groups of muscles**. When those groups are thrown into action, the individual muscles are mapped out on the surface by the grooves that correspond to their intermuscular septa. The **posterior peroneal septum** is opposite a well-marked furrow which extends from the back of the head of the fibula to the hollow behind the lateral malleolus. In front of it are two **peroneal muscles**—the *longus* giving rise to a prominence in the upper half of the leg, and the *brevis* prominent in the lower half. Behind the septum there is a prominence formed by the lateral border of the **soleus**, which projects beyond the border of the **gastrocnemius**.

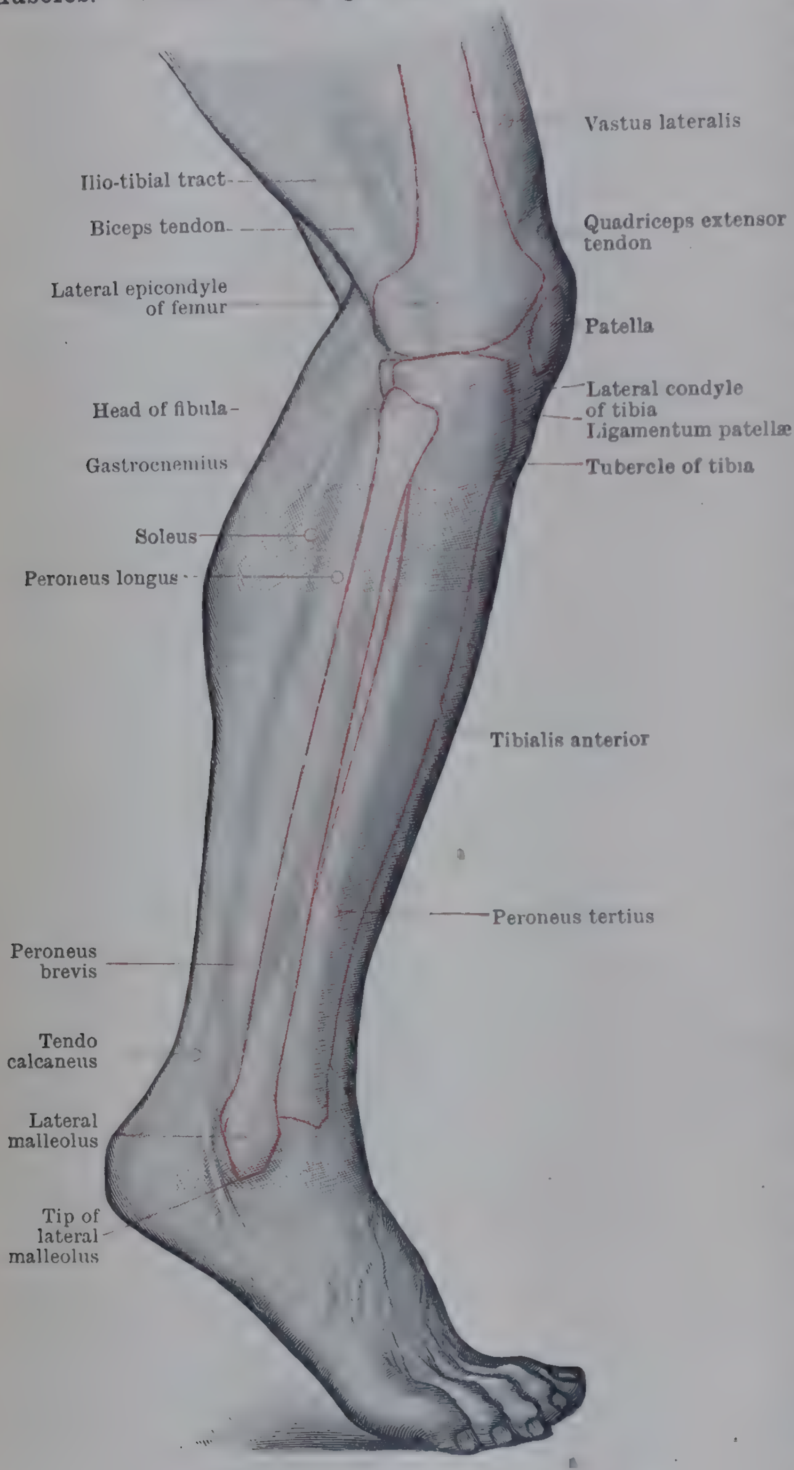

Fig. 1245.—Lateral Side of Knee and Leg.

It is along the line of the posterior peroneal intermuscular septum that incisions should be made to expose the fibula; to avoid the musculo-cutaneous nerve, however, the incision is not carried higher than 2·5 cm. below the head of the fibula.

The furrow between the extensors and the two peronei marks the **anterior peroneal septum**: it is much less distinct than the furrow of the posterior septum, and runs from the anterior border of the head of the fibula to the anterior border of the lateral malleolus; the **cutaneous portion of the musculo-cutaneous nerve** corresponds to the lower half of the furrow. At the junction of the middle and lower thirds of the leg the extensor muscles incline medially over the front of the tibia.

The **anterior tibial artery** reaches the front of the interosseous membrane 2·5 cm. below the head of the fibula; in the upper two-thirds of its course it lies on the interosseous membrane; in its lower third it winds on to the front of the tibia to terminate at a point opposite the ankle joint midway between the two malleoli. *Incisions to expose the vessel* should strike the lateral border of the tibialis anterior, which corresponds to a line drawn from a point midway between the lateral condyle of the tibia and the head of the fibula to the termination of the vessel.

When the muscles of the calf are thrown into action, a groove is seen between the two heads of the **gastrocnemius**, the fleshy fibres of which extend a little below the middle of the leg. The fleshy fibres of the **soleus** extend to the junction of the middle and lower thirds of the leg and project beyond the margins of the gastrocnemius. The narrowest part of the **tendo calcaneus** is opposite the bases of the malleoli, and it is there that the tendon is divided in the operation of tenotomy. The **short saphenous vein**, which lies a little to the lateral side of the tendon, gradually reaches the middle of the calf, along which it runs upwards to the middle of the popliteal fossa. The **long saphenous vein** and the **saphenous nerve** lie along the medial margin of the tibia, except in the lower part of the leg, where they course obliquely over the medial surface of the tibia.

The **posterior tibial** and **peroneal arteries** are exposed through an incision beginning to the medial side of the tendo calcaneus and extending upwards between the two heads of the gastrocnemius. The incision is deepened in the median plane, to divide the gastrocnemius, soleus, and tendo calcaneus into two halves, separation of which exposes the vessels and the posterior tibial nerve on the lateral aspect of the posterior tibial artery.

FOOT AND ANKLE

The tip of the **lateral malleolus** is 0·5 cm. lower than the tip of the **medial malleolus** (Pl. XXV, Fig. 1, p. 304). Above the lateral malleolus is the triangular subcutaneous surface of the fibula, the apex of which corresponds to the distal end of the anterior peroneal septum.

The **line of the ankle joint** can be felt on each side of the extensor tendons, and, when the foot is extended, the anterior part of the upper surface of the body of the **talus** forms a visible prominence below the anterior edge of the distal end of

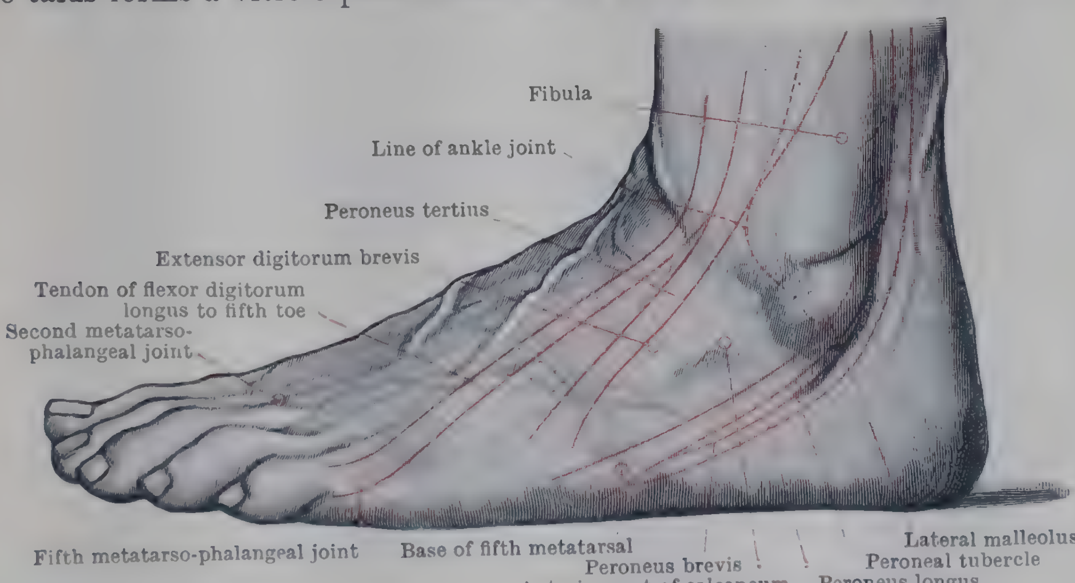

Fig. 1246.—Lateral Side of Foot and Ankle.

the tibia. The posterior surface of the talus is small, but it may be felt below and behind the medial malleolus at the anterior part of the hollow between it and the heel. In *effusions into the ankle joint*, the hollows in front of and behind the malleoli are obliterated, and the extensor tendons are raised from the front of the joint.

A finger's breadth below the tip of the medial malleolus is the **sustentaculum tali**; 3 cm. in front of the sustentaculum is the **tuberosity of the navicular bone** which is generally visible and always distinctly palpable. The **talo-calcanean joint** is immediately above the sustentaculum; and immediately above the joint the **tendon of the tibialis posterior** may be made visible as it extends from behind the tip of the medial malleolus to the tuberosity of the navicular. Three centimetres in front of the tuberosity of the navicular is the **joint between the medial cuneiform and the first metatarsal**; the ridge at the base of the first metatarsal furnishes a good guide to the joint. The first **metatarso-phalangeal joint** is a little in front of the middle of the ball of the big toe.

The **base of the fifth metatarsal bone** makes a prominence on the lateral border of the foot about midway between the point of the heel and the root of the little toe. A finger's breadth vertically below the tip of the lateral malleolus is the **peroneal tubercle** of the calcaneum, and midway between the two is the **talo-calcanean joint**; the peroneal tubercle is, when present, a trustworthy guide to the level at which the **two peroneal tendons** cross the lateral surface of the calcaneum. The anterior part of the **calcaneum** is felt in the triangular interval between the tendons of the peroneus brevis and tertius. The **calcaneo-cuboid joint** is barely a finger's breadth behind the base of the fifth metatarsal (Pls. XXV, Fig. 2, p. 304, and XXVII, p. 320). On the dorsum of the foot the tarsal joints are obscured by the extensor tendons. The **synovial membrane** of the **ankle joint** is prolonged on to the neck of the talus.

The **line of the tarso-metatarsal joints** extends nearly 2·5 cm. farther forwards on the medial border of the foot than on the lateral border; and it takes a zigzag course on account of the second metatarsal bone extending backwards between the medial and lateral cuneiform bones. The joint between the second metatarsal and intermediate cuneiform is nearly 1·5 cm. behind that between the first metatarsal

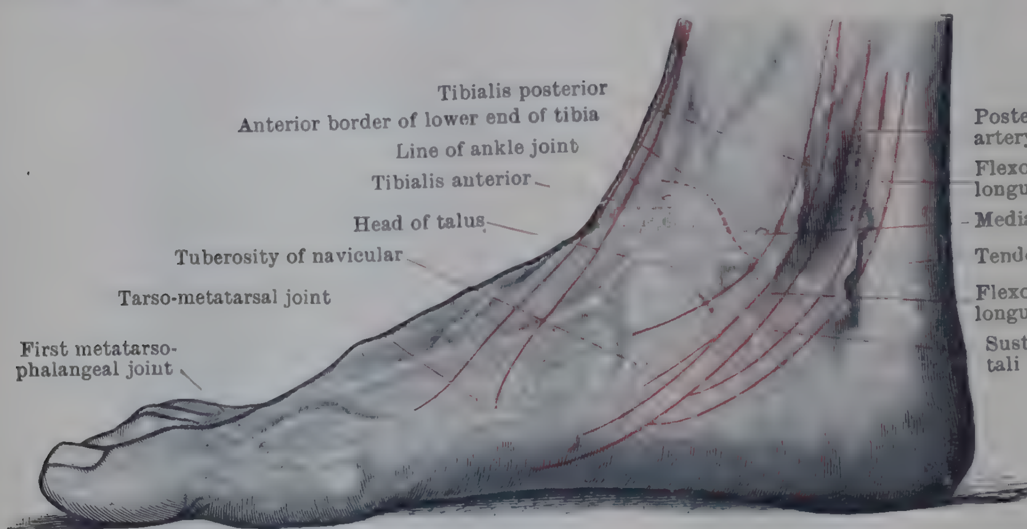

FIG. 1247.—MEDIAL SIDE OF FOOT AND ANKLE.

and medial cuneiform, and 0·5 cm. behind that between the third metatarsal and the lateral cuneiform.

The **metatarso-phalangeal joints** are 2·5 cm. behind the web of the toes. When a toe is disarticulated, the plantar ligament of the joint is detached from the phalanx, but left otherwise uninjured, for the bands of the deep transverse ligament of the sole are attached to its margins.

The **tendon** of the **tibialis posterior** may be felt, and, when the foot is inverted, seen, as it extends from behind the tip of the medial malleolus to the tuberosity of the navicular; it crosses the deltoid ligament and the talus immediately above the sustentaculum tali.

In the commonest form of club-foot — *talipes equino-varus* — the tuberosity of the navicular is approximated to the medial malleolus, and tenotomy of the tibialis posterior should be performed, therefore, through a puncture a little below the tip of the medial malleolus; after dividing the tendon, the knife is carried down to the bone in order to divide the **plantar calcaneo-navicular ligament** and to open the **talo-navicular joint**—a procedure called for before the foot can be brought into good position.

The following tendons—named from medial to lateral side—cross the front of the ankle joint: the **tibialis anterior** (the largest and most prominent), the **extensor hallucis longus**, the **extensor digitorum longus**, and the **peroneus tertius**. The **extensor digitorum brevis** makes the fleshy pad that overlies the dorsal surface of the calcaneo-cuboid joint. When the foot is everted, the tendon of the **peroneus brevis** may be seen extending from the tip of the lateral malleolus to the **base of the fifth metatarsal bone**; immediately below it is the tendon of the **peroneus longus**, which,

as it winds round the cuboid, is obscured by the fleshy fibres of the abductor digiti minimi muscle. The **abductor hallucis muscle**, although described along with the sole, forms a fleshy pad along the medial border of the foot below the sustentaculum tali.

An incision from the tuberosity of the navicular to the middle of the medial border of the heel will expose the various tendons, vessels, and nerves as they pass from the medial malleolus into the sole, deep to the abductor hallucis.

The **dorsalis pedis artery** may be mapped out on the surface by a line drawn from a point opposite the ankle joint midway between the two malleoli to the posterior end of the first interosseous space. The **long saphenous vein** and the

TABLE II.—SEGMENTAL INNERVATION OF MUSCLES OF LOWER LIMB.

saphenous nerve lie between the anterior border of the medial malleolus and the tendon of the tibialis anterior; the **short saphenous vein** and the **sural nerve** take the same course as the tendon of the peroneus brevis.

The **medial plantar vessels** and **nerve** lie along the **medial intermuscular septum**, which corresponds to a line drawn from the medial tubercle of the calcaneum to the interval between the first and second toes. The **lateral plantar vessels** and **nerve** may be exposed by an incision along the **lateral intermuscular septum**, which runs in a line drawn from the middle of the lower surface of the heel to the fourth toe. To map out the course of the **plantar arch**, a line is drawn across the sole from the medial side of the base of the fifth metatarsal bone to the posterior end of the first interosseous space.

Lumbo-Sacral Plexus.—The segmental innervation of the muscles of the lower limb is shown in Table II. For the cutaneous distribution of the nerves of the lumbo sacral plexus, see Fig. 941, p. 1096, and for the dermatomes of the lower limb, Fig. 942, p. 1097.

RADIOGRAPHIC ANATOMY

X-RAYS, since their discovery by Röntgen in 1895, have become of increasing importance in Medicine. Their possible value in diagnosis and treatment was soon recognized; and improvement in the design of apparatus has been so rapid that even the most extravagant early claims have been exceeded.

While it is true that X-rays are the product of complex electrical disturbances, it is not always appreciated that a knowledge of higher physics and of intricate electrical machinery is not the most essential factor in their application to medical problems. The purely technical aspects of the nature and production of X-rays are the province of the physicists and the electrical engineers; and even the actual processes of radiography—the preparation of radiographic films—are now usually left to the non-medical technician or radiographer. The radiologist, who is a qualified medical man, is concerned mainly with the interpretation of the radiograph and he requires to have only sufficient knowledge of the technical factors and processes to enable him to interpret it correctly. He is primarily concerned, therefore, with what he *sees* in the radiograph, which implies a thorough knowledge of anatomy and, when disease is present, of pathology.

Appropriate treatment can be applied, as a rule, only after the exact extent and nature of a disease have been ascertained. By ordinary methods of examination such information is difficult to secure if the diseased structures and organs lie at some depth in the body. It can often be obtained, however, by X-ray examination. In order that the treatment should be not only appropriate but also successful it is very important that the necessary information should be obtained while the disease is still in an early stage; for, in advanced stages, destruction may be so marked or the process so widespread that cure is usually impossible. X-ray examination may play an important part in the early recognition of disease, and there are few conditions in which it is not of some value and many in which it has become the most important single means of examination. But in the early stages of disease there is very little departure from the normal: it follows that the radiologist must be very familiar with the radiographic picture of the healthy body so that he will not overlook very slight changes and will not fail to assist the clinician at the only stage at which the disease may be curable. The more familiar he is with the normal anatomical appearances, the less likely he is to make such an error.

The interpretation of a radiograph is, however, by no means a simple matter. It is well known that it may be difficult to recognize even familiar objects viewed from an unusual angle or in an unusual manner; and distortion may easily cause a normal structure to appear abnormal. In a radiograph, the various structures through which the X-ray beam has passed are visible as areas of blackening of different density. The images all lie in the plane of the film and they may be so superimposed and so foreshortened that at first it is difficult to recognize them.

In order to interpret radiographs correctly, the observer must first be familiar with the parts as examined by ordinary means. He must know also the essential points in the process of radiography including the projections commonly employed.

In addition to the recognition of normal anatomical structures and of changes due to disease in its early stages, X-ray examination with a *fluorescent screen* provides a means of observing the form and movement of organs during life. Such a study enhances the observer's knowledge of anatomy and adds greatly to its interest. To the student it is of special value, for in the dissecting room he is apt to think only of the structure of the organs and of their shape and appearance as found in the cadaver. He has difficulty in appreciating that many of the parts he is dissecting are very different in their appearance during life and he thus often fails to correlate structure and function. For example, his conception of the stomach as a flaccid, inert bag is immediately rectified when he is able to observe directly the alterations in shape which it undergoes as it fills and empties and the peristaltic movement of its walls. Visualization of the movements of the ribs and

diaphragm during respiration, of the constant beating of the heart and of the movements of the joints cannot fail to add to his interest and make him appreciate anatomy in a new light.

For the assistance of the student a brief account of the production of X-rays and of the technique of radiography will now be given. For further information on the subject, which is obviously outside the scope of this Appendix, he must consult one of the many special books now available.

NATURE AND PROPERTIES OF X-RAYS

X-rays form part of the electro-magnetic spectrum, of which the longest wave-lengths are known as wireless waves. Wireless waves are usually measured in metres but, as we proceed down the scale of wave-lengths through the bands of visible light and ultra-violet light, we come to X-rays whose wave-lengths are of the order of a hundred-millionth part of a centimetre.

An X-ray tube consists of a high-vacuum glass cylinder into the ends of which two metal electrodes project (Fig. 1248). X-rays are produced by bombardment of the positive electrode or anode by electrons. The speed of the electrons when they strike the anode is very great and approaches the speed of light (which travels at 186,000 miles per second). Each electron carries a negative charge; and radiating lines of force extend out from it as from any other charged body. When the electrons

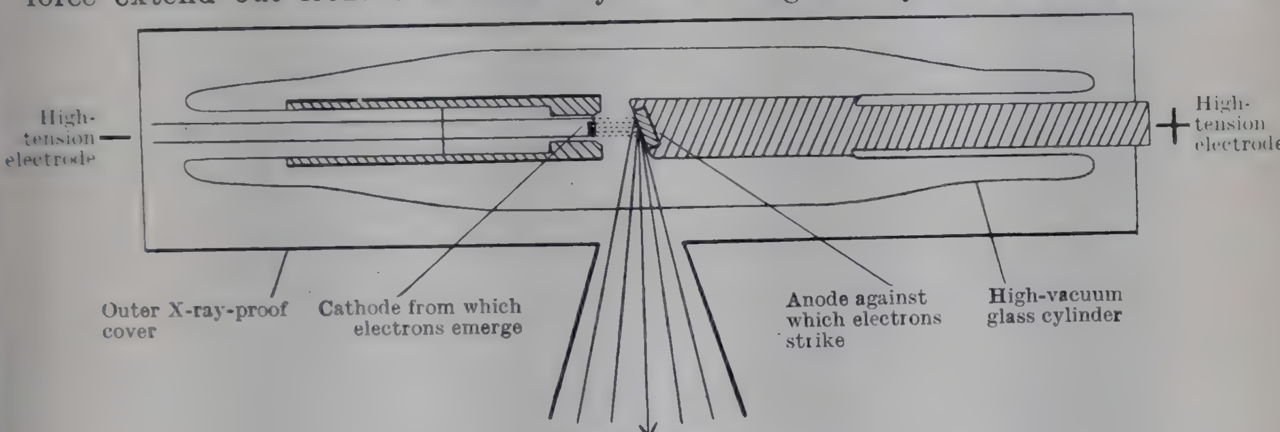

Fig. 1248.—Diagram of X-Ray Tube.

strike the anode they are brought violently to rest, and the collision causes vibrations to pass along the lines of force in a manner similar to the vibrations that pass along a tightly stretched rope struck at one point. These vibrations along the lines of force constitute X-rays. The higher the speed of the electron at the time of its impact, the more violent are the vibrations in the lines of force and the shorter the wave-length of the X-ray produced. Now, the speed of the electron, as it passes from the negative electrode or cathode to the anode, is determined by the voltage applied to the tube, so that the higher the voltage the shorter is the wave-length of the beam produced. Normally, voltages of the order of 40,000 to 100,000 volts are used in diagnostic radiography.

In addition to the control of the wave-length by the voltage, one may control the *amount* of X-rays by varying the amount of current (measured in ampères) that passes through the tube. It has been found that the output of X-rays is directly proportional to the current. The current used, however, is quite small and is usually only a fraction of an ampère.

When Röntgen discovered the new rays he called them *x*-rays to indicate that they were an unknown quantity. They still retain that name, though a great deal is now known about them and about their properties. The chief properties of X-rays are as follows:—

(1) They have the power of penetrating matter.
(2) They can blacken a photographic film.
(3) They produce fluorescence in certain substances.
(4) They have a special biological action.

Penetration of Matter.—One of the most useful properties of X-rays is their power of penetrating solid matter; and the shorter the wave-length the greater is the power of penetration. In their passage through matter, the rays are absorbed and the amount of absorption is dependent on the atomic number of the absorbing substance and its density. Hence, if the X-ray beam is made to pass through a limb, it will be absorbed to a different degree by the soft tissues and by the bones, because the bones not only are denser but also contain calcium, which is of higher atomic number than the carbon, hydrogen, oxygen, and nitrogen of the soft parts.

Effect on Photographic Film.—X-rays, like light-rays, have the power of blackening a photographic film; and the amount of blackening produced is dependent on the amount of X-rays and the time during which they act. If, then, a photographic film is placed on the opposite side of the limb from the tube, there will be less blackening produced where the rays have been absorbed by the bones. But the rays that pass through the less absorptive soft parts will retain much of their original intensity and will blacken the film to a considerable degree and so cause the white shadows of the bones to stand out (Pl. XVIII, p. 273). The radiographic film, like the ordinary photographic film, requires to be developed and fixed before the image can be examined and these processes are carried out in the ordinary way in the dark-room. The completed film is called **a radiograph.**

Fluorescence Effect.—The third property of X-rays is their power of producing fluorescence in certain metallic salts. The salts commonly employed in X-ray work are zinc sulphide, calcium tungstate, and barium platino-cyanide. *Fluoroscopic examination* is carried out by means of a glass screen coated with either zinc sulphide or barium platino-cyanide. The screen, like the film, is placed on the opposite side of the patient from the tube and, when the current is switched on, fluorescence occurs. The brightness of the fluorescence at any point on the screen, like the blackening of the film, is dependent on the intensity of the beam; where absorption occurs, there is diminished intensity and hence less fluorescence. The fluorescent images, like the radiographic images, are sharp in their definition, and the various structures through which the beam is passing can be readily recognized. Although the detail is not so good as in a radiograph, screen-examination has the great advantage that it permits the observer to study the movement, and, to some extent, the function of the part examined. Fluorescence is used also for another purpose. If an X-ray film is placed between two pieces of cardboard coated with calcium tungstate, it has been found that the exposure can be reduced by 10 to 20 times because the fluorescence produced by the calcium tungstate actually causes greater blackening than that produced directly by the X-rays. "Screened films" are always used, therefore, when the exposure must be of short duration.

Biological Action.—Within recent years, the biological properties of X-rays have become of great importance in the treatment of malignant disease. A full explanation cannot be given here, but it may suffice to state that the rays have the remarkable property of destroying cancer-cells without necessarily destroying the normal healthy cells; and a patient treated by X-rays may thus be cured of malignant disease without operative removal of the affected part. Where organs essential to life are involved, this means of treatment is obviously of the greatest value. In excessive dosage the rays will destroy all living tissue—normal as well as abnormal—and the treatment of cancer requires to be very carefully controlled so that just the right amount of radiation is given. When the whole body is exposed at intervals over a prolonged period, even small doses of X-rays are dangerous. Severe anæmia may occur and may prove fatal. It is therefore of the utmost importance that radiologists, radiographers, and all those concerned in the manufacture of X-ray apparatus should take every precaution to prevent themselves from being exposed to the rays. Nowadays, the dangers are well-known and preventive measures can be taken so that health need not be impaired or endangered.

RADIOGRAPHY

In the actual taking of a radiograph the various factors are selected to produce the clearest possible image. When the thick parts of the body are examined, considerable absorption of the X-ray beam takes place and a more penetrating ray must therefore be used. This is obtained by the use of higher voltages on the tube. When thinner parts are examined, the voltage is reduced because there is less absorption and too penetrating a beam produces a radiograph of poor contrast. In stout patients, contrast may be made still greater by the use of a special lead-grid called a Potter-Bucky diaphragm. In radiography, we speak of a "Bucky radiograph" when this device has been used. The radiographic images are merely the shadows of the structures through which the X-ray beam has passed; and it need hardly be said that there is no question of focusing the beam by means of a lens as in ordinary photography. But, in order that the definition of the shadows may be as sharp as possible, it is important that the rays should all come from the smallest possible source; for, if the source is large, there will be a "penumbra effect"—*i.e.*, a blurring of the margins of the shadows. In modern tubes, the source or "focal spot" on the anode is only a few millimetres square and is often of the order of one square millimetre. When moving objects are examined, it is important also that the radiograph should be taken in the shortest possible time in order that blurring of the margins of the shadows by movement may be avoided. The higher the output of X-rays from the tube, the shorter will be the exposure-time required. With the high currents now available, radiographs of the chest may be taken in $\frac{1}{25}$th of a second or less, and this speed is sufficient to give a sharp definition to the outline of the heart in spite of its constant movement.

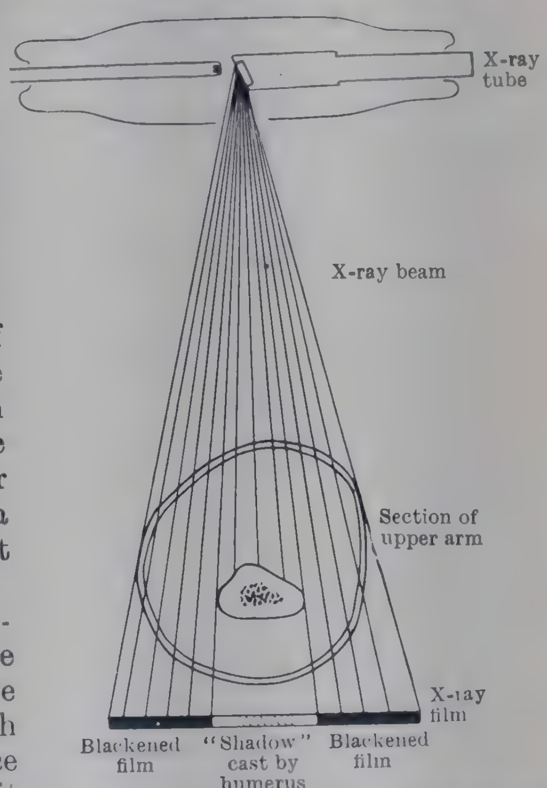

FIG. 1249.—DIAGRAM SHOWING THE ARRANGEMENT OF THE X-RAY TUBE, THE OBJECT AND THE FILM IN RADIOGRAPHY.

Note the enlargement due to divergence of the rays.

There is still another point to be considered. The greater the distance of the tube from the object to be examined, the more closely will the size of the shadow approach that of the object. Increased tube-distance will thus diminish distortion and render it possible to ascertain more accurately the relative size of the objects examined. A tube film-distance of about two metres is usually employed when it is desired to measure the size of the heart, but in ordinary work a distance of 70 to 100 centimetres is generally sufficient. Whatever distance is employed it is obvious that the shadows of the parts nearest the film will always suffer least distortion (Fig. 1249). The film is placed, therefore, on that side of the patient which is nearest to the structure or organ to be examined. Thus, the film is placed in front of the patient (an "anterior film") if the gall-bladder is to be examined, and behind the patient (a "posterior film") when the kidney is being investigated.

In the examination of certain areas (for example the skull, vertebral column, and thorax), stereoscopic examination is of great value. Stereoscopic radiographs may be obtained by two exposures of the same part on two separate films but with the position of the tube altered by a short distance. The patient must maintain exactly the same position, and the usual displacement of the tube is 6 cm. The radiographs are viewed in a stereoscope which, by means of mirrors or prisms, brings the images on the two radiographs together so that they fuse and can be seen in stereoscopic relief.

The foregoing is but a brief outline of the subject, but it may serve to indicate how a radiograph is produced and the possible scope of X-rays in the study of parts not readily capable of examination by ordinary means. It will be appreciated that the shadows in a radiograph, produced by the passage of a beam of X-rays through a part of the body, are similar to those shadows which a beam of ordinary light produces when it passes through some material that is not uniformly transparent. The sharpness of definition and the contrast in the shadows of the radiograph can be controlled by the voltage employed, the length of time of the exposure, the size of the focal spot, the use of a Potter-Bucky diaphragm, and other technical devices with which modern X-ray plants are provided.

It may have been noted that no mention has been made of the production of positive images or "printing". Radiographs are all examined as "negatives", not only because this saves time and expense, but also because the detail is always better in the original "negative" than in the most carefully produced "positive". With the exception of those that illustrate injected blood-vessels (Pls. LXXXI-LXXXVII), all the radiographs in the Plates of this text-book are reproduced as "negatives", and the student must note that the shadows of dense parts in the path of the X-ray beam appear white while the easily penetrated parts appear black. In a well-taken radiograph there should be all degrees of density ranging from the whitest parts to the blackest areas and not merely extremes of black and white, for this latter state of affairs shows that the radiographer has not selected the various factors so as to bring out as clearly as possible slight variations in density of the tissues.

INTERPRETATION OF RADIOGRAPHS

When the shadows in a radiograph come to be interpreted it must be clearly understood that, if all the tissues through which the beam passes are of the same density, there will be uniform absorption of the beam by these tissues and the radiograph will be uniformly blackened. One tissue or part can be distinguished from another only if the adjacent tissues are of a greater or lesser density. The absolute density of the part is of no importance. This point may perhaps be made clear by the following examples.

The heart is clearly visible in a radiograph of the chest, but the uterus, which is of approximately equal density, can be seen only rarely when the pelvis is examined. The heart is, of course, surrounded by air-filled lung which is much less dense, but the uterus is surrounded by tissues of density equal to that of itself. If, however, the parts of the lungs adjacent to the heart become solid as the result of disease, the heart can no longer be distinguished from the lung. For the same reason, in a radiograph of a joint, the articular cartilage cannot be seen, because the cartilage is equal in density to the soft parts and therefore casts a shadow of the same density; it becomes evident, however, if air is injected into the joint (Pl. XXXV, p. 382) or after the release of vapour on "cracking" a metacarpo-phalangeal joint (Roston & Haines, 1947). The blood is equal in density to the soft tissues because the amount of iron it contains is so small that it does not influence absorption; thus, normal blood-vessels cannot be seen in a radiograph.

With the exception of the skeleton and the air-filled lungs the tissues of the body are all approximately of equal density. With good technique, however, slight difference of density can be made out between some of the soft tissues. Thus, the kidney can be distinguished because the perirenal fat does not absorb the rays to quite the same extent. The outlines of muscles can be distinguished occasionally in a radiograph of the limbs because of the presence of fat and loose areolar tissue between the muscles. The margin of the psoas major can often be seen because the muscle is denser than the coils of intestine lateral to it (Pls. LXIX, p. 744, LXXI, Fig. 1, p. 745). Radiographs, especially lateral views, of the neck demonstrate the trachea because the air it contains absorbs less radiation than the surrounding tissue (Pls. LXI, p. 696, LXV, p. 704); and, for the same reason, gas

in the intestines may be seen. The air-bubble of the stomach can be seen when the patient is in the erect position but the liquid contents are not visible because they are of the same density as the adjacent parts. In the head, in addition to the bones, the air-sinuses are clearly seen; but the outlines of the ventricles of the brain are not visible until the cerebro-spinal fluid has been replaced by air or oxygen.

SPECIAL METHODS OF EXAMINATION

The examples given in the preceding paragraphs serve to indicate the limitations of X-ray examination and at the same time they indicate why special methods must be adopted in the examination of some organs. These special methods depend on the employment of **contrast-media** of different kinds. Contrast-media are divided into two main groups:—(1) Those which increase the density of the part and depend on the use of solutions or suspensions of salts of high atomic number. (2) Those which diminish density and in which air or oxygen is used. Some details will now be given of the actual techniques employed in the examination of particular organs and in the use of these contrast-media.

Alimentary Canal.—In the examination of the alimentary canal by X-rays a watery suspension of barium sulphate known as a *barium-meal* is employed. The salt is insoluble and therefore non-toxic; and barium, having a high atomic number, absorbs X-rays almost completely.

Examination of the œsophagus, stomach, and small intestine is usually carried out in the morning, the patient having taken neither solid nor liquid food since the evening before. The examination is mainly by fluoroscopy or "screening"; but radiographs may be taken for record purposes. Screening not only has the advantage of permitting the observer to see the passage of the barium and the peristaltic movements but also allows of palpation of the stomach and small intestine while they are visible on the screen.

The "barium-meal" is given to the patient standing erect behind the fluorescent screen in a completely darkened room. The tube is switched on and the patient is instructed to drink two mouthfuls of barium. The rapid passage of the barium down the **œsophagus** can be observed very clearly, especially if the patient is rotated to the left so that the shadow of the heart does not obscure the field (Pl. L, p. 593). (A "barium-paste" is sometimes used as it passes down the œsophagus more slowly.) The screen is then lowered and the patient is rotated again to face the observer. The barium is carefully watched as it enters the **stomach** and by suitable palpation it may be massaged or spread over the mucous membrane, to which it adheres. The thin coat of barium demonstrates the folds of mucous membrane as they pass from the fundus towards the pylorus (Pl. LI, p. 608). More barium is then given until the stomach is filled, when its outline and peristaltic movements may be observed (Pl. LVI, p. 621). In a few minutes—sometimes immediately—barium enters the first part of the duodenum, forming the "duodenal cap" (p. 621); and its subsequent passage through the duodenum and the rest of the small intestine may be studied at varying intervals according to the type of investigation being made.

The **large intestine** is examined best by a **barium-enema**. A "meal" may give some information, particularly in the cæcal region (Pl. LVII, p. 648), but it has the disadvantage that the passage of the barium is so slow that it cannot readily be detected on the screen and recourse must be had to multiple radiographs. Even with multiple radiographs certain parts may not be seen filled with barium. The barium-enema (Pl. LVIII, p. 648) is given through a special nozzle inserted in the rectum and connected by a length of rubber-tubing to a container for barium. The patient is examined in the supine position with the fluorescent screen above him and the X-ray tube under the couch on which he lies. The passage of barium from the rectum to the cæcum can be closely followed and, with the exception of the flexures and the pelvic colon, all parts of the large intestine are accessible to palpation.

Air also may be employed in the examination of the colon in conjunction with

barium. A barium-enema is given in the ordinary way and then the patient is allowed to evacuate the excess of barium. Some barium remains adherent to the mucous membrane and, when air is blown in, the walls of the intestine are separated and are rendered more clearly visible. This procedure is known as a "double-contrast enema" (Pl. LIX, p. 649).

The **appendix** can be examined either by the use of a "meal" or by an enema. Not infrequently the appendix is retrocæcal and the cæcum must be first displaced before the shadow of the appendix can be demonstrated.

Gall-Bladder.—The gall-bladder is not normally visible, but advantage has been taken of the fact that *phenol-phthalein* is excreted by the liver when taken by the mouth or injected into a vein. Phenol-phthalein itself is not opaque to X-rays, but, when iodine is combined in the molecule, the iodine, being of high atomic number, renders the compound capable of absorbing rays to a considerable extent. In practice, sodium tetra-iodo-phenol-phthalein (S.T.I.P.P.) is employed. Purification of the salt has made administration by the mouth almost free from unpleasant effects, and this route, in preference to intravenous injection, is now almost universally employed.

The shadow of the gall-bladder takes some time to appear because the salt is only very slowly excreted by the liver. It passes to the gall-bladder with the bile, and there it becomes concentrated. The best shadow is obtained usually about 14 to 16 hours after the salt has been swallowed. The patient is therefore told to take the salt dissolved in a glass of water in the evening of the day before examination. Radiographs are made next morning with the patient in the prone position, and if the gall-bladder is normal it can be clearly seen. It is important that the patient should not take any food from the time he has swallowed the salt until the completion of the examination, because food, and particularly fatty food, causes the gall-bladder to contract and expel its contents. Indeed, a "fatty meal" may be given to complete the investigation. The degree of contraction of the walls of the gall-bladder can be studied and the shadow of the salt may even be seen as it passes down the cystic duct and the bile-duct. Maximum contraction is observed usually about an hour after the fatty meal (Pl. LX, p. 649).

Urinary Organs.—There are two methods of investigating the renal tract. A complex iodine salt may be injected intravenously and radiographs then made as the salt is being excreted by the kidneys. This method is known as *excretion urography* or *descending pyelography*, and it has the advantage that the kidneys also are increased in density as the salt passes through their tubules (Pl. LXXI, Fig. **1**, p. 745). The disadvantage of the method is that the shadow cast by the ureters is less dense than in the second method of examination. The technique is simple. Twenty c.cm. of a solution of the salt are injected into a vein, and radiographs are taken almost immediately with the patient supine. The injection does not upset the patient and the whole examination can be completed in a short time.

In the second method, an instrument—the cystoscope—is passed along the anæsthetised urethra into the bladder. The cystoscope permits inspection of the interior of the bladder and, through the instrument, flexible hollow tubes (catheters) are inserted into the ureteral orifices and passed up the ureters to the kidneys. A solution of sodium iodide is then injected and, because of the greater concentration of iodine in this solution, very clear radiographs may be obtained of the calyces and of the whole length of the ureters (Pl. LXX, p. 744). This second method is known as *retrograde pyelography* and it is to be preferred in most cases because of the better detail that is obtained, and also because the walls of the bladder may be inspected at the same time. The kidney-substance is not increased in density as with the first method, but this is not of great importance, for in most radiographs the renal outlines are normally visible.

The outline of the **urinary bladder** may be rendered visible by both methods of examination (Pl. LXXI, Fig. **2**, p. 745).

The **male urethra** is usually examined by retrograde injection of sodium iodide.

Nervous System.—Air is the contrast-medium usually employed, as substances opaque to X-rays are not free from danger.

Air is passed into the ventricles of the brain after the withdrawal of cerebro-spinal fluid, and the ventricles then absorb radiation to a less extent than the surrounding brain and so can be seen in the radiograph (Pls. LXXIV, p. 945; LXXVI, p. 961.

The air may be injected through a long needle inserted directly into the lateral ventricles after small apertures have been drilled in the posterior portions of the parietal bones. This method is called *ventriculography* and it is the one usually employed. About 20 c.cm. of air are injected, and, by altering the position of the patient's head, the different parts of the lateral ventricles become filled with air. Thus, if the patient lies with the right side of the head on the table, the air will pass into the left lateral ventricle; with the face directed upwards the anterior horns of both ventricles can be seen, and, with the face downwards, the posterior horns are filled. The third ventricle and the aqueduct of the mid-brain are only occasionally visible with the usual quantities of air injected. The walls of the third ventricle and of the aqueduct are only so slightly separated that surface tension interferes with their being filled with air.

Air may be injected also into the vertebral canal in the lumbar region. The cerebro-spinal fluid is withdrawn from the subarachnoid space and is replaced by a slightly smaller volume of air. The air rapidly passes up the vertebral canal in the subarachnoid space and enters the ventricular system through the foramina in the roof of the fourth ventricle. As a rule some air escapes over the surface of the brain and outlines the sulci. This method is known as *encephalography* (Pl. LXXV, p. 960).

In the examination of the spinal subarachnoid space an *iodised oil* may be used. The usual preparation is a 40 per cent solution of iodine in poppy-seed oil ("lipiodol") and the iodine-content is sufficient to make the preparation opaque to X-rays. The injection is made between the spines of the fourth and fifth lumbar vertebræ. Its density when used in this strength is greater than that of the cerebro-spinal fluid, so that, when the patient is in the erect position, the oil collects in the lower lumbar and sacral portions of the vertebral canal. It is possible, by means of a tilting table on which the patient is placed, to make the oil flow towards the thoracic region or even as high as the neck. The passage of the oil is controlled by observation on the fluorescent screen. The oil, if left in the sub-arachnoid space, often becomes irritant and it should be removed by aspiration on completion of the examination.

Vascular System.—**Blood-vessels** may be made opaque to X-rays by the injection of salts of a high atomic number (Pls. LXXX-LXXXVII). Sodium iodide may be used but, as it may cause damage to the intima of the vessels and to the blood, only a dilute solution may be used, and, in consequence, the definition in the radiograph is poor. A colloidal suspension of *thorium dioxide* ("thorotrast"), on the other hand, markedly increases the density of the blood, so that the vessel and its branches become clearly visible. But this substance is radioactive—and therefore not free from danger—and organic iodine compounds are now usually employed.

Arteries are more commonly injected than veins, and the radiograph must be taken just before the injection is completed. If there is delay, the contrast-medium may have left the arteries and passed almost entirely into the veins. The internal carotid artery (or the common carotid, which is more accessible) and the vertebral artery are injected by the neuro-surgeon to display the condition of the cerebral vessels (Pl. LXXX, p. 1287).

Respiratory System.—As indicated on p. 721, it is exceedingly difficult to see the bronchi in an ordinary radiograph. If, however, their walls are coated with iodised oil they can be clearly demonstrated (Pls. LXII, LXIII, p. 696). The oil is usually injected into the bronchi through a rubber tube passed *via* the nasal cavity, the pharynx, larynx, and trachea after these parts have been anæsthetised. The examination is best conducted with the aid of the fluorescent screen and a tilting table. If the patient is placed in the correct position, it is possible to outline either the right or the left bronchus and, indeed, it is often possible to fill only the bronchus to the lobe it is desired to examine. This selective method of examination has great advantages as it may be difficult to disentangle the

shadows when all the bronchi are outlined. It is important that the examination should be conducted with great care and gentleness, for if the patient should cough, the alveoli become filled and obscure the bronchi.

Injection of "lipiodol" by means of a needle passed through the skin of the neck and the crico-thyroid ligament does not permit selective filling of the bronchi but this may be the only possible method with children.

Radiography of the bronchi after the injection of iodised oil has been largely superseded, except in special cases, by bronchoscopy, since it has been found that direct inspection of the interior of the trachea and bronchi through a bronchoscope is much more reliable and gives information of greater value.

Female Genital Organs.—Iodised oil may be used also in radiography of the uterus and the uterine tube. The cervix is dilated and the oil is injected directly into the uterus through a metal tube. If slight pressure is used some of the oil passes into the tubes and may reach the peritoneal cavity (Pl. LXXII, p. 745).

Other Uses of Iodised Oil.—Iodised oil may be injected into the **paranasal air-sinuses** and into the ducts of the salivary glands (Pl. XLIX, p. 592); and it may be used also to outline inflammatory sinuses and fistulæ.

Other Uses of Air or Oxygen.—Air may be injected into the peritoneal cavity by means of a needle passed through the linea alba immediately below the umbilicus. By the use of large quantities of air the **liver** and **spleen** may be demonstrated when the patient is in the erect position, and, if the patient is inverted, the pelvic organs can be seen. The method has fallen into disfavour because it is not free from risk, and also because it does not give any indication of the nature of the disease process even when enlargement and irregularity of outline of these organs have been demonstrated.

While the renal outlines can usually be seen in the ordinary radiograph, the suprarenal glands cannot be demonstrated unless a contrast-agent is used. Air may be injected into the perirenal fat through a needle inserted from behind about the level of the third lumbar transverse process. The air tends to collect between the kidney and its fat and passes upwards around the suprarenal gland and between it and the kidney. The **suprarenal gland** is thus outlined as well as the **kidney** (Pl. LXIX, p. 744), but the method is rarely used except for the demonstration of the gland, as the examination of the kidney by pyelography gives information of greater value than the mere outlining of that organ.

As already mentioned (p. 1554), air may be introduced into the synovial cavity of a joint, by which means the articular cartilage becomes apparent, and, in the case of the knee joint, the shadows of the semilunar cartilages may be seen (Pl. XXXV, p. 382).

Thorium Dioxide in Examination of Liver and Spleen.—This method is mentioned only to complete the list of the uses of contrast-agents. As already stated, thorium is a radio-active salt and for that reason is dangerous. In animals it has been found that thorium dioxide which has been injected intravenously collects in the reticulo-endothelial system of the liver and spleen and that these organs are increased in density and are thus more clearly visible in a radiograph. In Man, the method is never justifiable, because in time the liver and spleen become severely damaged by the radio-activity of the salt, and there may also be destruction of the bone-marrow and even the production of malignant tumours.
